Additionally by default the `install` target will install the LLVM testing tools as the public tools. This can be changed well by setting `LLVM_INSTALL_TOOLCHAIN_ONLY` to `On`. The LLVM tools are intended for development and testing of LLVM, and should only be included in distributions that support LLVM development.

When building with `LLVM_DISTRIBUTION_COMPONENTS` the build system also generates a `distribution` target which builds all the components specified in the list. This is a convenience build target to allow building just the distributed pieces without needing to build all configured targets.

Special Notes for Library-only Distributions

One of the most powerful features of LLVM is its library-first design mentality and the way you can compose a wide variety of tools using different portions of LLVM. Even in this situation using `BUILD_SHARED_LIBS` is not supported. If you want to distribute LLVM as a shared library for use in a tool, the recommended method is using `LLVM_BUILD_LLVM_DYLIB`, and you can use `LLVM_DYLIB_COMPONENTS` to configure which LLVM components are part of `libLLVM`.

2.33.3 Options for Optimizing LLVM

There are four main build optimizations that our CMake build system supports. When performing a bootstrap build it is not beneficial to do anything other than setting `CMAKE_BUILD_TYPE` to `Release` for the stage-1 compiler. This is because the more intensive optimizations are expensive to perform and the stage-1 compiler is thrown away. All of the further options described should be set on the stage-2 compiler either using a CMake cache file, or by prefixing the option with `BOOTSTRAP_`.

The first and simplest to use is the compiler optimization level by setting the `CMAKE_BUILD_TYPE` option. The main values of interest are `Release` or `RelWithDebInfo`. By default the `Release` option uses the `-O3` optimization level, and `RelWithDebInfo` uses `-O2`. If you want to generate debug information and use `-O3` you can override the `CMAKE_LANG_FLAGS_RELWITHDEBINFO` option for C and CXX. `DistributionExample.cmake` does this.

Another easy to use option is Link-Time-Optimization. You can set the `LLVM_ENABLE_LTO` option on your stage-2 build to `Thin` or `Full` to enable building LLVM with LTO. These options will significantly increase link time of the binaries in the distribution, but it will create much faster binaries. This option should not be used if your distribution includes static archives, as the objects inside the archive will be LLVM bitcode, which is not portable.

The [Advanced Build Configurations](#) documentation describes the built-in tooling for generating LLVM profiling information to drive Profile-Guided-Optimization. The in-tree profiling tests are very limited, and generating the profile

takes a significant amount of time, but it can result in a significant improvement in the performance of the generated binaries.

In addition to PGO profiling we also have limited support in-tree for generating linker order files. These files provide the linker with a suggested ordering for functions in the final binary layout. This can measurably speed up clang by physically grouping functions that are called temporally close to each other. The current tooling is only available on Darwin systems with `dtrace(1)`. It is worth noting that `dtrace` is non-deterministic, and so the order file generation using `dtrace` is also non-deterministic.

2.33.4 Options for Reducing Size

Warning: Any steps taken to reduce the binary size will come at a cost of runtime performance in the generated binaries.

The simplest and least significant way to reduce binary size is to set the `CMAKE_BUILD_TYPE` variable to `MinSizeRel`, which will set the compiler optimization level to `-Os` which optimizes for binary size. This will have both the least benefit to size and the least impact on performance.

The most impactful way to reduce binary size is to dynamically link LLVM into all the tools. This reduces code size by decreasing duplication of common code between the LLVM-based tools. This can be done by setting the following two CMake options to `On`: `LLVM_BUILD_LLVM_DYLIB` and `LLVM_LINK_LLVM_DYLIB`.

Warning: Distributions should never be built using the `BUILD_SHARED_LIBS` CMake option. (*See the warning above for more explanation.*)

2.33.5 Relevant CMake Options

This section provides documentation of the CMake options that are intended to help construct distributions. This is not an exhaustive list, and many additional options are documented in the [Building LLVM with CMake](#) page. Some key options that are already documented include: `LLVM_TARGETS_TO_BUILD`, `LLVM_ENABLE_PROJECTS`, `LLVM_BUILD_LLVM_DYLIB`, and `LLVM_LINK_LLVM_DYLIB`.

LLVM_ENABLE_RUNTIMES:STRING When building a distribution that includes LLVM runtime projects (i.e. `libcxx`, `compiler-rt`, `libcxxabi`, `libunwind`...), it is important to build those projects with the just-built compiler.

LLVM_DISTRIBUTION_COMPONENTS:STRING This variable can be set to a semi-colon separated list of LLVM build system components to install. All LLVM-based tools are components, as well as most of the libraries and runtimes. Component names match the names of the build system targets.

LLVM_RUNTIME_DISTRIBUTION_COMPONENTS:STRING This variable can be set to a semi-colon separated list of runtime library components. This is used in conjunction with `LLVM_ENABLE_RUNTIMES` to specify components of runtime libraries that you want to include in your distribution. Just like with `LLVM_DISTRIBUTION_COMPONENTS`, component names match the names of the build system targets.

LLVM_DYLIB_COMPONENTS:STRING This variable can be set to a semi-colon separated name of LLVM library components. LLVM library components are either library names with the LLVM prefix removed (i.e. `Support`, `Demangle`...), LLVM target names, or special purpose component names. The special purpose component names are:

1. `all` - All LLVM available component libraries
2. `Native` - The LLVM target for the Native system
3. `AllTargetsAsmPrinters` - All the included target ASM printers libraries

4. AllTargetsAsmParsers - All the included target ASM parsers libraries
5. AllTargetsDescs - All the included target descriptions libraries
6. AllTargetsDisassemblers - All the included target disassemblers libraries
7. AllTargetsInfos - All the included target info libraries

LLVM_INSTALL_TOOLCHAIN_ONLY:BOOL This option defaults to `Off`: when set to `On` it removes many of the LLVM development and testing tools as well as component libraries from the default `install` target. Including the development tools is not recommended for distributions as many of the LLVM tools are only intended for development and testing use.

2.34 Remarks

- *Introduction to the LLVM remark diagnostics*
- *Enabling optimization remarks*
 - *Remark diagnostics*
 - *Serialized remarks*
- *YAML remarks*
- *opt-viewer*
 - *opt-viewer.py*
 - *opt-stats.py*
 - *opt-diff.py*
- *Emitting remark diagnostics in the object file*
- *C API*

2.34.1 Introduction to the LLVM remark diagnostics

LLVM is able to emit diagnostics from passes describing whether an optimization has been performed or missed for a particular reason, which should give more insight to users about what the compiler did during the compilation pipeline.

There are three main remark types:

Passed

Remarks that describe a successful optimization performed by the compiler.

Example

```
foo inlined into bar with (cost=always): always inline attribute
```

Missed

Remarks that describe an attempt to an optimization by the compiler that could not be performed.

Example

```
foo not inlined into bar because it should never be inlined
(cost=never): noline function attribute
```

Analysis

Remarks that describe the result of an analysis, that can bring more information to the user regarding the generated code.

Example

```
16 stack bytes in function
```

```
10 instructions in function
```

2.34.2 Enabling optimization remarks

There are two modes that are supported for enabling optimization remarks in LLVM: through remark diagnostics, or through serialized remarks.

Remark diagnostics

Optimization remarks can be emitted as diagnostics. These diagnostics will be propagated to front-ends if desired, or emitted by tools like *llc* or *opt*.

-pass-remarks=<regex>

Enables optimization remarks from passes whose name match the given (POSIX) regular expression.

-pass-remarks-missed=<regex>

Enables missed optimization remarks from passes whose name match the given (POSIX) regular expression.

-pass-remarks-analysis=<regex>

Enables optimization analysis remarks from passes whose name match the given (POSIX) regular expression.

Serialized remarks

While diagnostics are useful during development, it is often more useful to refer to optimization remarks post-compilation, typically during performance analysis.

For that, LLVM can serialize the remarks produced for each compilation unit to a file that can be consumed later.

By default, the format of the serialized remarks is *YAML*, and it can be accompanied by a *section* in the object files to easily retrieve it.

llc and *opt* support the following options:

Basic options

-pass-remarks-output=<filename>

Enables the serialization of remarks to a file specified in <filename>.

By default, the output is serialized to *YAML*.

-pass-remarks-format=<format>

Specifies the output format of the serialized remarks.

Supported formats:

- *yaml* (default)

Content configuration

-pass-remarks-filter=<regex>

Only passes whose name match the given (POSIX) regular expression will be serialized to the final output.

-pass-remarks-with-hotness

With PGO, include profile count in optimization remarks.

-pass-remarks-hotness-threshold

The minimum profile count required for an optimization remark to be emitted.

Other tools that support remarks:

llvm-lto

-lto-pass-remarks-output=<filename>

-lto-pass-remarks-filter=<regex>

-lto-pass-remarks-format=<format>

-lto-pass-remarks-with-hotness

-lto-pass-remarks-hotness-threshold

gold-plugin and **lld**

-opt-remarks-filename=<filename>

-opt-remarks-filter=<regex>

-opt-remarks-format=<format>

-opt-remarks-with-hotness

2.34.3 YAML remarks

A typical remark serialized to YAML looks like this:

```
--- !<TYPE>
Pass: <pass>
Name: <name>
DebugLoc: { File: <file>, Line: <line>, Column: <column> }
Function: <function>
Hotness: <hotness>
Args:
  - <key>: <value>
    DebugLoc: { File: <arg-file>, Line: <arg-line>, Column: <arg-column> }
```

The following entries are mandatory:

- **<TYPE>**: can be Passed, Missed, Analysis, AnalysisFPCommute, AnalysisAliasing, Failure.
- **<pass>**: the name of the pass that emitted this remark.
- **<name>**: the name of the remark coming from **<pass>**.
- **<function>**: the mangled name of the function.

If a **DebugLoc** entry is specified, the following fields are required:

- **<file>**

- <line>
- <column>

If an `arg` entry is specified, the following fields are required:

- <key>
- <value>

If a `DebugLoc` entry is specified within an `arg` entry, the following fields are required:

- <arg-file>
- <arg-line>
- <arg-column>

2.34.4 opt-viewer

The `opt-viewer` directory contains a collection of tools that visualize and summarize serialized remarks.

opt-viewer.py

Output a HTML page which gives visual feedback on compiler interactions with your program.

Examples

```
$ opt-viewer.py my_yaml_file.opt.yaml
```

```
$ opt-viewer.py my_build_dir/
```

opt-stats.py

Output statistics about the optimization remarks in the input set.

Example

```
$ opt-stats.py my_yaml_file.opt.yaml

Total number of remarks          3

Top 10 remarks by pass:
  inline                        33%
  asm-printer                   33%
  prologuepilog                 33%

Top 10 remarks:
  asm-printer/InstructionCount   33%
  inline/NoDefinition            33%
  prologuepilog/StackSize        33%
```

opt-diff.py

Produce a new YAML file which contains all of the changes in optimizations between two YAML files.

Typically, this tool should be used to do diffs between:

- new compiler + fixed source vs old compiler + fixed source
- fixed compiler + new source vs fixed compiler + old source

This diff file can be displayed using *opt-viewer.py*.

Example

```
$ opt-diff.py my_opt_yaml1.opt.yaml my_opt_yaml2.opt.yaml -o my_opt_diff.opt.  
→yaml  
$ opt-viewer.py my_opt_diff.opt.yaml
```

2.34.5 Emitting remark diagnostics in the object file

A section containing metadata on remark diagnostics will be emitted when `-remarks-section` is passed. The section contains:

- a magic number: "REMARKS\0"
- the version number: a little-endian `uint64_t`
- the total size of the string table (the size itself excluded): little-endian `uint64_t`
- a list of null-terminated strings
- the absolute file path to the serialized remark diagnostics: a null-terminated string.

The section is named:

- `__LLVM,__remarks` (MachO)
- `.remarks` (ELF)

2.34.6 C API

LLVM provides a library that can be used to parse remarks through a shared library named `libRemarks`.

The typical usage through the C API is like the following:

```
LLVMRemarkParserRef Parser = LLVMRemarkParserCreateYAML(Buf, Size);  
LLVMRemarkEntryRef Remark = NULL;  
while ((Remark = LLVMRemarkParserGetNext(Parser)) {  
    // use Remark  
    LLVMRemarkEntryDispose(Remark); // Release memory.  
}  
bool HasError = LLVMRemarkParserHasError(Parser);  
LLVMRemarkParserDispose(Parser);
```

3.1 LLVM Atomic Instructions and Concurrency Guide

- *Introduction*
- *Optimization outside atomic*
- *Atomic instructions*
- *Atomic orderings*
 - *NotAtomic*
 - *Unordered*
 - *Monotonic*
 - *Acquire*
 - *Release*
 - *AcquireRelease*
 - *SequentiallyConsistent*
- *Atomics and IR optimization*
- *Atomics and Codegen*
- *Libcalls: `__atomic_*`*
- *Libcalls: `__sync_*`*

3.1.1 Introduction

LLVM supports instructions which are well-defined in the presence of threads and asynchronous signals.

The atomic instructions are designed specifically to provide readable IR and optimized code generation for the following:

- The C++11 `<atomic>` header. ([C++11 draft available here.](#)) ([C11 draft available here.](#))
- Proper semantics for Java-style memory, for both `volatile` and regular shared variables. ([Java Specification](#))
- gcc-compatible `__sync_*` builtins. ([Description](#))
- Other scenarios with atomic semantics, including `static` variables with non-trivial constructors in C++.

Atomic and volatile in the IR are orthogonal; "volatile" is the C/C++ volatile, which ensures that every volatile load and store happens and is performed in the stated order. A couple examples: if a `SequentiallyConsistent` store is immediately followed by another `SequentiallyConsistent` store to the same address, the first store can be erased. This transformation is not allowed for a pair of volatile stores. On the other hand, a non-volatile non-atomic load can be moved across a volatile load freely, but not an `Acquire` load.

This document is intended to provide a guide to anyone either writing a frontend for LLVM or working on optimization passes for LLVM with a guide for how to deal with instructions with special semantics in the presence of concurrency. This is not intended to be a precise guide to the semantics; the details can get extremely complicated and unreadable, and are not usually necessary.

3.1.2 Optimization outside atomic

The basic 'load' and 'store' allow a variety of optimizations, but can lead to undefined results in a concurrent environment; see *NotAtomic*. This section specifically goes into the one optimizer restriction which applies in concurrent environments, which gets a bit more of an extended description because any optimization dealing with stores needs to be aware of it.

From the optimizer's point of view, the rule is that if there are not any instructions with atomic ordering involved, concurrency does not matter, with one exception: if a variable might be visible to another thread or signal handler, a store cannot be inserted along a path where it might not execute otherwise. Take the following example:

```
/* C code, for readability; run through clang -O2 -S -emit-llvm to get
   equivalent IR */
int x;
void f(int* a) {
    for (int i = 0; i < 100; i++) {
        if (a[i])
            x += 1;
    }
}
```

The following is equivalent in non-concurrent situations:

```
int x;
void f(int* a) {
    int xtemp = x;
    for (int i = 0; i < 100; i++) {
        if (a[i])
            xtemp += 1;
    }
    x = xtemp;
}
```

However, LLVM is not allowed to transform the former to the latter: it could indirectly introduce undefined behavior if another thread can access `x` at the same time. (This example is particularly of interest because before the concurrency model was implemented, LLVM would perform this transformation.)

Note that speculative loads are allowed; a load which is part of a race returns `undef`, but does not have undefined behavior.

3.1.3 Atomic instructions

For cases where simple loads and stores are not sufficient, LLVM provides various atomic instructions. The exact guarantees provided depend on the ordering; see [Atomic orderings](#).

`load atomic` and `store atomic` provide the same basic functionality as non-atomic loads and stores, but provide additional guarantees in situations where threads and signals are involved.

`cmpxchg` and `atomicrmw` are essentially like an atomic load followed by an atomic store (where the store is conditional for `cmpxchg`), but no other memory operation can happen on any thread between the load and store.

A `fence` provides Acquire and/or Release ordering which is not part of another operation; it is normally used along with Monotonic memory operations. A Monotonic load followed by an Acquire fence is roughly equivalent to an Acquire load, and a Monotonic store following a Release fence is roughly equivalent to a Release store. Sequentially-Consistent fences behave as both an Acquire and a Release fence, and offer some additional complicated guarantees, see the C++11 standard for details.

Frontends generating atomic instructions generally need to be aware of the target to some degree; atomic instructions are guaranteed to be lock-free, and therefore an instruction which is wider than the target natively supports can be impossible to generate.

3.1.4 Atomic orderings

In order to achieve a balance between performance and necessary guarantees, there are six levels of atomicity. They are listed in order of strength; each level includes all the guarantees of the previous level except for Acquire/Release. (See also [LangRef Ordering](#).)

NotAtomic

NotAtomic is the obvious, a load or store which is not atomic. (This isn't really a level of atomicity, but is listed here for comparison.) This is essentially a regular load or store. If there is a race on a given memory location, loads from that location return `undef`.

Relevant standard This is intended to match shared variables in C/C++, and to be used in any other context where memory access is necessary, and a race is impossible. (The precise definition is in [LangRef Memory Model](#).)

Notes for frontends The rule is essentially that all memory accessed with basic loads and stores by multiple threads should be protected by a lock or other synchronization; otherwise, you are likely to run into undefined behavior. If your frontend is for a "safe" language like Java, use `Unordered` to load and store any shared variable. Note that NotAtomic volatile loads and stores are not properly atomic; do not try to use them as a substitute. (Per the C/C++ standards, volatile does provide some limited guarantees around asynchronous signals, but atomics are generally a better solution.)

Notes for optimizers Introducing loads to shared variables along a codepath where they would not otherwise exist is allowed; introducing stores to shared variables is not. See [Optimization outside atomic](#).

Notes for code generation The one interesting restriction here is that it is not allowed to write to bytes outside of the bytes relevant to a store. This is mostly relevant to unaligned stores: it is not allowed in general to convert an unaligned store into two aligned stores of the same width as the unaligned store. Backends are also expected to

generate an i8 store as an i8 store, and not an instruction which writes to surrounding bytes. (If you are writing a backend for an architecture which cannot satisfy these restrictions and cares about concurrency, please send an email to llvm-dev.)

Unordered

Unordered is the lowest level of atomicity. It essentially guarantees that races produce somewhat sane results instead of having undefined behavior. It also guarantees the operation to be lock-free, so it does not depend on the data being part of a special atomic structure or depend on a separate per-process global lock. Note that code generation will fail for unsupported atomic operations; if you need such an operation, use explicit locking.

Relevant standard This is intended to match the Java memory model for shared variables.

Notes for frontends This cannot be used for synchronization, but is useful for Java and other "safe" languages which need to guarantee that the generated code never exhibits undefined behavior. Note that this guarantee is cheap on common platforms for loads of a native width, but can be expensive or unavailable for wider loads, like a 64-bit store on ARM. (A frontend for Java or other "safe" languages would normally split a 64-bit store on ARM into two 32-bit unordered stores.)

Notes for optimizers In terms of the optimizer, this prohibits any transformation that transforms a single load into multiple loads, transforms a store into multiple stores, narrows a store, or stores a value which would not be stored otherwise. Some examples of unsafe optimizations are narrowing an assignment into a bitfield, re-materializing a load, and turning loads and stores into a memcpy call. Reordering unordered operations is safe, though, and optimizers should take advantage of that because unordered operations are common in languages that need them.

Notes for code generation These operations are required to be atomic in the sense that if you use unordered loads and unordered stores, a load cannot see a value which was never stored. A normal load or store instruction is usually sufficient, but note that an unordered load or store cannot be split into multiple instructions (or an instruction which does multiple memory operations, like LDRD on ARM without LPAE, or not naturally-aligned LDRD on LPAE ARM).

Monotonic

Monotonic is the weakest level of atomicity that can be used in synchronization primitives, although it does not provide any general synchronization. It essentially guarantees that if you take all the operations affecting a specific address, a consistent ordering exists.

Relevant standard This corresponds to the C++11/C11 `memory_order_relaxed`; see those standards for the exact definition.

Notes for frontends If you are writing a frontend which uses this directly, use with caution. The guarantees in terms of synchronization are very weak, so make sure these are only used in a pattern which you know is correct. Generally, these would either be used for atomic operations which do not protect other memory (like an atomic counter), or along with a `fence`.

Notes for optimizers In terms of the optimizer, this can be treated as a read+write on the relevant memory location (and alias analysis will take advantage of that). In addition, it is legal to reorder non-atomic and Unordered loads around Monotonic loads. CSE/DSE and a few other optimizations are allowed, but Monotonic operations are unlikely to be used in ways which would make those optimizations useful.

Notes for code generation Code generation is essentially the same as that for unordered for loads and stores. No fences are required. `cmpxchg` and `atomicrmw` are required to appear as a single operation.

Acquire

Acquire provides a barrier of the sort necessary to acquire a lock to access other memory with normal loads and stores.

Relevant standard This corresponds to the C++11/C11 `memory_order_acquire`. It should also be used for C++11/C11 `memory_order_consume`.

Notes for frontends If you are writing a frontend which uses this directly, use with caution. Acquire only provides a semantic guarantee when paired with a Release operation.

Notes for optimizers Optimizers not aware of atomics can treat this like a nothrow call. It is also possible to move stores from before an Acquire load or read-modify-write operation to after it, and move non-Acquire loads from before an Acquire operation to after it.

Notes for code generation Architectures with weak memory ordering (essentially everything relevant today except x86 and SPARC) require some sort of fence to maintain the Acquire semantics. The precise fences required varies widely by architecture, but for a simple implementation, most architectures provide a barrier which is strong enough for everything (`dmb` on ARM, `sync` on PowerPC, etc.). Putting such a fence after the equivalent Monotonic operation is sufficient to maintain Acquire semantics for a memory operation.

Release

Release is similar to Acquire, but with a barrier of the sort necessary to release a lock.

Relevant standard This corresponds to the C++11/C11 `memory_order_release`.

Notes for frontends If you are writing a frontend which uses this directly, use with caution. Release only provides a semantic guarantee when paired with a Acquire operation.

Notes for optimizers Optimizers not aware of atomics can treat this like a nothrow call. It is also possible to move loads from after a Release store or read-modify-write operation to before it, and move non-Release stores from after an Release operation to before it.

Notes for code generation See the section on Acquire; a fence before the relevant operation is usually sufficient for Release. Note that a store-store fence is not sufficient to implement Release semantics; store-store fences are generally not exposed to IR because they are extremely difficult to use correctly.

AcquireRelease

AcquireRelease (`acq_rel` in IR) provides both an Acquire and a Release barrier (for fences and operations which both read and write memory).

Relevant standard This corresponds to the C++11/C11 `memory_order_acq_rel`.

Notes for frontends If you are writing a frontend which uses this directly, use with caution. Acquire only provides a semantic guarantee when paired with a Release operation, and vice versa.

Notes for optimizers In general, optimizers should treat this like a nothrow call; the possible optimizations are usually not interesting.

Notes for code generation This operation has Acquire and Release semantics; see the sections on Acquire and Release.

SequentiallyConsistent

SequentiallyConsistent (`seq_cst` in IR) provides Acquire semantics for loads and Release semantics for stores. Additionally, it guarantees that a total ordering exists between all SequentiallyConsistent operations.

Relevant standard This corresponds to the C++11/C11 `memory_order_seq_cst`, Java `volatile`, and the gcc-compatible `__sync_*` builtins which do not specify otherwise.

Notes for frontends If a frontend is exposing atomic operations, these are much easier to reason about for the programmer than other kinds of operations, and using them is generally a practical performance tradeoff.

Notes for optimizers Optimizers not aware of atomics can treat this like a nothrow call. For SequentiallyConsistent loads and stores, the same reorderings are allowed as for Acquire loads and Release stores, except that SequentiallyConsistent operations may not be reordered.

Notes for code generation SequentiallyConsistent loads minimally require the same barriers as Acquire operations and SequentiallyConsistent stores require Release barriers. Additionally, the code generator must enforce ordering between SequentiallyConsistent stores followed by SequentiallyConsistent loads. This is usually done by emitting either a full fence before the loads or a full fence after the stores; which is preferred varies by architecture.

3.1.5 Atomics and IR optimization

Predicates for optimizer writers to query:

- `isSimple()`: A load or store which is not volatile or atomic. This is what, for example, `memcpyopt` would check for operations it might transform.
- `isUnordered()`: A load or store which is not volatile and at most Unordered. This would be checked, for example, by LICM before hoisting an operation.
- `mayReadFromMemory()/mayWriteToMemory()`: Existing predicate, but note that they return true for any operation which is volatile or at least Monotonic.
- `isStrongerThan / isAtLeastOrStrongerThan`: These are predicates on orderings. They can be useful for passes that are aware of atomics, for example to do DSE across a single atomic access, but not across a release-acquire pair (see `MemoryDependencyAnalysis` for an example of this)
- Alias analysis: Note that AA will return `ModRef` for anything Acquire or Release, and for the address accessed by any Monotonic operation.

To support optimizing around atomic operations, make sure you are using the right predicates; everything should work if that is done. If your pass should optimize some atomic operations (Unordered operations in particular), make sure it doesn't replace an atomic load or store with a non-atomic operation.

Some examples of how optimizations interact with various kinds of atomic operations:

- `memcpyopt`: An atomic operation cannot be optimized into part of a `memcpy/memset`, including unordered loads/stores. It can pull operations across some atomic operations.
- LICM: Unordered loads/stores can be moved out of a loop. It just treats monotonic operations like a read+write to a memory location, and anything stricter than that like a nothrow call.
- DSE: Unordered stores can be DSE'ed like normal stores. Monotonic stores can be DSE'ed in some cases, but it's tricky to reason about, and not especially important. It is possible in some case for DSE to operate across a stronger atomic operation, but it is fairly tricky. DSE delegates this reasoning to `MemoryDependencyAnalysis` (which is also used by other passes like GVN).
- Folding a load: Any atomic load from a constant global can be constant-folded, because it cannot be observed. Similar reasoning allows `sroa` with atomic loads and stores.

3.1.6 Atomics and Codegen

Atomic operations are represented in the SelectionDAG with `ATOMIC_*` opcodes. On architectures which use barrier instructions for all atomic ordering (like ARM), appropriate fences can be emitted by the AtomicExpand Codegen pass if `setInsertFencesForAtomic()` was used.

The `MachineMemOperand` for all atomic operations is currently marked as volatile; this is not correct in the IR sense of volatile, but CodeGen handles anything marked volatile very conservatively. This should get fixed at some point.

One very important property of the atomic operations is that if your backend supports any inline lock-free atomic operations of a given size, you should support *ALL* operations of that size in a lock-free manner.

When the target implements atomic `cmpxchg` or LL/SC instructions (as most do) this is trivial: all the other operations can be implemented on top of those primitives. However, on many older CPUs (e.g. ARMv5, SparcV8, Intel 80386) there are atomic load and store instructions, but no `cmpxchg` or LL/SC. As it is invalid to implement atomic load using the native instruction, but `cmpxchg` using a library call to a function that uses a mutex, atomic load must *also* expand to a library call on such architectures, so that it can remain atomic with regards to a simultaneous `cmpxchg`, by using the same mutex.

`AtomicExpandPass` can help with that: it will expand all atomic operations to the proper `__atomic_*` libcalls for any size above the maximum set by `setMaxAtomicSizeInBitsSupported` (which defaults to 0).

On x86, all atomic loads generate a `MOV`. SequentiallyConsistent stores generate an `XCHG`, other stores generate a `MOV`. SequentiallyConsistent fences generate an `MFENCE`, other fences do not cause any code to be generated. `cmpxchg` uses the `LOCK CMPXCHG` instruction. `atomicrmw xchg` uses `XCHG`, `atomicrmw add` and `atomicrmw sub` use `XADD`, and all other `atomicrmw` operations generate a loop with `LOCK CMPXCHG`. Depending on the users of the result, some `atomicrmw` operations can be translated into operations like `LOCK AND`, but that does not work in general.

On ARM (before v8), MIPS, and many other RISC architectures, Acquire, Release, and SequentiallyConsistent semantics require barrier instructions for every such operation. Loads and stores generate normal instructions. `cmpxchg` and `atomicrmw` can be represented using a loop with LL/SC-style instructions which take some sort of exclusive lock on a cache line (`LDREX` and `STREX` on ARM, etc.).

It is often easiest for backends to use `AtomicExpandPass` to lower some of the atomic constructs. Here are some lowerings it can do:

- `cmpxchg` -> loop with load-linked/store-conditional by overriding `shouldExpandAtomicCmpXchgInIR()`, `emitLoadLinked()`, `emitStoreConditional()`
- large loads/stores -> ll-sc/`cmpxchg` by overriding `shouldExpandAtomicStoreInIR()/shouldExpandAtomicLoadInIR()`
- strong atomic accesses -> monotonic accesses + fences by overriding `shouldInsertFencesForAtomic()`, `emitLeadingFence()`, and `emitTrailingFence()`
- atomic rmw -> loop with `cmpxchg` or load-linked/store-conditional by overriding `expandAtomicRMWInIR()`
- expansion to `__atomic_*` libcalls for unsupported sizes.
- part-word `atomicrmw/cmpxchg` -> target-specific intrinsic by overriding `shouldExpandAtomicRMWInIR`, `emitMaskedAtomicRMWIntrinsic`, `shouldExpandAtomicCmpXchgInIR`, and `emitMaskedAtomicCmpXchgIntrinsic`.

For an example of these look at the ARM (first five lowerings) or RISC-V (last lowering) backend.

`AtomicExpandPass` supports two strategies for lowering `atomicrmw/cmpxchg` to load-linked/store-conditional (LL/SC) loops. The first expands the LL/SC loop in IR, calling target lowering hooks to emit intrinsics for the LL and SC operations. However, many architectures have strict requirements for LL/SC loops to ensure forward progress, such as restrictions on the number and type of instructions in the loop. It isn't possible to enforce these restrictions when the loop is expanded in LLVM IR, and so affected targets may prefer to expand to LL/SC loops at a very late

stage (i.e. after register allocation). AtomicExpandPass can help support lowering of part-word atomicrmw or cmpxchg using this strategy by producing IR for any shifting and masking that can be performed outside of the LL/SC loop.

3.1.7 Libcalls: `__atomic_*`

There are two kinds of atomic library calls that are generated by LLVM. Please note that both sets of library functions somewhat confusingly share the names of builtin functions defined by clang. Despite this, the library functions are not directly related to the builtins: it is *not* the case that `__atomic_*` builtins lower to `__atomic_*` library calls and `__sync_*` builtins lower to `__sync_*` library calls.

The first set of library functions are named `__atomic_*`. This set has been "standardized" by GCC, and is described below. (See also [GCC's documentation](#))

LLVM's AtomicExpandPass will translate atomic operations on data sizes above `MaxAtomicSizeInBitsSupported` into calls to these functions.

There are four generic functions, which can be called with data of any size or alignment:

```
void __atomic_load(size_t size, void *ptr, void *ret, int ordering)
void __atomic_store(size_t size, void *ptr, void *val, int ordering)
void __atomic_exchange(size_t size, void *ptr, void *val, void *ret, int ordering)
bool __atomic_compare_exchange(size_t size, void *ptr, void *expected, void *desired,
    ↪ int success_order, int failure_order)
```

There are also size-specialized versions of the above functions, which can only be used with *naturally-aligned* pointers of the appropriate size. In the signatures below, "N" is one of 1, 2, 4, 8, and 16, and "iN" is the appropriate integer type of that size; if no such integer type exists, the specialization cannot be used:

```
iN __atomic_load_N(iN *ptr, iN val, int ordering)
void __atomic_store_N(iN *ptr, iN val, int ordering)
iN __atomic_exchange_N(iN *ptr, iN val, int ordering)
bool __atomic_compare_exchange_N(iN *ptr, iN *expected, iN desired, int success_order,
    ↪ int failure_order)
```

Finally there are some read-modify-write functions, which are only available in the size-specific variants (any other sizes use a `__atomic_compare_exchange` loop):

```
iN __atomic_fetch_add_N(iN *ptr, iN val, int ordering)
iN __atomic_fetch_sub_N(iN *ptr, iN val, int ordering)
iN __atomic_fetch_and_N(iN *ptr, iN val, int ordering)
iN __atomic_fetch_or_N(iN *ptr, iN val, int ordering)
iN __atomic_fetch_xor_N(iN *ptr, iN val, int ordering)
iN __atomic_fetch_nand_N(iN *ptr, iN val, int ordering)
```

This set of library functions have some interesting implementation requirements to take note of:

- They support all sizes and alignments -- including those which cannot be implemented natively on any existing hardware. Therefore, they will certainly use mutexes in for some sizes/alignments.
- As a consequence, they cannot be shipped in a statically linked compiler-support library, as they have state which must be shared amongst all DSOs loaded in the program. They must be provided in a shared library used by all objects.
- The set of atomic sizes supported lock-free must be a superset of the sizes any compiler can emit. That is: if a new compiler introduces support for inline-lock-free atomics of size N, the `__atomic_*` functions must also have a lock-free implementation for size N. This is a requirement so that code produced by an old compiler

(which will have called the `__atomic_*` function) interoperates with code produced by the new compiler (which will use native the atomic instruction).

Note that it's possible to write an entirely target-independent implementation of these library functions by using the compiler atomic builtins themselves to implement the operations on naturally-aligned pointers of supported sizes, and a generic mutex implementation otherwise.

3.1.8 Libcalls: `__sync_*`

Some targets or OS/target combinations can support lock-free atomics, but for various reasons, it is not practical to emit the instructions inline.

There's two typical examples of this.

Some CPUs support multiple instruction sets which can be switched back and forth on function-call boundaries. For example, MIPS supports the MIPS16 ISA, which has a smaller instruction encoding than the usual MIPS32 ISA. ARM, similarly, has the Thumb ISA. In MIPS16 and earlier versions of Thumb, the atomic instructions are not encodable. However, those instructions are available via a function call to a function with the longer encoding.

Additionally, a few OS/target pairs provide kernel-supported lock-free atomics. ARM/Linux is an example of this: the kernel *provides* a function which on older CPUs contains a "magically-restartable" atomic sequence (which looks atomic so long as there's only one CPU), and contains actual atomic instructions on newer multicore models. This sort of functionality can typically be provided on any architecture, if all CPUs which are missing atomic compare-and-swap support are uniprocessor (no SMP). This is almost always the case. The only common architecture without that property is SPARC -- SPARCV8 SMP systems were common, yet it doesn't support any sort of compare-and-swap operation.

In either of these cases, the Target in LLVM can claim support for atomics of an appropriate size, and then implement some subset of the operations via libcalls to a `__sync_*` function. Such functions *must* not use locks in their implementation, because unlike the `__atomic_*` routines used by AtomicExpandPass, these may be mixed-and-matched with native instructions by the target lowering.

Further, these routines do not need to be shared, as they are stateless. So, there is no issue with having multiple copies included in one binary. Thus, typically these routines are implemented by the statically-linked compiler runtime support library.

LLVM will emit a call to an appropriate `__sync_*` routine if the target ISelLowering code has set the corresponding `ATOMIC_CMPXCHG`, `ATOMIC_SWAP`, or `ATOMIC_LOAD_*` operation to "Expand", and if it has opted-into the availability of those library functions via a call to `initSyncLibcalls()`.

The full set of functions that may be called by LLVM is (for N being 1, 2, 4, 8, or 16):

```

iN __sync_val_compare_and_swap_N(iN *ptr, iN expected, iN desired)
iN __sync_lock_test_and_set_N(iN *ptr, iN val)
iN __sync_fetch_and_add_N(iN *ptr, iN val)
iN __sync_fetch_and_sub_N(iN *ptr, iN val)
iN __sync_fetch_and_and_N(iN *ptr, iN val)
iN __sync_fetch_and_or_N(iN *ptr, iN val)
iN __sync_fetch_and_xor_N(iN *ptr, iN val)
iN __sync_fetch_and_nand_N(iN *ptr, iN val)
iN __sync_fetch_and_max_N(iN *ptr, iN val)
iN __sync_fetch_and_umin_N(iN *ptr, iN val)
iN __sync_fetch_and_min_N(iN *ptr, iN val)
iN __sync_fetch_and_uamin_N(iN *ptr, iN val)

```

This list doesn't include any function for atomic load or store; all known architectures support atomic loads and stores directly (possibly by emitting a fence on either side of a normal load or store.)

There's also, somewhat separately, the possibility to lower `ATOMIC_FENCE` to `__sync_synchronize()`. This may happen or not happen independent of all the above, controlled purely by `setOperationAction(ISD::ATOMIC_FENCE, ...)`.

3.2.1 Introduction

This document attempts to describe a few coding standards that are being used in the LLVM source tree. Although no coding standards should be regarded as absolute requirements to be followed in all instances, coding standards are particularly important for large-scale code bases that follow a library-based design (like LLVM).

While this document may provide guidance for some mechanical formatting issues, whitespace, or other "microscopic details", these are not fixed standards. Always follow the golden rule:

If you are extending, enhancing, or bug fixing already implemented code, use the style that is already being used so that the source is uniform and easy to follow.

Note that some code bases (e.g. `libc++`) have really good reasons to deviate from the coding standards. In the case of `libc++`, this is because the naming and other conventions are dictated by the C++ standard. If you think there is a specific good reason to deviate from the standards here, please bring it up on the LLVM-dev mailing list.

There are some conventions that are not uniformly followed in the code base (e.g. the naming convention). This is because they are relatively new, and a lot of code was written before they were put in place. Our long term goal is for the entire codebase to follow the convention, but we explicitly *do not* want patches that do large-scale reformatting of existing code. On the other hand, it is reasonable to rename the methods of a class if you're about to change it in some other way. Just do the reformatting as a separate commit from the functionality change.

The ultimate goal of these guidelines is to increase the readability and maintainability of our common source base. If you have suggestions for topics to be included, please mail them to [Chris](#).

3.2.2 Languages, Libraries, and Standards

Most source code in LLVM and other LLVM projects using these coding standards is C++ code. There are some places where C code is used either due to environment restrictions, historical restrictions, or due to third-party source code imported into the tree. Generally, our preference is for standards conforming, modern, and portable C++ code as the implementation language of choice.

C++ Standard Versions

LLVM, Clang, and LLD are currently written using C++11 conforming code, although we restrict ourselves to features which are available in the major toolchains supported as host compilers. The LLDB project is even more aggressive in the set of host compilers supported and thus uses still more features. Regardless of the supported features, code is expected to (when reasonable) be standard, portable, and modern C++11 code. We avoid unnecessary vendor-specific extensions, etc.

C++ Standard Library

Use the C++ standard library facilities whenever they are available for a particular task. LLVM and related projects emphasize and rely on the standard library facilities for as much as possible. Common support libraries providing functionality missing from the standard library for which there are standard interfaces or active work on adding standard interfaces will often be implemented in the LLVM namespace following the expected standard interface.

There are some exceptions such as the standard I/O streams library which are avoided. Also, there is much more detailed information on these subjects in the *LLVM Programmer's Manual*.

Supported C++11 Language and Library Features

While LLVM, Clang, and LLD use C++11, not all features are available in all of the toolchains which we support. The set of features supported for use in LLVM is the intersection of those supported in the minimum requirements described in the *Getting Started with the LLVM System* page, section *Software*. The ultimate definition of this set is what build bots with those respective toolchains accept. Don't argue with the build bots. However, we have some guidance below to help you know what to expect.

Each toolchain provides a good reference for what it accepts:

- Clang: https://clang.llvm.org/cxx_status.html
- GCC: <https://gcc.gnu.org/projects/cxx-status.html#cxx11>
- MSVC: <https://msdn.microsoft.com/en-us/library/hh567368.aspx>

In most cases, the MSVC list will be the dominating factor. Here is a summary of the features that are expected to work. Features not on this list are unlikely to be supported by our host compilers.

- Rvalue references: [N2118](#)
 - But *not* Rvalue references for `*this` or member qualifiers ([N2439](#))
- Static assert: [N1720](#)
- `auto` type deduction: [N1984](#), [N1737](#)
- Trailing return types: [N2541](#)
- Lambdas: [N2927](#)
 - But *not* lambdas with default arguments.
- `decltype`: [N2343](#)
- Nested closing right angle brackets: [N1757](#)
- Extern templates: [N1987](#)
- `nullptr`: [N2431](#)
- Strongly-typed and forward declarable enums: [N2347](#), [N2764](#)
- Local and unnamed types as template arguments: [N2657](#)
- Range-based for-loop: [N2930](#)
 - But `{}` are required around inner `do {} while()` loops. As a result, `{}` are required around function-like macros inside range-based for loops.
- `override` and `final`: [N2928](#), [N3206](#), [N3272](#)
- Atomic operations and the C++11 memory model: [N2429](#)
- Variadic templates: [N2242](#)
- Explicit conversion operators: [N2437](#)
- Defaulted and deleted functions: [N2346](#)
- Initializer lists: [N2627](#)
- Delegating constructors: [N1986](#)
- Default member initializers (non-static data member initializers): [N2756](#)
 - Feel free to use these wherever they make sense and where the `=` syntax is allowed. Don't use braced initialization syntax.

The supported features in the C++11 standard libraries are less well tracked, but also much greater. Most of the standard libraries implement most of C++11's library. The most likely lowest common denominator is Linux support. For libc++, the support is just poorly tested and undocumented but expected to be largely complete. YMMV. For libstdc++, the support is documented in detail in [the libstdc++ manual](#). There are some very minor missing facilities that are unlikely to be common problems, and there are a few larger gaps that are worth being aware of:

- Not all of the type traits are implemented
- No regular expression library.
- While most of the atomics library is well implemented, the fences are missing. Fortunately, they are rarely needed.
- The locale support is incomplete.

Other than these areas you should assume the standard library is available and working as expected until some build bot tells you otherwise. If you're in an uncertain area of one of the above points, but you cannot test on a Linux system, your best approach is to minimize your use of these features, and watch the Linux build bots to find out if your usage triggered a bug. For example, if you hit a type trait which doesn't work we can then add support to LLVM's traits header to emulate it.

Other Languages

Any code written in the Go programming language is not subject to the formatting rules below. Instead, we adopt the formatting rules enforced by the [gofmt](#) tool.

Go code should strive to be idiomatic. Two good sets of guidelines for what this means are [Effective Go](#) and [Go Code Review Comments](#).

3.2.3 Mechanical Source Issues

Source Code Formatting

Commenting

Comments are one critical part of readability and maintainability. Everyone knows they should comment their code, and so should you. When writing comments, write them as English prose, which means they should use proper capitalization, punctuation, etc. Aim to describe what the code is trying to do and why, not *how* it does it at a micro level. Here are a few critical things to document:

File Headers

Every source file should have a header on it that describes the basic purpose of the file. If a file does not have a header, it should not be checked into the tree. The standard header looks like this:

```
//==== llvm/Instruction.h - Instruction class definition -----*- C++ -*-====//
//
// Part of the LLVM Project, under the Apache License v2.0 with LLVM Exceptions.
// See https://llvm.org/LICENSE.txt for license information.
// SPDX-License-Identifier: Apache-2.0 WITH LLVM-exception
//
//=====
///
/// \file
```

(continues on next page)

(continued from previous page)

```

/// This file contains the declaration of the Instruction class, which is the
/// base class for all of the VM instructions.
///
//=====

```

A few things to note about this particular format: The `"-*- C++ -*-"` string on the first line is there to tell Emacs that the source file is a C++ file, not a C file (Emacs assumes `.h` files are C files by default).

Note: This tag is not necessary in `.cpp` files. The name of the file is also on the first line, along with a very short description of the purpose of the file. This is important when printing out code and flipping through lots of pages.

The next section in the file is a concise note that defines the license that the file is released under. This makes it perfectly clear what terms the source code can be distributed under and should not be modified in any way.

The main body is a `doxygen` comment (identified by the `///` comment marker instead of the usual `/**`) describing the purpose of the file. The first sentence (or a passage beginning with `\brief`) is used as an abstract. Any additional information should be separated by a blank line. If an algorithm is being implemented or something tricky is going on, a reference to the paper where it is published should be included, as well as any notes or *gotchas* in the code to watch out for.

Class overviews

Classes are one fundamental part of a good object oriented design. As such, a class definition should have a comment block that explains what the class is used for and how it works. Every non-trivial class is expected to have a `doxygen` comment block.

Method information

Methods defined in a class (as well as any global functions) should also be documented properly. A quick note about what it does and a description of the borderline behaviour is all that is necessary here (unless something particularly tricky or insidious is going on). The hope is that people can figure out how to use your interfaces without reading the code itself.

Good things to talk about here are what happens when something unexpected happens: does the method return null? Abort? Format your hard disk?

Comment Formatting

In general, prefer C++ style comments (`/**` for normal comments, `///` for `doxygen` documentation comments). They take less space, require less typing, don't have nesting problems, etc. There are a few cases when it is useful to use C style (`/* */`) comments however:

1. When writing C code: Obviously if you are writing C code, use C style comments.
2. When writing a header file that may be `#included` by a C source file.
3. When writing a source file that is used by a tool that only accepts C style comments.
4. When documenting the significance of constants used as actual parameters in a call. This is most helpful for `bool` parameters, or passing `0` or `nullptr`. Typically you add the formal parameter name, which ought to be meaningful. For example, it's not clear what the parameter means in this call:

```
Object.emitName(nullptr);
```

An in-line C-style comment makes the intent obvious:

```
Object.emitName(/*Prefix=*/nullptr);
```

Commenting out large blocks of code is discouraged, but if you really have to do this (for documentation purposes or as a suggestion for debug printing), use `#if 0` and `#endif`. These nest properly and are better behaved in general than C style comments.

Doxygen Use in Documentation Comments

Use the `\file` command to turn the standard file header into a file-level comment.

Include descriptive paragraphs for all public interfaces (public classes, member and non-member functions). Don't just restate the information that can be inferred from the API name. The first sentence (or a paragraph beginning with `\brief`) is used as an abstract. Try to use a single sentence as the `\brief` adds visual clutter. Put detailed discussion into separate paragraphs.

To refer to parameter names inside a paragraph, use the `\p` name command. Don't use the `\arg` name command since it starts a new paragraph that contains documentation for the parameter.

Wrap non-inline code examples in `\code ... \endcode`.

To document a function parameter, start a new paragraph with the `\param` name command. If the parameter is used as an out or an in/out parameter, use the `\param [out]` name or `\param [in,out]` name command, respectively.

To describe function return value, start a new paragraph with the `\returns` command.

A minimal documentation comment:

```
/// Sets the xyzzy property to \p Baz.  
void setXyzzy(bool Baz);
```

A documentation comment that uses all Doxygen features in a preferred way:

```
/// Does foo and bar.  
///  
/// Does not do foo the usual way if \p Baz is true.  
///  
/// Typical usage:  
/// \code  
///   fooBar(false, "quux", Res);  
/// \endcode  
///  
/// \param Quux kind of foo to do.  
/// \param [out] Result filled with bar sequence on foo success.  
///  
/// \returns true on success.  
bool fooBar(bool Baz, StringRef Quux, std::vector<int> &Result);
```

Don't duplicate the documentation comment in the header file and in the implementation file. Put the documentation comments for public APIs into the header file. Documentation comments for private APIs can go to the implementation file. In any case, implementation files can include additional comments (not necessarily in Doxygen markup) to explain implementation details as needed.

Don't duplicate function or class name at the beginning of the comment. For humans it is obvious which function or class is being documented; automatic documentation processing tools are smart enough to bind the comment to the correct declaration.

Wrong:

```
// In Something.h:

/// Something - An abstraction for some complicated thing.
class Something {
public:
    /// fooBar - Does foo and bar.
    void fooBar();
};

// In Something.cpp:

/// fooBar - Does foo and bar.
void Something::fooBar() { ... }
```

Correct:

```
// In Something.h:

/// An abstraction for some complicated thing.
class Something {
public:
    /// Does foo and bar.
    void fooBar();
};

// In Something.cpp:

/// Builds a B-tree in order to do foo. See paper by...
void Something::fooBar() { ... }
```

It is not required to use additional Doxygen features, but sometimes it might be a good idea to do so.

Consider:

- adding comments to any narrow namespace containing a collection of related functions or types;
- using top-level groups to organize a collection of related functions at namespace scope where the grouping is smaller than the namespace;
- using member groups and additional comments attached to member groups to organize within a class.

For example:

```
class Something {
    /// \name Functions that do Foo.
    /// @{
    void fooBar();
    void fooBaz();
    /// @}
    ...
};
```

#include Style

Immediately after the *header file comment* (and include guards if working on a header file), the *minimal list of #includes* required by the file should be listed. We prefer these #includes to be listed in this order:

1. Main Module Header
2. Local/Private Headers
3. LLVM project/subproject headers (`clang/...`, `lldb/...`, `llvm/...`, etc)
4. System #includes

and each category should be sorted lexicographically by the full path.

The *Main Module Header* file applies to `.cpp` files which implement an interface defined by a `.h` file. This #include should always be included **first** regardless of where it lives on the file system. By including a header file first in the `.cpp` files that implement the interfaces, we ensure that the header does not have any hidden dependencies which are not explicitly #included in the header, but should be. It is also a form of documentation in the `.cpp` file to indicate where the interfaces it implements are defined.

LLVM project and subproject headers should be grouped from most specific to least specific, for the same reasons described above. For example, LLDB depends on both clang and LLVM, and clang depends on LLVM. So an LLDB source file should include `lldb` headers first, followed by `clang` headers, followed by `llvm` headers, to reduce the possibility (for example) of an LLDB header accidentally picking up a missing include due to the previous inclusion of that header in the main source file or some earlier header file. clang should similarly include its own headers before including `llvm` headers. This rule applies to all LLVM subprojects.

Source Code Width

Write your code to fit within 80 columns of text. This helps those of us who like to print out code and look at your code in an `xterm` without resizing it.

The longer answer is that there must be some limit to the width of the code in order to reasonably allow developers to have multiple files side-by-side in windows on a modest display. If you are going to pick a width limit, it is somewhat arbitrary but you might as well pick something standard. Going with 90 columns (for example) instead of 80 columns wouldn't add any significant value and would be detrimental to printing out code. Also many other projects have standardized on 80 columns, so some people have already configured their editors for it (vs something else, like 90 columns).

This is one of many contentious issues in coding standards, but it is not up for debate.

Whitespace

In all cases, prefer spaces to tabs in source files. People have different preferred indentation levels, and different styles of indentation that they like; this is fine. What isn't fine is that different editors/viewers expand tabs out to different tab stops. This can cause your code to look completely unreadable, and it is not worth dealing with.

As always, follow the *Golden Rule* above: follow the style of existing code if you are modifying and extending it. If you like four spaces of indentation, **DO NOT** do that in the middle of a chunk of code with two spaces of indentation. Also, do not reindent a whole source file: it makes for incredible diffs that are absolutely worthless.

Do not commit changes that include trailing whitespace. If you find trailing whitespace in a file, do not remove it unless you're otherwise changing that line of code. Some common editors will automatically remove trailing whitespace when saving a file which causes unrelated changes to appear in diffs and commits.

Indent Code Consistently

Okay, in your first year of programming you were told that indentation is important. If you didn't believe and internalize this then, now is the time. Just do it. With the introduction of C++11, there are some new formatting challenges that merit some suggestions to help have consistent, maintainable, and tool-friendly formatting and indentation.

Format Lambdas Like Blocks Of Code

When formatting a multi-line lambda, format it like a block of code, that's what it is. If there is only one multi-line lambda in a statement, and there are no expressions lexically after it in the statement, drop the indent to the standard two space indent for a block of code, as if it were an if-block opened by the preceding part of the statement:

```
std::sort(foo.begin(), foo.end(), [&](Foo a, Foo b) -> bool {
    if (a.blah < b.blah)
        return true;
    if (a.baz < b.baz)
        return true;
    return a.bam < b.bam;
});
```

To take best advantage of this formatting, if you are designing an API which accepts a continuation or single callable argument (be it a functor, or a `std::function`), it should be the last argument if at all possible.

If there are multiple multi-line lambdas in a statement, or there is anything interesting after the lambda in the statement, indent the block two spaces from the indent of the []:

```
dyn_switch(V->stripPointerCasts(),
    [] (PHINode *PN) {
        // process phis...
    },
    [] (SelectInst *SI) {
        // process selects...
    },
    [] (LoadInst *LI) {
        // process loads...
    },
    [] (AllocaInst *AI) {
        // process allocas...
    });
```

Braced Initializer Lists

With C++11, there are significantly more uses of braced lists to perform initialization. These allow you to easily construct aggregate temporaries in expressions among other niceness. They now have a natural way of ending up nested within each other and within function calls in order to build up aggregates (such as option structs) from local variables. To make matters worse, we also have many more uses of braces in an expression context that are *not* performing initialization.

The historically common formatting of braced initialization of aggregate variables does not mix cleanly with deep nesting, general expression contexts, function arguments, and lambdas. We suggest new code use a simple rule for formatting braced initialization lists: act as-if the braces were parentheses in a function call. The formatting rules exactly match those already well understood for formatting nested function calls. Examples:

```
foo({a, b, c}, {1, 2, 3});

llvm::Constant *Mask[] = {
    llvm::ConstantInt::get(llvm::Type::getInt32Ty(llvm::Context()), 0),
    llvm::ConstantInt::get(llvm::Type::getInt32Ty(llvm::Context()), 1),
    llvm::ConstantInt::get(llvm::Type::getInt32Ty(llvm::Context()), 2)};
```

This formatting scheme also makes it particularly easy to get predictable, consistent, and automatic formatting with tools like [Clang Format](#).

Language and Compiler Issues

Treat Compiler Warnings Like Errors

If your code has compiler warnings in it, something is wrong --- you aren't casting values correctly, you have "questionable" constructs in your code, or you are doing something legitimately wrong. Compiler warnings can cover up legitimate errors in output and make dealing with a translation unit difficult.

It is not possible to prevent all warnings from all compilers, nor is it desirable. Instead, pick a standard compiler (like `gcc`) that provides a good thorough set of warnings, and stick to it. At least in the case of `gcc`, it is possible to work around any spurious errors by changing the syntax of the code slightly. For example, a warning that annoys me occurs when I write code like this:

```
if (V = getValue()) {
    ...
}
```

`gcc` will warn me that I probably want to use the `==` operator, and that I probably mistyped it. In most cases, I haven't, and I really don't want the spurious errors. To fix this particular problem, I rewrite the code like this:

```
if ((V = getValue())) {
    ...
}
```

which shuts `gcc` up. Any `gcc` warning that annoys you can be fixed by massaging the code appropriately.

Write Portable Code

In almost all cases, it is possible and within reason to write completely portable code. If there are cases where it isn't possible to write portable code, isolate it behind a well defined (and well documented) interface.

In practice, this means that you shouldn't assume much about the host compiler (and Visual Studio tends to be the lowest common denominator). If advanced features are used, they should only be an implementation detail of a library which has a simple exposed API, and preferably be buried in `libSystem`.

Do not use RTTI or Exceptions

In an effort to reduce code and executable size, LLVM does not use RTTI (e.g. `dynamic_cast<>;`) or exceptions. These two language features violate the general C++ principle of *"you only pay for what you use"*, causing executable bloat even if exceptions are never used in the code base, or if RTTI is never used for a class. Because of this, we turn them off globally in the code.

That said, LLVM does make extensive use of a hand-rolled form of RTTI that use templates like `isa<>`, `cast<>`, and `dyn_cast<>`. This form of RTTI is opt-in and can be *added to any class*. It is also substantially more efficient than `dynamic_cast<>`.

Do not use Static Constructors

Static constructors and destructors (e.g. global variables whose types have a constructor or destructor) should not be added to the code base, and should be removed wherever possible. Besides *well known problems* where the order of initialization is undefined between globals in different source files, the entire concept of static constructors is at odds with the common use case of LLVM as a library linked into a larger application.

Consider the use of LLVM as a JIT linked into another application (perhaps for *OpenGL*, *custom languages*, *shaders in movies*, etc). Due to the design of static constructors, they must be executed at startup time of the entire application, regardless of whether or how LLVM is used in that larger application. There are two problems with this:

- The time to run the static constructors impacts startup time of applications --- a critical time for GUI apps, among others.
- The static constructors cause the app to pull many extra pages of memory off the disk: both the code for the constructor in each `.o` file and the small amount of data that gets touched. In addition, touched/dirty pages put more pressure on the VM system on low-memory machines.

We would really like for there to be zero cost for linking in an additional LLVM target or other library into an application, but static constructors violate this goal.

That said, LLVM unfortunately does contain static constructors. It would be a *great project* for someone to purge all static constructors from LLVM, and then enable the `-Wglobal-constructors` warning flag (when building with Clang) to ensure we do not regress in the future.

Use of `class` and `struct` Keywords

In C++, the `class` and `struct` keywords can be used almost interchangeably. The only difference is when they are used to declare a class: `class` makes all members private by default while `struct` makes all members public by default.

Unfortunately, not all compilers follow the rules and some will generate different symbols based on whether `class` or `struct` was used to declare the symbol (e.g., MSVC). This can lead to problems at link time.

- All declarations and definitions of a given `class` or `struct` must use the same keyword. For example:

```
class Foo;

// Breaks mangling in MSVC.
struct Foo { int Data; };
```

- As a rule of thumb, `struct` should be kept to structures where *all* members are declared public.

```
// Foo feels like a class... this is strange.
struct Foo {
private:
    int Data;
public:
    Foo() : Data(0) { }
    int getData() const { return Data; }
    void setData(int D) { Data = D; }
};

// Bar isn't POD, but it does look like a struct.
struct Bar {
    int Data;
    Bar() : Data(0) { }
};
```

Do not use Braced Initializer Lists to Call a Constructor

In C++11 there is a "generalized initialization syntax" which allows calling constructors using braced initializer lists. Do not use these to call constructors with any interesting logic or if you care that you're calling some *particular* constructor. Those should look like function calls using parentheses rather than like aggregate initialization. Similarly, if you need to explicitly name the type and call its constructor to create a temporary, don't use a braced initializer list. Instead, use a braced initializer list (without any type for temporaries) when doing aggregate initialization or something notionally equivalent. Examples:

```
class Foo {
public:
    // Construct a Foo by reading data from the disk in the whizbang format, ...
    Foo(std::string filename);

    // Construct a Foo by looking up the Nth element of some global data ...
    Foo(int N);

    // ...
};

// The Foo constructor call is very deliberate, no braces.
std::fill(foo.begin(), foo.end(), Foo("name"));

// The pair is just being constructed like an aggregate, use braces.
bar_map.insert({my_key, my_value});
```

If you use a braced initializer list when initializing a variable, use an equals before the open curly brace:

```
int data[] = {0, 1, 2, 3};
```

Use auto Type Deduction to Make Code More Readable

Some are advocating a policy of "almost always `auto`" in C++11, however LLVM uses a more moderate stance. Use `auto` if and only if it makes the code more readable or easier to maintain. Don't "almost always" use `auto`, but do use `auto` with initializers like `cast<Foo>(...)` or other places where the type is already obvious from the context. Another time when `auto` works well for these purposes is when the type would have been abstracted away anyways, often behind a container's typedef such as `std::vector<T>::iterator`.

Beware unnecessary copies with auto

The convenience of `auto` makes it easy to forget that its default behavior is a copy. Particularly in range-based `for` loops, careless copies are expensive.

As a rule of thumb, use `auto &` unless you need to copy the result, and use `auto *` when copying pointers.

```
// Typically there's no reason to copy.
for (const auto &Val : Container) { observe(Val); }
for (auto &Val : Container) { Val.change(); }

// Remove the reference if you really want a new copy.
for (auto Val : Container) { Val.change(); saveSomewhere(Val); }

// Copy pointers, but make it clear that they're pointers.
for (const auto *Ptr : Container) { observe(*Ptr); }
for (auto *Ptr : Container) { Ptr->change(); }
```

Beware of non-determinism due to ordering of pointers

In general, there is no relative ordering among pointers. As a result, when unordered containers like sets and maps are used with pointer keys the iteration order is undefined. Hence, iterating such containers may result in non-deterministic code generation. While the generated code might not necessarily be "wrong code", this non-determinism might result in unexpected runtime crashes or simply hard to reproduce bugs on the customer side making it harder to debug and fix.

As a rule of thumb, in case an ordered result is expected, remember to sort an unordered container before iteration. Or use ordered containers like `vector/MapVector/SetVector` if you want to iterate pointer keys.

Beware of non-deterministic sorting order of equal elements

`std::sort` uses a non-stable sorting algorithm in which the order of equal elements is not guaranteed to be preserved. Thus using `std::sort` for a container having equal elements may result in non-deterministic behavior. To uncover such instances of non-determinism, LLVM has introduced a new `llvm::sort` wrapper function. For an `EXPENSIVE_CHECKS` build this will randomly shuffle the container before sorting. As a rule of thumb, always make sure to use `llvm::sort` instead of `std::sort`.

3.2.4 Style Issues

The High-Level Issues

Self-contained Headers

Header files should be self-contained (compile on their own) and end in `.h`. Non-header files that are meant for inclusion should end in `.inc` and be used sparingly.

All header files should be self-contained. Users and refactoring tools should not have to adhere to special conditions to include the header. Specifically, a header should have header guards and include all other headers it needs.

There are rare cases where a file designed to be included is not self-contained. These are typically intended to be included at unusual locations, such as the middle of another file. They might not use header guards, and might not include their prerequisites. Name such files with the `.inc` extension. Use sparingly, and prefer self-contained headers when possible.

In general, a header should be implemented by one or more `.cpp` files. Each of these `.cpp` files should include the header that defines their interface first. This ensures that all of the dependences of the header have been properly added to the header itself, and are not implicit. System headers should be included after user headers for a translation unit.

Library Layering

A directory of header files (for example `include/llvm/Foo`) defines a library (`Foo`). Dependencies between libraries are defined by the `LLVMBuild.txt` file in their implementation (`lib/Foo`). One library (both its headers and implementation) should only use things from the libraries listed in its dependencies.

Some of this constraint can be enforced by classic Unix linkers (Mac & Windows linkers, as well as `lld`, do not enforce this constraint). A Unix linker searches left to right through the libraries specified on its command line and never revisits a library. In this way, no circular dependencies between libraries can exist.

This doesn't fully enforce all inter-library dependencies, and importantly doesn't enforce header file circular dependencies created by inline functions. A good way to answer the "is this layered correctly" would be to consider whether a Unix linker would succeed at linking the program if all inline functions were defined out-of-line. (& for all valid orderings of dependencies - since linking resolution is linear, it's possible that some implicit dependencies can sneak through: A depends on B and C, so valid orderings are "C B A" or "B C A", in both cases the explicit dependencies come before their use. But in the first case, B could still link successfully if it implicitly depended on C, or the opposite in the second case)

`#include` as Little as Possible

`#include` hurts compile time performance. Don't do it unless you have to, especially in header files.

But wait! Sometimes you need to have the definition of a class to use it, or to inherit from it. In these cases go ahead and `#include` that header file. Be aware however that there are many cases where you don't need to have the full definition of a class. If you are using a pointer or reference to a class, you don't need the header file. If you are simply returning a class instance from a prototyped function or method, you don't need it. In fact, for most cases, you simply don't need the definition of a class. And not `#include`ing speeds up compilation.

It is easy to try to go too overboard on this recommendation, however. You **must** include all of the header files that you are using --- you can include them either directly or indirectly through another header file. To make sure that you don't accidentally forget to include a header file in your module header, make sure to include your module header **first** in the implementation file (as mentioned above). This way there won't be any hidden dependencies that you'll find out about later.

Keep "Internal" Headers Private

Many modules have a complex implementation that causes them to use more than one implementation (.cpp) file. It is often tempting to put the internal communication interface (helper classes, extra functions, etc) in the public module header file. Don't do this!

If you really need to do something like this, put a private header file in the same directory as the source files, and include it locally. This ensures that your private interface remains private and undisturbed by outsiders.

Note: It's okay to put extra implementation methods in a public class itself. Just make them private (or protected) and all is well.

Use Early Exits and `continue` to Simplify Code

When reading code, keep in mind how much state and how many previous decisions have to be remembered by the reader to understand a block of code. Aim to reduce indentation where possible when it doesn't make it more difficult to understand the code. One great way to do this is by making use of early exits and the `continue` keyword in long loops. As an example of using an early exit from a function, consider this "bad" code:

```
Value *doSomething(Instruction *I) {
    if (!I->isTerminator() &&
        I->hasOneUse() && doOtherThing(I)) {
        ... some long code ....
    }

    return 0;
}
```

This code has several problems if the body of the 'if' is large. When you're looking at the top of the function, it isn't immediately clear that this *only* does interesting things with non-terminator instructions, and only applies to things with the other predicates. Second, it is relatively difficult to describe (in comments) why these predicates are important because the if statement makes it difficult to lay out the comments. Third, when you're deep within the body of the code, it is indented an extra level. Finally, when reading the top of the function, it isn't clear what the result is if the predicate isn't true; you have to read to the end of the function to know that it returns null.

It is much preferred to format the code like this:

```
Value *doSomething(Instruction *I) {
    // Terminators never need 'something' done to them because ...
    if (I->isTerminator())
        return 0;

    // We conservatively avoid transforming instructions with multiple uses
    // because goats like cheese.
    if (!I->hasOneUse())
        return 0;

    // This is really just here for example.
    if (!doOtherThing(I))
        return 0;

    ... some long code ....
}
```

This fixes these problems. A similar problem frequently happens in `for` loops. A silly example is something like this:

```
for (Instruction &I : BB) {
  if (auto *BO = dyn_cast<BinaryOperator>(&I)) {
    Value *LHS = BO->getOperand(0);
    Value *RHS = BO->getOperand(1);
    if (LHS != RHS) {
      ...
    }
  }
}
```

When you have very, very small loops, this sort of structure is fine. But if it exceeds more than 10-15 lines, it becomes difficult for people to read and understand at a glance. The problem with this sort of code is that it gets very nested very quickly. Meaning that the reader of the code has to keep a lot of context in their brain to remember what is going immediately on in the loop, because they don't know if/when the `if` conditions will have `elses` etc. It is strongly preferred to structure the loop like this:

```
for (Instruction &I : BB) {
  auto *BO = dyn_cast<BinaryOperator>(&I);
  if (!BO) continue;

  Value *LHS = BO->getOperand(0);
  Value *RHS = BO->getOperand(1);
  if (LHS == RHS) continue;

  ...
}
```

This has all the benefits of using early exits for functions: it reduces nesting of the loop, it makes it easier to describe why the conditions are true, and it makes it obvious to the reader that there is no `else` coming up that they have to push context into their brain for. If a loop is large, this can be a big understandability win.

Don't use `else` after a `return`

For similar reasons above (reduction of indentation and easier reading), please do not use `'else'` or `'else if'` after something that interrupts control flow --- like `return`, `break`, `continue`, `goto`, etc. For example, this is *bad*:

```
case 'J': {
  if (Signed) {
    Type = Context.getsigjmp_bufType();
    if (Type.isNull()) {
      Error = ASTContext::GE_Missing_sigjmp_buf;
      return QualType();
    } else {
      break;
    }
  } else {
    Type = Context.getjmp_bufType();
    if (Type.isNull()) {
      Error = ASTContext::GE_Missing_jmp_buf;
      return QualType();
    } else {
      break;
    }
  }
}
```

It is better to write it like this:

```
case 'J':
    if (Signed) {
        Type = Context.getsigjmp_bufType();
        if (Type.isNull()) {
            Error = ASTContext::GE_Missing_sigjmp_buf;
            return QualType();
        }
    } else {
        Type = Context.getjmp_bufType();
        if (Type.isNull()) {
            Error = ASTContext::GE_Missing_jmp_buf;
            return QualType();
        }
    }
    break;
```

Or better yet (in this case) as:

```
case 'J':
    if (Signed)
        Type = Context.getsigjmp_bufType();
    else
        Type = Context.getjmp_bufType();

    if (Type.isNull()) {
        Error = Signed ? ASTContext::GE_Missing_sigjmp_buf :
                        ASTContext::GE_Missing_jmp_buf;
        return QualType();
    }
    break;
```

The idea is to reduce indentation and the amount of code you have to keep track of when reading the code.

Turn Predicate Loops into Predicate Functions

It is very common to write small loops that just compute a boolean value. There are a number of ways that people commonly write these, but an example of this sort of thing is:

```
bool FoundFoo = false;
for (unsigned I = 0, E = BarList.size(); I != E; ++I)
    if (BarList[I]->isFoo()) {
        FoundFoo = true;
        break;
    }

if (FoundFoo) {
    ...
}
```

This sort of code is awkward to write, and is almost always a bad sign. Instead of this sort of loop, we strongly prefer to use a predicate function (which may be *static*) that uses *early exits* to compute the predicate. We prefer the code to be structured like this:

```
/// \returns true if the specified list has an element that is a foo.
static bool containsFoo(const std::vector<Bar*> &List) {
    for (unsigned I = 0, E = List.size(); I != E; ++I)
        if (List[I]->isFoo())
            return true;
    return false;
}
...

if (containsFoo(BarList)) {
    ...
}
```

There are many reasons for doing this: it reduces indentation and factors out code which can often be shared by other code that checks for the same predicate. More importantly, it *forces you to pick a name* for the function, and forces you to write a comment for it. In this silly example, this doesn't add much value. However, if the condition is complex, this can make it a lot easier for the reader to understand the code that queries for this predicate. Instead of being faced with the in-line details of how we check to see if the BarList contains a foo, we can trust the function name and continue reading with better locality.

The Low-Level Issues

Name Types, Functions, Variables, and Enumerators Properly

Poorly-chosen names can mislead the reader and cause bugs. We cannot stress enough how important it is to use *descriptive* names. Pick names that match the semantics and role of the underlying entities, within reason. Avoid abbreviations unless they are well known. After picking a good name, make sure to use consistent capitalization for the name, as inconsistency requires clients to either memorize the APIs or to look it up to find the exact spelling.

In general, names should be in camel case (e.g. `TextFileReader` and `isLValue()`). Different kinds of declarations have different rules:

- **Type names** (including classes, structs, enums, typedefs, etc) should be nouns and start with an upper-case letter (e.g. `TextFileReader`).
- **Variable names** should be nouns (as they represent state). The name should be camel case, and start with an upper case letter (e.g. `Leader` or `Boats`).
- **Function names** should be verb phrases (as they represent actions), and command-like function should be imperative. The name should be camel case, and start with a lower case letter (e.g. `openFile()` or `isFoo()`).
- **Enum declarations** (e.g. `enum Foo { ... }`) are types, so they should follow the naming conventions for types. A common use for enums is as a discriminator for a union, or an indicator of a subclass. When an enum is used for something like this, it should have a `Kind` suffix (e.g. `ValueKind`).
- **Enumerators** (e.g. `enum { Foo, Bar }`) and **public member variables** should start with an upper-case letter, just like types. Unless the enumerators are defined in their own small namespace or inside a class, enumerators should have a prefix corresponding to the enum declaration name. For example, `enum ValueKind { ... }`; may contain enumerators like `VK_Argument`, `VK_BasicBlock`, etc. Enumerators that are just convenience constants are exempt from the requirement for a prefix. For instance:

```
enum {
    MaxSize = 42,
    Density = 12
};
```

As an exception, classes that mimic STL classes can have member names in STL's style of lower-case words separated by underscores (e.g. `begin()`, `push_back()`, and `empty()`). Classes that provide multiple iterators should add a singular prefix to `begin()` and `end()` (e.g. `global_begin()` and `use_begin()`).

Here are some examples of good and bad names:

```
class VehicleMaker {
    ...
    Factory<Tire> F;           // Bad -- abbreviation and non-descriptive.
    Factory<Tire> Factory;     // Better.
    Factory<Tire> TireFactory; // Even better -- if VehicleMaker has more than one
                                // kind of factories.
};

Vehicle makeVehicle(VehicleType Type) {
    VehicleMaker M;           // Might be OK if having a short life-span.
    Tire Tmpl = M.makeTire();  // Bad -- 'Tmpl' provides no information.
    Light Headlight = M.makeLight("head"); // Good -- descriptive.
    ...
}
```

Assert Liberally

Use the "assert" macro to its fullest. Check all of your preconditions and assumptions, you never know when a bug (not necessarily even yours) might be caught early by an assertion, which reduces debugging time dramatically. The "<cassert>" header file is probably already included by the header files you are using, so it doesn't cost anything to use it.

To further assist with debugging, make sure to put some kind of error message in the assertion statement, which is printed if the assertion is tripped. This helps the poor debugger make sense of why an assertion is being made and enforced, and hopefully what to do about it. Here is one complete example:

```
inline Value *getOperand(unsigned I) {
    assert(I < Operands.size() && "getOperand() out of range!");
    return Operands[I];
}
```

Here are more examples:

```
assert(Ty->isPointerType() && "Can't allocate a non-pointer type!");

assert((Opcode == Shl || Opcode == Shr) && "ShiftInst Opcode invalid!");

assert(idx < getNumSuccessors() && "Successor # out of range!");

assert(V1.getType() == V2.getType() && "Constant types must be identical!");

assert(isa<PHINode>(Succ->front()) && "Only works on PHId BBs!");
```

You get the idea.

In the past, asserts were used to indicate a piece of code that should not be reached. These were typically of the form:

```
assert(0 && "Invalid radix for integer literal");
```

This has a few issues, the main one being that some compilers might not understand the assertion, or warn about a missing return in builds where assertions are compiled out.

Today, we have something much better: `llvm_unreachable`:

```
llvm_unreachable("Invalid radix for integer literal");
```

When assertions are enabled, this will print the message if it's ever reached and then exit the program. When assertions are disabled (i.e. in release builds), `llvm_unreachable` becomes a hint to compilers to skip generating code for this branch. If the compiler does not support this, it will fall back to the "abort" implementation.

Neither assertions or `llvm_unreachable` will abort the program on a release build. If the error condition can be triggered by user input then the recoverable error mechanism described in *LLVM Programmer's Manual* should be used instead. In cases where this is not practical, `report_fatal_error` may be used.

Another issue is that values used only by assertions will produce an "unused value" warning when assertions are disabled. For example, this code will warn:

```
unsigned Size = V.size();
assert(Size > 42 && "Vector smaller than it should be");

bool NewToSet = Myset.insert(Value);
assert(NewToSet && "The value shouldn't be in the set yet");
```

These are two interesting different cases. In the first case, the call to `V.size()` is only useful for the assert, and we don't want it executed when assertions are disabled. Code like this should move the call into the assert itself. In the second case, the side effects of the call must happen whether the assert is enabled or not. In this case, the value should be cast to void to disable the warning. To be specific, it is preferred to write the code like this:

```
assert(V.size() > 42 && "Vector smaller than it should be");

bool NewToSet = Myset.insert(Value); (void)NewToSet;
assert(NewToSet && "The value shouldn't be in the set yet");
```

Do Not Use `using namespace std`

In LLVM, we prefer to explicitly prefix all identifiers from the standard namespace with an `"std::"` prefix, rather than rely on `"using namespace std;"`.

In header files, adding a `'using namespace XXX'` directive pollutes the namespace of any source file that `#includes` the header. This is clearly a bad thing.

In implementation files (e.g. `.cpp` files), the rule is more of a stylistic rule, but is still important. Basically, using explicit namespace prefixes makes the code **clearer**, because it is immediately obvious what facilities are being used and where they are coming from. And **more portable**, because namespace clashes cannot occur between LLVM code and other namespaces. The portability rule is important because different standard library implementations expose different symbols (potentially ones they shouldn't), and future revisions to the C++ standard will add more symbols to the `std` namespace. As such, we never use `'using namespace std;'` in LLVM.

The exception to the general rule (i.e. it's not an exception for the `std` namespace) is for implementation files. For example, all of the code in the LLVM project implements code that lives in the `'llvm'` namespace. As such, it is ok, and actually clearer, for the `.cpp` files to have a `'using namespace llvm;'` directive at the top, after the `#includes`. This reduces indentation in the body of the file for source editors that indent based on braces, and keeps the conceptual context cleaner. The general form of this rule is that any `.cpp` file that implements code in any namespace may use that namespace (and its parents'), but should not use any others.

Provide a Virtual Method Anchor for Classes in Headers

If a class is defined in a header file and has a vtable (either it has virtual methods or it derives from classes with virtual methods), it must always have at least one out-of-line virtual method in the class. Without this, the compiler will copy the vtable and RTTI into every `.o` file that `#includes` the header, bloating `.o` file sizes and increasing link times.

Don't use default labels in fully covered switches over enumerations

`-Wswitch` warns if a switch, without a default label, over an enumeration does not cover every enumeration value. If you write a default label on a fully covered switch over an enumeration then the `-Wswitch` warning won't fire when new elements are added to that enumeration. To help avoid adding these kinds of defaults, Clang has the warning `-Wcovered-switch-default` which is off by default but turned on when building LLVM with a version of Clang that supports the warning.

A knock-on effect of this stylistic requirement is that when building LLVM with GCC you may get warnings related to "control may reach end of non-void function" if you return from each case of a covered switch-over-enum because GCC assumes that the enum expression may take any representable value, not just those of individual enumerators. To suppress this warning, use `llvm_unreachable` after the switch.

Use range-based `for` loops wherever possible

The introduction of range-based `for` loops in C++11 means that explicit manipulation of iterators is rarely necessary. We use range-based `for` loops wherever possible for all newly added code. For example:

```
BasicBlock *BB = ...
for (Instruction &I : *BB)
    ... use I ...
```

Don't evaluate `end()` every time through a loop

In cases where range-based `for` loops can't be used and it is necessary to write an explicit iterator-based loop, pay close attention to whether `end()` is re-evaluated on each loop iteration. One common mistake is to write a loop in this style:

```
BasicBlock *BB = ...
for (auto I = BB->begin(); I != BB->end(); ++I)
    ... use I ...
```

The problem with this construct is that it evaluates `"BB->end()"` every time through the loop. Instead of writing the loop like this, we strongly prefer loops to be written so that they evaluate it once before the loop starts. A convenient way to do this is like so:

```
BasicBlock *BB = ...
for (auto I = BB->begin(), E = BB->end(); I != E; ++I)
    ... use I ...
```

The observant may quickly point out that these two loops may have different semantics: if the container (a basic block in this case) is being mutated, then `"BB->end()"` may change its value every time through the loop and the second loop may not in fact be correct. If you actually do depend on this behavior, please write the loop in the first form and add a comment indicating that you did it intentionally.

Why do we prefer the second form (when correct)? Writing the loop in the first form has two problems. First it may be less efficient than evaluating it at the start of the loop. In this case, the cost is probably minor --- a few extra loads

every time through the loop. However, if the base expression is more complex, then the cost can rise quickly. I've seen loops where the end expression was actually something like: `"SomeMap[X]->end()"` and map lookups really aren't cheap. By writing it in the second form consistently, you eliminate the issue entirely and don't even have to think about it.

The second (even bigger) issue is that writing the loop in the first form hints to the reader that the loop is mutating the container (a fact that a comment would handily confirm!). If you write the loop in the second form, it is immediately obvious without even looking at the body of the loop that the container isn't being modified, which makes it easier to read the code and understand what it does.

While the second form of the loop is a few extra keystrokes, we do strongly prefer it.

`#include <iostream>` is Forbidden

The use of `#include <iostream>` in library files is hereby **forbidden**, because many common implementations transparently inject a *static constructor* into every translation unit that includes it.

Note that using the other stream headers (`<sstream>` for example) is not problematic in this regard --- just `<iostream>`. However, `raw_ostream` provides various APIs that are better performing for almost every use than `std::ostream` style APIs.

Note: New code should always use *raw_ostream* for writing, or the `llvm::MemoryBuffer` API for reading files.

Use `raw_ostream`

LLVM includes a lightweight, simple, and efficient stream implementation in `llvm/Support/raw_ostream.h`, which provides all of the common features of `std::ostream`. All new code should use `raw_ostream` instead of `ostream`.

Unlike `std::ostream`, `raw_ostream` is not a template and can be forward declared as `class raw_ostream`. Public headers should generally not include the `raw_ostream` header, but use forward declarations and constant references to `raw_ostream` instances.

Avoid `std::endl`

The `std::endl` modifier, when used with `ostreams` outputs a newline to the output stream specified. In addition to doing this, however, it also flushes the output stream. In other words, these are equivalent:

```
std::cout << std::endl;
std::cout << '\n' << std::flush;
```

Most of the time, you probably have no reason to flush the output stream, so it's better to use a literal `'\n'`.

Don't use `inline` when defining a function in a class definition

A member function defined in a class definition is implicitly inline, so don't put the `inline` keyword in this case.

Don't:

```
class Foo {
public:
    inline void bar() {
        // ...
    }
};
```

Do:

```
class Foo {
public:
    void bar() {
        // ...
    }
};
```

Microscopic Details

This section describes preferred low-level formatting guidelines along with reasoning on why we prefer them.

Spaces Before Parentheses

We prefer to put a space before an open parenthesis only in control flow statements, but not in normal function call expressions and function-like macros. For example, this is good:

```
if (X) ...
for (I = 0; I != 100; ++I) ...
while (LLVMRocks) ...

somefunc(42);
assert(3 != 4 && "laws of math are failing me");

A = foo(42, 92) + bar(X);
```

and this is bad:

```
if(X) ...
for(I = 0; I != 100; ++I) ...
while(LLVMRocks) ...

somefunc (42);
assert (3 != 4 && "laws of math are failing me");

A = foo (42, 92) + bar (X);
```

The reason for doing this is not completely arbitrary. This style makes control flow operators stand out more, and makes expressions flow better. The function call operator binds very tightly as a postfix operator. Putting a space after a function name (as in the last example) makes it appear that the code might bind the arguments of the left-hand-side

of a binary operator with the argument list of a function and the name of the right side. More specifically, it is easy to misread the "A" example as:

```
A = foo ((42, 92) + bar) (X);
```

when skimming through the code. By avoiding a space in a function, we avoid this misinterpretation.

Prefer Preincrement

Hard fast rule: Preincrement ($++X$) may be no slower than postincrement ($X++$) and could very well be a lot faster than it. Use preincrementation whenever possible.

The semantics of postincrement include making a copy of the value being incremented, returning it, and then preincrementing the "work value". For primitive types, this isn't a big deal. But for iterators, it can be a huge issue (for example, some iterators contains stack and set objects in them... copying an iterator could invoke the copy ctor's of these as well). In general, get in the habit of always using preincrement, and you won't have a problem.

Namespace Indentation

In general, we strive to reduce indentation wherever possible. This is useful because we want code to *fit into 80 columns* without wrapping horribly, but also because it makes it easier to understand the code. To facilitate this and avoid some insanely deep nesting on occasion, don't indent namespaces. If it helps readability, feel free to add a comment indicating what namespace is being closed by a `}`. For example:

```
namespace llvm {
namespace knowledge {

/// This class represents things that Smith can have an intimate
/// understanding of and contains the data associated with it.
class Grokable {
...
public:
    explicit Grokable() { ... }
    virtual ~Grokable() = 0;

    ...
};

} // end namespace knowledge
} // end namespace llvm
```

Feel free to skip the closing comment when the namespace being closed is obvious for any reason. For example, the outer-most namespace in a header file is rarely a source of confusion. But namespaces both anonymous and named in source files that are being closed half way through the file probably could use clarification.

Anonymous Namespaces

After talking about namespaces in general, you may be wondering about anonymous namespaces in particular. Anonymous namespaces are a great language feature that tells the C++ compiler that the contents of the namespace are only visible within the current translation unit, allowing more aggressive optimization and eliminating the possibility of symbol name collisions. Anonymous namespaces are to C++ as "static" is to C functions and global variables. While "static" is available in C++, anonymous namespaces are more general: they can make entire classes private to a file.

The problem with anonymous namespaces is that they naturally want to encourage indentation of their body, and they reduce locality of reference: if you see a random function definition in a C++ file, it is easy to see if it is marked static, but seeing if it is in an anonymous namespace requires scanning a big chunk of the file.

Because of this, we have a simple guideline: make anonymous namespaces as small as possible, and only use them for class declarations. For example, this is good:

```
namespace {
class StringSort {
...
public:
    StringSort(...)
    bool operator<(const char *RHS) const;
};
} // end anonymous namespace

static void runHelper() {
    ...
}

bool StringSort::operator<(const char *RHS) const {
    ...
}
```

This is bad:

```
namespace {

class StringSort {
...
public:
    StringSort(...)
    bool operator<(const char *RHS) const;
};

void runHelper() {
    ...
}

bool StringSort::operator<(const char *RHS) const {
    ...
}

} // end anonymous namespace
```

This is bad specifically because if you're looking at "runHelper" in the middle of a large C++ file, that you have no immediate way to tell if it is local to the file. When it is marked static explicitly, this is immediately obvious. Also, there is no reason to enclose the definition of "operator<" in the namespace just because it was declared there.

3.2.5 See Also

A lot of these comments and recommendations have been culled from other sources. Two particularly important books for our work are:

1. [Effective C++](#) by Scott Meyers. Also interesting and useful are "More Effective C++" and "Effective STL" by the same author.
2. [Large-Scale C++ Software Design](#) by John Lakos

If you get some free time, and you haven't read them: do so, you might learn something.

3.3.1 Introduction

This document describes the CommandLine argument processing library. It will show you how to use it, and what it can do. The CommandLine library uses a declarative approach to specifying the command line options that your program takes. By default, these options declarations implicitly hold the value parsed for the option declared (of course this *can be changed*).

Although there are a **lot** of command line argument parsing libraries out there in many different languages, none of them fit well with what I needed. By looking at the features and problems of other libraries, I designed the CommandLine library to have the following features:

1. Speed: The CommandLine library is very quick and uses little resources. The parsing time of the library is directly proportional to the number of arguments parsed, not the number of options recognized. Additionally, command line argument values are captured transparently into user defined global variables, which can be accessed like any other variable (and with the same performance).
2. Type Safe: As a user of CommandLine, you don't have to worry about remembering the type of arguments that you want (is it an int? a string? a bool? an enum?) and keep casting it around. Not only does this help prevent error prone constructs, it also leads to dramatically cleaner source code.
3. No subclasses required: To use CommandLine, you instantiate variables that correspond to the arguments that you would like to capture, you don't subclass a parser. This means that you don't have to write **any** boilerplate code.
4. Globally accessible: Libraries can specify command line arguments that are automatically enabled in any tool that links to the library. This is possible because the application doesn't have to keep a list of arguments to pass to the parser. This also makes supporting *dynamically loaded options* trivial.
5. Cleaner: CommandLine supports enum and other types directly, meaning that there is less error and more security built into the library. You don't have to worry about whether your integral command line argument

accidentally got assigned a value that is not valid for your enum type.

6. **Powerful:** The CommandLine library supports many different types of arguments, from simple *boolean flags* to *scalars arguments* (*strings*, *integers*, *enums*, *doubles*), to *lists of arguments*. This is possible because CommandLine is...
7. **Extensible:** It is very simple to add a new argument type to CommandLine. Simply specify the parser that you want to use with the command line option when you declare it. *Custom parsers* are no problem.
8. **Labor Saving:** The CommandLine library cuts down on the amount of grunt work that you, the user, have to do. For example, it automatically provides a `-help` option that shows the available command line options for your tool. Additionally, it does most of the basic correctness checking for you.
9. **Capable:** The CommandLine library can handle lots of different forms of options often found in real programs. For example, *positional* arguments, *ls* style *grouping* options (to allow processing `'ls -lad'` naturally), *ld* style *prefix* options (to parse `'-lmalloc -L/usr/lib'`), and interpreter style options.

This document will hopefully let you jump in and start using CommandLine in your utility quickly and painlessly. Additionally it should be a simple reference manual to figure out how stuff works.

3.3.2 Quick Start Guide

This section of the manual runs through a simple CommandLine'ification of a basic compiler tool. This is intended to show you how to jump into using the CommandLine library in your own program, and show you some of the cool things it can do.

To start out, you need to include the CommandLine header file into your program:

```
#include "llvm/Support/CommandLine.h"
```

Additionally, you need to add this as the first line of your main program:

```
int main(int argc, char **argv) {  
    cl::ParseCommandLineOptions(argc, argv);  
    ...  
}
```

... which actually parses the arguments and fills in the variable declarations.

Now that you are ready to support command line arguments, we need to tell the system which ones we want, and what type of arguments they are. The CommandLine library uses a declarative syntax to model command line arguments with the global variable declarations that capture the parsed values. This means that for every command line option that you would like to support, there should be a global variable declaration to capture the result. For example, in a compiler, we would like to support the Unix-standard `'-o <filename>'` option to specify where to put the output. With the CommandLine library, this is represented like this:

```
cl::opt<string> OutputFilename("o", cl::desc("Specify output filename"), cl::value_  
↪ desc("filename"));
```

This declares a global variable "OutputFilename" that is used to capture the result of the "o" argument (first parameter). We specify that this is a simple scalar option by using the `"cl::opt"` template (as opposed to the `"cl::list"` template), and tell the CommandLine library that the data type that we are parsing is a string.

The second and third parameters (which are optional) are used to specify what to output for the `"-help"` option. In this case, we get a line that looks like this:

```
USAGE: compiler [options]
```

```
OPTIONS:
```

```
-h                - Alias for -help
-help            - display available options (-help-hidden for more)
-o <filename>    - Specify output filename
```

Because we specified that the command line option should parse using the `string` data type, the variable declared is automatically usable as a real string in all contexts that a normal C++ string object may be used. For example:

```
...
std::ofstream Output(OutputFilename.c_str());
if (Output.good()) ...
...
```

There are many different options that you can use to customize the command line option handling library, but the above example shows the general interface to these options. The options can be specified in any order, and are specified with helper functions like `cl::desc(...)`, so there are no positional dependencies to remember. The available options are discussed in detail in the [Reference Guide](#).

Continuing the example, we would like to have our compiler take an input filename as well as an output filename, but we do not want the input filename to be specified with a hyphen (ie, not `-filename.c`). To support this style of argument, the CommandLine library allows for *positional* arguments to be specified for the program. These positional arguments are filled with command line parameters that are not in option form. We use this feature like this:

```
cl::opt<string> InputFilename(cl::Positional, cl::desc("<input file>"), cl::init("-
↪"));
```

This declaration indicates that the first positional argument should be treated as the input filename. Here we use the `cl::init` option to specify an initial value for the command line option, which is used if the option is not specified (if you do not specify a `cl::init` modifier for an option, then the default constructor for the data type is used to initialize the value). Command line options default to being optional, so if we would like to require that the user always specify an input filename, we would add the `cl::Required` flag, and we could eliminate the `cl::init` modifier, like this:

```
cl::opt<string> InputFilename(cl::Positional, cl::desc("<input file>"), cl::Required);
```

Again, the CommandLine library does not require the options to be specified in any particular order, so the above declaration is equivalent to:

```
cl::opt<string> InputFilename(cl::Positional, cl::Required, cl::desc("<input file>"));
```

By simply adding the `cl::Required` flag, the CommandLine library will automatically issue an error if the argument is not specified, which shifts all of the command line option verification code out of your application into the library. This is just one example of how using flags can alter the default behaviour of the library, on a per-option basis. By adding one of the declarations above, the `-help` option synopsis is now extended to:

```
USAGE: compiler [options] <input file>
```

```
OPTIONS:
```

```
-h                - Alias for -help
-help            - display available options (-help-hidden for more)
-o <filename>    - Specify output filename
```

... indicating that an input filename is expected.

Boolean Arguments

In addition to input and output filenames, we would like the compiler example to support three boolean flags: "-f" to force writing binary output to a terminal, "--quiet" to enable quiet mode, and "-q" for backwards compatibility with some of our users. We can support these by declaring options of boolean type like this:

```
cl::opt<bool> Force ("f", cl::desc("Enable binary output on terminals"));
cl::opt<bool> Quiet ("quiet", cl::desc("Don't print informational messages"));
cl::opt<bool> Quiet2("q", cl::desc("Don't print informational messages"), cl::Hidden);
```

This does what you would expect: it declares three boolean variables ("Force", "Quiet", and "Quiet2") to recognize these options. Note that the "-q" option is specified with the "*cl::Hidden*" flag. This modifier prevents it from being shown by the standard "-help" output (note that it is still shown in the "-help-hidden" output).

The CommandLine library uses a *different parser* for different data types. For example, in the string case, the argument passed to the option is copied literally into the content of the string variable... we obviously cannot do that in the boolean case, however, so we must use a smarter parser. In the case of the boolean parser, it allows no options (in which case it assigns the value of true to the variable), or it allows the values "true" or "false" to be specified, allowing any of the following inputs:

```
compiler -f           # No value, 'Force' == true
compiler -f=true      # Value specified, 'Force' == true
compiler -f=TRUE      # Value specified, 'Force' == true
compiler -f=FALSE     # Value specified, 'Force' == false
```

... you get the idea. The *bool parser* just turns the string values into boolean values, and rejects things like 'compiler -f=foo'. Similarly, the *float*, *double*, and *int* parsers work like you would expect, using the 'strtol' and 'strtod' C library calls to parse the string value into the specified data type.

With the declarations above, "compiler -help" emits this:

```
USAGE: compiler [options] <input file>

OPTIONS:
  -f      - Enable binary output on terminals
  -o      - Override output filename
  -quiet  - Don't print informational messages
  -help   - display available options (-help-hidden for more)
```

and "compiler -help-hidden" prints this:

```
USAGE: compiler [options] <input file>

OPTIONS:
  -f      - Enable binary output on terminals
  -o      - Override output filename
  -q      - Don't print informational messages
  -quiet  - Don't print informational messages
  -help   - display available options (-help-hidden for more)
```

This brief example has shown you how to use the '*cl::opt*' class to parse simple scalar command line arguments. In addition to simple scalar arguments, the CommandLine library also provides primitives to support CommandLine option *aliases*, and *lists* of options.

Argument Aliases

So far, the example works well, except for the fact that we need to check the quiet condition like this now:

```
...
  if (!Quiet && !Quiet2) printInformationalMessage(...);
...
```

... which is a real pain! Instead of defining two values for the same condition, we can use the `cl::alias` class to make the `-q` option an **alias** for the `-quiet` option, instead of providing a value itself:

```
cl::opt<bool> Force ("f", cl::desc("Overwrite output files"));
cl::opt<bool> Quiet ("quiet", cl::desc("Don't print informational messages"));
cl::alias      QuietA("q", cl::desc("Alias for -quiet"), cl::aliasopt(Quiet));
```

The third line (which is the only one we modified from above) defines a `-q` alias that updates the `"Quiet"` variable (as specified by the `cl::aliasopt` modifier) whenever it is specified. Because aliases do not hold state, the only thing the program has to query is the `Quiet` variable now. Another nice feature of aliases is that they automatically hide themselves from the `-help` output (although, again, they are still visible in the `-help-hidden` output).

Now the application code can simply use:

```
...
  if (!Quiet) printInformationalMessage(...);
...
```

... which is much nicer! The `cl::alias` can be used to specify an alternative name for any variable type, and has many uses.

Selecting an alternative from a set of possibilities

So far we have seen how the `CommandLine` library handles builtin types like `std::string`, `bool` and `int`, but how does it handle things it doesn't know about, like enums or `'int*'s`?

The answer is that it uses a table-driven generic parser (unless you specify your own parser, as described in the [Extension Guide](#)). This parser maps literal strings to whatever type is required, and requires you to tell it what this mapping should be.

Let's say that we would like to add four optimization levels to our optimizer, using the standard flags `-g`, `-O0`, `-O1`, and `-O2`. We could easily implement this with boolean options like above, but there are several problems with this strategy:

1. A user could specify more than one of the options at a time, for example, `compiler -O3 -O2`. The `CommandLine` library would not be able to catch this erroneous input for us.
2. We would have to test 4 different variables to see which ones are set.
3. This doesn't map to the numeric levels that we want... so we cannot easily see if some level \geq `"-O1"` is enabled.

To cope with these problems, we can use an enum value, and have the `CommandLine` library fill it in with the appropriate level directly, which is used like this:

```
enum OptLevel {
  g, O1, O2, O3
};

cl::opt<OptLevel> OptimizationLevel(cl::desc("Choose optimization level:"),
  cl::values(
```

(continues on next page)

(continued from previous page)

```

    clEnumVal(g , "No optimizations, enable debugging"),
    clEnumVal(O1, "Enable trivial optimizations"),
    clEnumVal(O2, "Enable default optimizations"),
    clEnumVal(O3, "Enable expensive optimizations"));

...
    if (OptimizationLevel >= O2) doPartialRedundancyElimination(...);
...

```

This declaration defines a variable "OptimizationLevel" of the "OptLevel" enum type. This variable can be assigned any of the values that are listed in the declaration. The CommandLine library enforces that the user can only specify one of the options, and it ensure that only valid enum values can be specified. The "clEnumVal" macros ensure that the command line arguments matched the enum values. With this option added, our help output now is:

```

USAGE: compiler [options] <input file>

OPTIONS:
  Choose optimization level:
    -g          - No optimizations, enable debugging
    -O1         - Enable trivial optimizations
    -O2         - Enable default optimizations
    -O3         - Enable expensive optimizations
    -f          - Enable binary output on terminals
    -help       - display available options (-help-hidden for more)
    -o <filename> - Specify output filename
    -quiet      - Don't print informational messages

```

In this case, it is sort of awkward that flag names correspond directly to enum names, because we probably don't want a enum definition named "g" in our program. Because of this, we can alternatively write this example like this:

```

enum OptLevel {
    Debug, O1, O2, O3
};

cl::opt<OptLevel> OptimizationLevel(cl::desc("Choose optimization level:"),
    cl::values(
        clEnumValN(Debug, "g", "No optimizations, enable debugging"),
        clEnumVal(O1, "Enable trivial optimizations"),
        clEnumVal(O2, "Enable default optimizations"),
        clEnumVal(O3, "Enable expensive optimizations")));

...
    if (OptimizationLevel == Debug) outputDebugInfo(...);
...

```

By using the "clEnumValN" macro instead of "clEnumVal", we can directly specify the name that the flag should get. In general a direct mapping is nice, but sometimes you can't or don't want to preserve the mapping, which is when you would use it.

Named Alternatives

Another useful argument form is a named alternative style. We shall use this style in our compiler to specify different debug levels that can be used. Instead of each debug level being its own switch, we want to support the following options, of which only one can be specified at a time: "--debug-level=none", "--debug-level=quick", "--debug-level=detailed". To do this, we use the exact same format as our optimization level flags, but we also specify an option name. For this case, the code looks like this:

```
enum DebugLev {
    nodebuginfo, quick, detailed
};

// Enable Debug Options to be specified on the command line
cl::opt<DebugLev> DebugLevel("debug_level", cl::desc("Set the debugging level:"),
    cl::values(
        clEnumValN(nodebuginfo, "none", "disable debug information"),
        clEnumVal(quick, "enable quick debug information"),
        clEnumVal(detailed, "enable detailed debug information")));
```

This definition defines an enumerated command line variable of type "enum DebugLev", which works exactly the same way as before. The difference here is just the interface exposed to the user of your program and the help output by the "-help" option:

```
USAGE: compiler [options] <input file>

OPTIONS:
  Choose optimization level:
    -g           - No optimizations, enable debugging
    -O1          - Enable trivial optimizations
    -O2          - Enable default optimizations
    -O3          - Enable expensive optimizations
  -debug_level  - Set the debugging level:
    =none       - disable debug information
    =quick      - enable quick debug information
    =detailed   - enable detailed debug information
  -f           - Enable binary output on terminals
  -help        - display available options (-help-hidden for more)
  -o <filename> - Specify output filename
  -quiet       - Don't print informational messages
```

Again, the only structural difference between the debug level declaration and the optimization level declaration is that the debug level declaration includes an option name ("debug_level"), which automatically changes how the library processes the argument. The CommandLine library supports both forms so that you can choose the form most appropriate for your application.

Parsing a list of options

Now that we have the standard run-of-the-mill argument types out of the way, let's get a little wild and crazy. Let's say that we want our optimizer to accept a **list** of optimizations to perform, allowing duplicates. For example, we might want to run: "compiler -dce -constprop -inline -dce -strip". In this case, the order of the arguments and the number of appearances is very important. This is what the "cl::list" template is for. First, start by defining an enum of the optimizations that you would like to perform:

```
enum Opts {
    // 'inline' is a C++ keyword, so name it 'inlining'
```

(continues on next page)

(continued from previous page)

```
dce, constprop, inlining, strip
};
```

Then define your "cl::list" variable:

```
cl::list<Opts> OptimizationList(cl::desc("Available Optimizations:"),
  cl::values(
    clEnumVal(dce, "Dead Code Elimination"),
    clEnumVal(constprop, "Constant Propagation"),
    clEnumValN(inlining, "inline", "Procedure Integration"),
    clEnumVal(strip, "Strip Symbols")));
```

This defines a variable that is conceptually of the type "std::vector<enum Opts>". Thus, you can access it with standard vector methods:

```
for (unsigned i = 0; i != OptimizationList.size(); ++i)
  switch (OptimizationList[i])
    ...
```

... to iterate through the list of options specified.

Note that the "cl::list" template is completely general and may be used with any data types or other arguments that you can use with the "cl::opt" template. One especially useful way to use a list is to capture all of the positional arguments together if there may be more than one specified. In the case of a linker, for example, the linker takes several '.o' files, and needs to capture them into a list. This is naturally specified as:

```
...
cl::list<std::string> InputFileNames(cl::Positional, cl::desc("<Input files>"),
  ↪ cl::OneOrMore);
...
```

This variable works just like a "vector<string>" object. As such, accessing the list is simple, just like above. In this example, we used the *cl::OneOrMore* modifier to inform the CommandLine library that it is an error if the user does not specify any .o files on our command line. Again, this just reduces the amount of checking we have to do.

Collecting options as a set of flags

Instead of collecting sets of options in a list, it is also possible to gather information for enum values in a **bit vector**. The representation used by the *cl::bits* class is an unsigned integer. An enum value is represented by a 0/1 in the enum's ordinal value bit position. 1 indicating that the enum was specified, 0 otherwise. As each specified value is parsed, the resulting enum's bit is set in the option's bit vector:

```
bits |= 1 << (unsigned)enum;
```

Options that are specified multiple times are redundant. Any instances after the first are discarded.

Reworking the above list example, we could replace *cl::list* with *cl::bits*:

```
cl::bits<Opts> OptimizationBits(cl::desc("Available Optimizations:"),
  cl::values(
    clEnumVal(dce, "Dead Code Elimination"),
    clEnumVal(constprop, "Constant Propagation"),
    clEnumValN(inlining, "inline", "Procedure Integration"),
    clEnumVal(strip, "Strip Symbols")));
```

To test to see if constprop was specified, we can use the *cl::bits::isSet* function:

```
if (OptimizationBits.isSet(constprop)) {
    ...
}
```

It's also possible to get the raw bit vector using the `cl::bits::getBits` function:

```
unsigned bits = OptimizationBits.getBits();
```

Finally, if external storage is used, then the location specified must be of **type** unsigned. In all other ways a `cl::bits` option is equivalent to a `cl::list` option.

Adding freeform text to help output

As our program grows and becomes more mature, we may decide to put summary information about what it does into the help output. The help output is styled to look similar to a Unix man page, providing concise information about a program. Unix man pages, however often have a description about what the program does. To add this to your CommandLine program, simply pass a third argument to the `cl::ParseCommandLineOptions` call in main. This additional argument is then printed as the overview information for your program, allowing you to include any additional information that you want. For example:

```
int main(int argc, char **argv) {
    cl::ParseCommandLineOptions(argc, argv, " CommandLine compiler example\n\n"
                                " This program blah blah blah...\n");
    ...
}
```

would yield the help output:

```
**OVERVIEW: CommandLine compiler example

    This program blah blah blah...**

USAGE: compiler [options] <input file>

OPTIONS:
    ...
    -help           - display available options (-help-hidden for more)
    -o <filename>   - Specify output filename
```

Grouping options into categories

If our program has a large number of options it may become difficult for users of our tool to navigate the output of `-help`. To alleviate this problem we can put our options into categories. This can be done by declaring option categories (`cl::OptionCategory` objects) and then placing our options into these categories using the `cl::cat` option attribute. For example:

```
cl::OptionCategory StageSelectionCat("Stage Selection Options",
                                     "These control which stages are run.");

cl::opt<bool> Preprocessor("E", cl::desc("Run preprocessor stage."),
                          cl::cat(StageSelectionCat));

cl::opt<bool> NoLink("c", cl::desc("Run all stages except linking."),
                    cl::cat(StageSelectionCat));
```

The output of `-help` will become categorized if an option category is declared. The output looks something like

```
OVERVIEW: This is a small program to demo the LLVM CommandLine API
USAGE: Sample [options]

OPTIONS:

  General options:

    -help                - Display available options (-help-hidden for more)
    -help-list           - Display list of available options (-help-list-hidden for
    ↪more)

  Stage Selection Options:
  These control which stages are run.

    -E                  - Run preprocessor stage.
    -c                  - Run all stages except linking.
```

In addition to the behaviour of `-help` changing when an option category is declared, the command line option `-help-list` becomes visible which will print the command line options as uncategorized list.

Note that Options that are not explicitly categorized will be placed in the `cl::GeneralCategory` category.

3.3.3 Reference Guide

Now that you know the basics of how to use the CommandLine library, this section will give you the detailed information you need to tune how command line options work, as well as information on more "advanced" command line option processing capabilities.

Positional Arguments

Positional arguments are those arguments that are not named, and are not specified with a hyphen. Positional arguments should be used when an option is specified by its position alone. For example, the standard Unix `grep` tool takes a regular expression argument, and an optional filename to search through (which defaults to standard input if a filename is not specified). Using the CommandLine library, this would be specified as:

```
cl::opt<string> Regex    (cl::Positional, cl::desc("<regular expression>"),
    ↪cl::Required);
cl::opt<string> Filename(cl::Positional, cl::desc("<input file>"), cl::init("-"));
```

Given these two option declarations, the `-help` output for our `grep` replacement would look like this:

```
USAGE: spiffygrep [options] <regular expression> <input file>

OPTIONS:
  -help - display available options (-help-hidden for more)
```

... and the resultant program could be used just like the standard `grep` tool.

Positional arguments are sorted by their order of construction. This means that command line options will be ordered according to how they are listed in a `.cpp` file, but will not have an ordering defined if the positional arguments are defined in multiple `.cpp` files. The fix for this problem is simply to define all of your positional arguments in one `.cpp` file.

Specifying positional options with hyphens

Sometimes you may want to specify a value to your positional argument that starts with a hyphen (for example, searching for `-foo` in a file). At first, you will have trouble doing this, because it will try to find an argument named `-foo`, and will fail (and single quotes will not save you). Note that the system `grep` has the same problem:

```
$ spiffygrep '-foo' test.txt
Unknown command line argument '-foo'. Try: spiffygrep -help'

$ grep '-foo' test.txt
grep: illegal option -- f
grep: illegal option -- o
grep: illegal option -- o
Usage: grep -hblcnsviw pattern file . . .
```

The solution for this problem is the same for both your tool and the system version: use the `--` marker. When the user specifies `--` on the command line, it is telling the program that all options after the `--` should be treated as positional arguments, not options. Thus, we can use it like this:

```
$ spiffygrep -- -foo test.txt
...output...
```

Determining absolute position with `getPosition()`

Sometimes an option can affect or modify the meaning of another option. For example, consider `gcc`'s `-x LANG` option. This tells `gcc` to ignore the suffix of subsequent positional arguments and force the file to be interpreted as if it contained source code in language `LANG`. In order to handle this properly, you need to know the absolute position of each argument, especially those in lists, so their interaction(s) can be applied correctly. This is also useful for options like `-llibname` which is actually a positional argument that starts with a dash.

So, generally, the problem is that you have two `cl::list` variables that interact in some way. To ensure the correct interaction, you can use the `cl::list::getPosition(optnum)` method. This method returns the absolute position (as found on the command line) of the `optnum` item in the `cl::list`.

The idiom for usage is like this:

```
static cl::list<std::string> Files(cl::Positional, cl::OneOrMore);
static cl::list<std::string> Libraries("l", cl::ZeroOrMore);

int main(int argc, char**argv) {
    // ...
    std::vector<std::string>::iterator fileIt = Files.begin();
    std::vector<std::string>::iterator libIt = Libraries.begin();
    unsigned libPos = 0, filePos = 0;
    while ( 1 ) {
        if ( libIt != Libraries.end() )
            libPos = Libraries.getPosition( libIt - Libraries.begin() );
        else
            libPos = 0;
        if ( fileIt != Files.end() )
            filePos = Files.getPosition( fileIt - Files.begin() );
        else
            filePos = 0;

        if ( filePos != 0 && (libPos == 0 || filePos < libPos) ) {
```

(continues on next page)

(continued from previous page)

```

    // Source File Is next
    ++fileIt;
}
else if ( libPos != 0 && (filePos == 0 || libPos < filePos) ) {
    // Library is next
    ++libIt;
}
else
    break; // we're done with the list
}
}

```

Note that, for compatibility reasons, the `cl::opt` also supports an unsigned `getPosition()` option that will provide the absolute position of that option. You can apply the same approach as above with a `cl::opt` and a `cl::list` option as you can with two lists.

The `cl::ConsumeAfter` modifier

The `cl::ConsumeAfter` *formatting option* is used to construct programs that use "interpreter style" option processing. With this style of option processing, all arguments specified after the last positional argument are treated as special interpreter arguments that are not interpreted by the command line argument.

As a concrete example, lets say we are developing a replacement for the standard Unix Bourne shell (`/bin/sh`). To run `/bin/sh`, first you specify options to the shell itself (like `-x` which turns on trace output), then you specify the name of the script to run, then you specify arguments to the script. These arguments to the script are parsed by the Bourne shell command line option processor, but are not interpreted as options to the shell itself. Using the `CommandLine` library, we would specify this as:

```

cl::opt<string> Script(cl::Positional, cl::desc("<input script>"), cl::init("-"));
cl::list<string> Argv(cl::ConsumeAfter, cl::desc("<program arguments>..."));
cl::opt<bool> Trace("x", cl::desc("Enable trace output"));

```

which automatically provides the help output:

```

USAGE: spiffysh [options] <input script> <program arguments>...

OPTIONS:
  -help - display available options (-help-hidden for more)
  -x    - Enable trace output

```

At runtime, if we run our new shell replacement as ``spiffysh -x test.sh -a -x -y bar'`, the `Trace` variable will be set to true, the `Script` variable will be set to `"test.sh"`, and the `Argv` list will contain `["-a", "-x", "-y", "bar"]`, because they were specified after the last positional argument (which is the script name).

There are several limitations to when `cl::ConsumeAfter` options can be specified. For example, only one `cl::ConsumeAfter` can be specified per program, there must be at least one *positional argument* specified, there must not be any *cl::list* positional arguments, and the `cl::ConsumeAfter` option should be a *cl::list* option.

Internal vs External Storage

By default, all command line options automatically hold the value that they parse from the command line. This is very convenient in the common case, especially when combined with the ability to define command line options in the files that use them. This is called the internal storage model.

Sometimes, however, it is nice to separate the command line option processing code from the storage of the value parsed. For example, let's say that we have a `-debug` option that we would like to use to enable debug information across the entire body of our program. In this case, the boolean value controlling the debug code should be globally accessible (in a header file, for example) yet the command line option processing code should not be exposed to all of these clients (requiring lots of `.cpp` files to `#include CommandLine.h`).

To do this, set up your `.h` file with your option, like this for example:

```
// DebugFlag.h - Get access to the '-debug' command line option
//

// DebugFlag - This boolean is set to true if the '-debug' command line option
// is specified. This should probably not be referenced directly, instead, use
// the DEBUG macro below.
//
extern bool DebugFlag;

// DEBUG macro - This macro should be used by code to emit debug information.
// In the '-debug' option is specified on the command line, and if this is a
// debug build, then the code specified as the option to the macro will be
// executed. Otherwise it will not be.
#ifdef NDEBUG
#define LLVM_DEBUG(X)
#else
#define LLVM_DEBUG(X) do { if (DebugFlag) { X; } } while (0)
#endif
```

This allows clients to blissfully use the `LLVM_DEBUG()` macro, or the `DebugFlag` explicitly if they want to. Now we just need to be able to set the `DebugFlag` boolean when the option is set. To do this, we pass an additional argument to our command line argument processor, and we specify where to fill in with the `cl::location` attribute:

```
bool DebugFlag; // the actual value
static cl::opt<bool, true> // The parser
Debug("debug", cl::desc("Enable debug output"), cl::Hidden, cl::location(DebugFlag));
```

In the above example, we specify `"true"` as the second argument to the `cl::opt` template, indicating that the template should not maintain a copy of the value itself. In addition to this, we specify the `cl::location` attribute, so that `DebugFlag` is automatically set.

Option Attributes

This section describes the basic attributes that you can specify on options.

- The option name attribute (which is required for all options, except *positional options*) specifies what the option name is. This option is specified in simple double quotes:

```
cl::opt<bool> Quiet("quiet");
```

- The `cl::desc` attribute specifies a description for the option to be shown in the `-help` output for the program. This attribute supports multi-line descriptions with lines separated by `'\n'`.

- The **cl::value_desc** attribute specifies a string that can be used to fine tune the `-help` output for a command line option. Look [here](#) for an example.
- The **cl::init** attribute specifies an initial value for a [scalar](#) option. If this attribute is not specified then the command line option value defaults to the value created by the default constructor for the type.

Warning: If you specify both **cl::init** and **cl::location** for an option, you must specify **cl::location** first, so that when the command-line parser sees **cl::init**, it knows where to put the initial value. (You will get an error at runtime if you don't put them in the right order.)

- The **cl::location** attribute where to store the value for a parsed command line option if using external storage. See the section on [Internal vs External Storage](#) for more information.
- The **cl::aliasopt** attribute specifies which option a [cl::alias](#) option is an alias for.
- The **cl::values** attribute specifies the string-to-value mapping to be used by the generic parser. It takes a list of (option, value, description) triplets that specify the option name, the value mapped to, and the description shown in the `-help` for the tool. Because the generic parser is used most frequently with enum values, two macros are often useful:
 1. The **clEnumVal** macro is used as a nice simple way to specify a triplet for an enum. This macro automatically makes the option name be the same as the enum name. The first option to the macro is the enum, the second is the description for the command line option.
 2. The **clEnumValN** macro is used to specify macro options where the option name doesn't equal the enum name. For this macro, the first argument is the enum value, the second is the flag name, and the second is the description.

You will get a compile time error if you try to use `cl::values` with a parser that does not support it.

- The **cl::multi_val** attribute specifies that this option takes has multiple values (example: `-sectalign sectname sectvalue`). This attribute takes one unsigned argument - the number of values for the option. This attribute is valid only on `cl::list` options (and will fail with compile error if you try to use it with other option types). It is allowed to use all of the usual modifiers on multi-valued options (besides `cl::ValueDisallowed`, obviously).
- The **cl::cat** attribute specifies the option category that the option belongs to. The category should be a [cl::OptionCategory](#) object.

Option Modifiers

Option modifiers are the flags and expressions that you pass into the constructors for [cl::opt](#) and [cl::list](#). These modifiers give you the ability to tweak how options are parsed and how `-help` output is generated to fit your application well.

These options fall into five main categories:

1. Hiding an option from `-help` output
2. Controlling the number of occurrences required and allowed
3. Controlling whether or not a value must be specified
4. Controlling other formatting options
5. Miscellaneous option modifiers

It is not possible to specify two options from the same category (you'll get a runtime error) to a single option, except for options in the miscellaneous category. The CommandLine library specifies defaults for all of these settings that are the most useful in practice and the most common, which mean that you usually shouldn't have to worry about these.

Hiding an option from `-help` output

The `cl::NotHidden`, `cl::Hidden`, and `cl::ReallyHidden` modifiers are used to control whether or not an option appears in the `-help` and `-help-hidden` output for the compiled program:

- The **`cl::NotHidden`** modifier (which is the default for `cl::opt` and `cl::list` options) indicates the option is to appear in both help listings.
- The **`cl::Hidden`** modifier (which is the default for `cl::alias` options) indicates that the option should not appear in the `-help` output, but should appear in the `-help-hidden` output.
- The **`cl::ReallyHidden`** modifier indicates that the option should not appear in any help output.

Controlling the number of occurrences required and allowed

This group of options is used to control how many time an option is allowed (or required) to be specified on the command line of your program. Specifying a value for this setting allows the CommandLine library to do error checking for you.

The allowed values for this option group are:

- The **`cl::Optional`** modifier (which is the default for the `cl::opt` and `cl::alias` classes) indicates that your program will allow either zero or one occurrence of the option to be specified.
- The **`cl::ZeroOrMore`** modifier (which is the default for the `cl::list` class) indicates that your program will allow the option to be specified zero or more times.
- The **`cl::Required`** modifier indicates that the specified option must be specified exactly one time.
- The **`cl::OneOrMore`** modifier indicates that the option must be specified at least one time.
- The **`cl::ConsumeAfter`** modifier is described in the *Positional arguments section*.

If an option is not specified, then the value of the option is equal to the value specified by the `cl::init` attribute. If the `cl::init` attribute is not specified, the option value is initialized with the default constructor for the data type.

If an option is specified multiple times for an option of the `cl::opt` class, only the last value will be retained.

Controlling whether or not a value must be specified

This group of options is used to control whether or not the option allows a value to be present. In the case of the CommandLine library, a value is either specified with an equal sign (e.g. `-index-depth=17`) or as a trailing string (e.g. `-o a.out`).

The allowed values for this option group are:

- The **`cl::ValueOptional`** modifier (which is the default for `bool` typed options) specifies that it is acceptable to have a value, or not. A boolean argument can be enabled just by appearing on the command line, or it can have an explicit `-foo=true`. If an option is specified with this mode, it is illegal for the value to be provided without the equal sign. Therefore `-foo true` is illegal. To get this behavior, you must use the `cl::ValueRequired` modifier.

- The **cl::ValueRequired** modifier (which is the default for all other types except for *unnamed alternatives using the generic parser*) specifies that a value must be provided. This mode informs the command line library that if an option is not provided with an equal sign, that the next argument provided must be the value. This allows things like '-o a.out' to work.
- The **cl::ValueDisallowed** modifier (which is the default for *unnamed alternatives using the generic parser*) indicates that it is a runtime error for the user to specify a value. This can be provided to disallow users from providing options to boolean options (like '-foo=true').

In general, the default values for this option group work just like you would want them to. As mentioned above, you can specify the *cl::ValueDisallowed* modifier to a boolean argument to restrict your command line parser. These options are mostly useful when *extending the library*.

Controlling other formatting options

The formatting option group is used to specify that the command line option has special abilities and is otherwise different from other command line arguments. As usual, you can only specify one of these arguments at most.

- The **cl::NormalFormatting** modifier (which is the default all options) specifies that this option is "normal".
- The **cl::Positional** modifier specifies that this is a positional argument that does not have a command line option associated with it. See the *Positional Arguments* section for more information.
- The **cl::ConsumeAfter** modifier specifies that this option is used to capture "interpreter style" arguments. See *this section for more information*.
- The **cl::Prefix** modifier specifies that this option prefixes its value. With 'Prefix' options, the equal sign does not separate the value from the option name specified. Instead, the value is everything after the prefix, including any equal sign if present. This is useful for processing odd arguments like `-lmalloc` and `-L/usr/lib` in a linker tool or `-DNAME=value` in a compiler tool. Here, the 'l', 'D' and 'L' options are normal string (or list) options, that have the **cl::Prefix** modifier added to allow the CommandLine library to recognize them. Note that **cl::Prefix** options must not have the **cl::ValueDisallowed** modifier specified.

Controlling options grouping

The **cl::Grouping** modifier can be combined with any formatting types except for *cl::Positional*. It is used to implement Unix-style tools (like `ls`) that have lots of single letter arguments, but only require a single dash. For example, the `'ls -labf'` command actually enables four different options, all of which are single letters.

Note that **cl::Grouping** options can have values only if they are used separately or at the end of the groups. For *cl::ValueRequired*, it is a runtime error if such an option is used elsewhere in the group.

The CommandLine library does not restrict how you use the **cl::Prefix** or **cl::Grouping** modifiers, but it is possible to specify ambiguous argument settings. Thus, it is possible to have multiple letter options that are prefix or grouping options, and they will still work as designed.

To do this, the CommandLine library uses a greedy algorithm to parse the input option into (potentially multiple) prefix and grouping options. The strategy basically looks like this:

```
parse(string OrigInput) {  
1. string Input = OrigInput;  
2. if (isOption(Input)) return getOption(Input).parse(); // Normal option  
3. while (!Input.empty() && !isOption(Input)) Input.pop_back(); // Remove the last  
   ↪ letter  
4. while (!Input.empty()) {
```

(continues on next page)

(continued from previous page)

```

    string MaybeValue = OrigInput.substr(Input.length())
    if (getOption(Input).isPrefix())
        return getOption(Input).parse(MaybeValue)
    if (!MaybeValue.empty() && MaybeValue[0] == '=')
        return getOption(Input).parse(MaybeValue.substr(1))
    if (!getOption(Input).isGrouping())
        return error()
    getOption(Input).parse()
    Input = OrigInput = MaybeValue
    while (!Input.empty() && !isOption(Input)) Input.pop_back();
    if (!Input.empty() && !getOption(Input).isGrouping())
        return error()
}
5. if (!OrigInput.empty()) error();
}

```

Miscellaneous option modifiers

The miscellaneous option modifiers are the only flags where you can specify more than one flag from the set: they are not mutually exclusive. These flags specify boolean properties that modify the option.

- The **cl::CommaSeparated** modifier indicates that any commas specified for an option's value should be used to split the value up into multiple values for the option. For example, these two options are equivalent when `cl::CommaSeparated` is specified: `"-foo=a -foo=b -foo=c"` and `"-foo=a, b, c"`. This option only makes sense to be used in a case where the option is allowed to accept one or more values (i.e. it is a *cl::list* option).
- The **cl::DefaultOption** modifier is used to specify that the option is a default that can be overridden by application specific parsers. For example, the `-help` alias, `-h`, is registered this way, so it can be overridden by applications that need to use the `-h` option for another purpose, either as a regular option or an alias for another option.
- The **cl::PositionalEatsArgs** modifier (which only applies to positional arguments, and only makes sense for lists) indicates that positional argument should consume any strings after it (including strings that start with a `"-"`) up until another recognized positional argument. For example, if you have two "eating" positional arguments, `"pos1"` and `"pos2"`, the string `"-pos1 -foo -bar baz -pos2 -bork"` would cause the `"-foo -bar -baz"` strings to be applied to the `"-pos1"` option and the `"-bork"` string to be applied to the `"-pos2"` option.
- The **cl::Sink** modifier is used to handle unknown options. If there is at least one option with `cl::Sink` modifier specified, the parser passes unrecognized option strings to it as values instead of signaling an error. As with `cl::CommaSeparated`, this modifier only makes sense with a *cl::list* option.

Response files

Some systems, such as certain variants of Microsoft Windows and some older Unices have a relatively low limit on command-line length. It is therefore customary to use the so-called 'response files' to circumvent this restriction. These files are mentioned on the command-line (using the "@file") syntax. The program reads these files and inserts the contents into argv, thereby working around the command-line length limits.

Top-Level Classes and Functions

Despite all of the built-in flexibility, the CommandLine option library really only consists of one function (`cl::ParseCommandLineOptions`) and three main classes: `cl::opt`, `cl::list`, and `cl::alias`. This section describes these three classes in detail.

The `cl::getRegisteredOptions` function

The `cl::getRegisteredOptions` function is designed to give a programmer access to declared non-positional command line options so that how they appear in `-help` can be modified prior to calling `cl::ParseCommandLineOptions`. Note this method should not be called during any static initialisation because it cannot be guaranteed that all options will have been initialised. Hence it should be called from `main`.

This function can be used to gain access to options declared in libraries that the tool writer may not have direct access to.

The function retrieves a *StringMap* that maps the option string (e.g. `-help`) to an `Option*`.

Here is an example of how the function could be used:

```
using namespace llvm;
int main(int argc, char **argv) {
    cl::OptionCategory AnotherCategory("Some options");

    StringMap<cl::Option*> &Map = cl::getRegisteredOptions();

    //Unhide useful option and put it in a different category
    assert(Map.count("print-all-options") > 0);
    Map["print-all-options"]->setHiddenFlag(cl::NotHidden);
    Map["print-all-options"]->setCategory(AnotherCategory);

    //Hide an option we don't want to see
    assert(Map.count("enable-no-infs-fp-math") > 0);
    Map["enable-no-infs-fp-math"]->setHiddenFlag(cl::Hidden);

    //Change --version to --show-version
    assert(Map.count("version") > 0);
    Map["version"]->setArgStr("show-version");

    //Change --help description
    assert(Map.count("help") > 0);
    Map["help"]->setDescription("Shows help");

    cl::ParseCommandLineOptions(argc, argv, "This is a small program to demo the LLVM_
↪ CommandLine API");
    ...
}
```

The `cl::ParseCommandLineOptions` function

The `cl::ParseCommandLineOptions` function is designed to be called directly from `main`, and is used to fill in the values of all of the command line option variables once `argc` and `argv` are available.

The `cl::ParseCommandLineOptions` function requires two parameters (`argc` and `argv`), but may also take an optional third parameter which holds *additional extra text* to emit when the `-help` option is invoked.

The `cl::ParseEnvironmentOptions` function

The `cl::ParseEnvironmentOptions` function has mostly the same effects as `cl::ParseCommandLineOptions`, except that it is designed to take values for options from an environment variable, for those cases in which reading the command line is not convenient or desired. It fills in the values of all the command line option variables just like `cl::ParseCommandLineOptions` does.

It takes four parameters: the name of the program (since `argv` may not be available, it can't just look in `argv[0]`), the name of the environment variable to examine, and the optional *additional extra text* to emit when the `-help` option is invoked.

`cl::ParseEnvironmentOptions` will break the environment variable's value up into words and then process them using `cl::ParseCommandLineOptions`. **Note:** Currently `cl::ParseEnvironmentOptions` does not support quoting, so an environment variable containing `-option "foo bar"` will be parsed as three words, `-option`, `"foo`, and `bar"`, which is different from what you would get from the shell with the same input.

The `cl::SetVersionPrinter` function

The `cl::SetVersionPrinter` function is designed to be called directly from `main` and *before* `cl::ParseCommandLineOptions`. Its use is optional. It simply arranges for a function to be called in response to the `--version` option instead of having the `CommandLine` library print out the usual version string for LLVM. This is useful for programs that are not part of LLVM but wish to use the `CommandLine` facilities. Such programs should just define a small function that takes no arguments and returns `void` and that prints out whatever version information is appropriate for the program. Pass the address of that function to `cl::SetVersionPrinter` to arrange for it to be called when the `--version` option is given by the user.

The `cl::opt` class

The `cl::opt` class is the class used to represent scalar command line options, and is the one used most of the time. It is a templated class which can take up to three arguments (all except for the first have default values though):

```
namespace cl {
  template <class DataType, bool ExternalStorage = false,
           class ParserClass = parser<DataType> >
    class opt;
}
```

The first template argument specifies what underlying data type the command line argument is, and is used to select a default parser implementation. The second template argument is used to specify whether the option should contain the storage for the option (the default) or whether external storage should be used to contain the value parsed for the option (see *Internal vs External Storage* for more information).

The third template argument specifies which parser to use. The default value selects an instantiation of the `parser` class based on the underlying data type of the option. In general, this default works well for most applications, so this option is only used when using a *custom parser*.

The `cl::list` class

The `cl::list` class is the class used to represent a list of command line options. It too is a templated class which can take up to three arguments:

```
namespace cl {  
    template <class DataType, class Storage = bool,  
              class ParserClass = parser<DataType> >  
        class list;  
}
```

This class works the exact same as the `cl::opt` class, except that the second argument is the **type** of the external storage, not a boolean value. For this class, the marker type 'bool' is used to indicate that internal storage should be used.

The `cl::bits` class

The `cl::bits` class is the class used to represent a list of command line options in the form of a bit vector. It is also a templated class which can take up to three arguments:

```
namespace cl {  
    template <class DataType, class Storage = bool,  
              class ParserClass = parser<DataType> >  
        class bits;  
}
```

This class works the exact same as the `cl::list` class, except that the second argument must be of **type** unsigned if external storage is used.

The `cl::alias` class

The `cl::alias` class is a nontemplated class that is used to form aliases for other arguments.

```
namespace cl {  
    class alias;  
}
```

The `cl::aliasopt` attribute should be used to specify which option this is an alias for. Alias arguments default to being `cl::Hidden`, and use the aliased options parser to do the conversion from string to data.

The `cl::extrahelp` class

The `cl::extrahelp` class is a nontemplated class that allows extra help text to be printed out for the `-help` option.

```
namespace cl {  
    struct extrahelp;  
}
```

To use the `extrahelp`, simply construct one with a `const char*` parameter to the constructor. The text passed to the constructor will be printed at the bottom of the help message, verbatim. Note that multiple `cl::extrahelp` **can** be used, but this practice is discouraged. If your tool needs to print additional help information, put all that help into a single `cl::extrahelp` instance.

For example:

```
cl::extrahelp("\nADDITIONAL HELP:\n\n This is the extra help\n");
```

The `cl::OptionCategory` class

The `cl::OptionCategory` class is a simple class for declaring option categories.

```
namespace cl {
    class OptionCategory;
}
```

An option category must have a name and optionally a description which are passed to the constructor as `const char*`.

Note that declaring an option category and associating it with an option before parsing options (e.g. statically) will change the output of `-help` from uncategorized to categorized. If an option category is declared but not associated with an option then it will be hidden from the output of `-help` but will be shown in the output of `-help-hidden`.

Builtin parsers

Parsers control how the string value taken from the command line is translated into a typed value, suitable for use in a C++ program. By default, the CommandLine library uses an instance of `parser<type>` if the command line option specifies that it uses values of type `'type'`. Because of this, custom option processing is specified with specializations of the `'parser'` class.

The CommandLine library provides the following builtin parser specializations, which are sufficient for most applications. It can, however, also be extended to work with new data types and new ways of interpreting the same data. See the [Writing a Custom Parser](#) for more details on this type of library extension.

- The generic `parser<t>` parser can be used to map strings values to any data type, through the use of the [cl::values](#) property, which specifies the mapping information. The most common use of this parser is for parsing enum values, which allows you to use the CommandLine library for all of the error checking to make sure that only valid enum values are specified (as opposed to accepting arbitrary strings). Despite this, however, the generic parser class can be used for any data type.
- The **`parser<bool>` specialization** is used to convert boolean strings to a boolean value. Currently accepted strings are "true", "TRUE", "True", "1", "false", "FALSE", "False", and "0".
- The **`parser<boolOrDefault>` specialization** is used for cases where the value is boolean, but we also need to know whether the option was specified at all. `boolOrDefault` is an enum with 3 values, `BOU_UNSET`, `BOU_TRUE` and `BOU_FALSE`. This parser accepts the same strings as ```parser<bool>```.
- The **`parser<string>` specialization** simply stores the parsed string into the string value specified. No conversion or modification of the data is performed.
- The **`parser<int>` specialization** uses the C `strtol` function to parse the string input. As such, it will accept a decimal number (with an optional '+' or '-' prefix) which must start with a non-zero digit. It accepts octal numbers, which are identified with a '0' prefix digit, and hexadecimal numbers with a prefix of '0x' or '0X'.
- The **`parser<double>` and `parser<float>` specializations** use the standard C `strtod` function to convert floating point strings into floating point values. As such, a broad range of string formats is supported, including exponential notation (ex: `1.7e15`) and properly supports locales.

3.3.4 Extension Guide

Although the CommandLine library has a lot of functionality built into it already (as discussed previously), one of its true strengths lie in its extensibility. This section discusses how the CommandLine library works under the covers and illustrates how to do some simple, common, extensions.

Writing a custom parser

One of the simplest and most common extensions is the use of a custom parser. As *discussed previously*, parsers are the portion of the CommandLine library that turns string input from the user into a particular parsed data type, validating the input in the process.

There are two ways to use a new parser:

1. Specialize the `cl::parser` template for your custom data type.

This approach has the advantage that users of your custom data type will automatically use your custom parser whenever they define an option with a value type of your data type. The disadvantage of this approach is that it doesn't work if your fundamental data type is something that is already supported.

2. Write an independent class, using it explicitly from options that need it.

This approach works well in situations where you would line to parse an option using special syntax for a not-very-special data-type. The drawback of this approach is that users of your parser have to be aware that they are using your parser instead of the builtin ones.

To guide the discussion, we will discuss a custom parser that accepts file sizes, specified with an optional unit after the numeric size. For example, we would like to parse "102kb", "41M", "1G" into the appropriate integer value. In this case, the underlying data type we want to parse into is 'unsigned'. We choose approach #2 above because we don't want to make this the default for all unsigned options.

To start out, we declare our new FileSizeParser class:

```
struct FileSizeParser : public cl::parser<unsigned> {
    // parse - Return true on error.
    bool parse(cl::Option &O,StringRef ArgName, const std::string &ArgValue,
               unsigned &Val);
};
```

Our new class inherits from the `cl::parser` template class to fill in the default, boiler plate code for us. We give it the data type that we parse into, the last argument to the `parse` method, so that clients of our custom parser know what object type to pass in to the `parse` method. (Here we declare that we parse into 'unsigned' variables.)

For most purposes, the only method that must be implemented in a custom parser is the `parse` method. The `parse` method is called whenever the option is invoked, passing in the option itself, the option name, the string to parse, and a reference to a return value. If the string to parse is not well-formed, the parser should output an error message and return true. Otherwise it should return false and set 'Val' to the parsed value. In our example, we implement `parse` as:

```
bool FileSizeParser::parse(cl::Option &O, StringRef ArgName,
                           const std::string &Arg, unsigned &Val) {
    const char *ArgStart = Arg.c_str();
    char *End;

    // Parse integer part, leaving 'End' pointing to the first non-integer char
    Val = (unsigned) strtol(ArgStart, &End, 0);

    while (1) {
```

(continues on next page)

(continued from previous page)

```

switch (*End++) {
case 0: return false;    // No error
case 'i':                // Ignore the 'i' in KiB if people use that
case 'b': case 'B':      // Ignore B suffix
    break;

case 'g': case 'G': Val *= 1024*1024*1024; break;
case 'm': case 'M': Val *= 1024*1024;      break;
case 'k': case 'K': Val *= 1024;          break;

default:
    // Print an error message if unrecognized character!
    return O.error("'" + Arg + "' value invalid for file size argument!");
}
}

```

This function implements a very simple parser for the kinds of strings we are interested in. Although it has some holes (it allows "123KKK" for example), it is good enough for this example. Note that we use the option itself to print out the error message (the `error` method always returns true) in order to get a nice error message (shown below). Now that we have our parser class, we can use it like this:

```

static cl::opt<unsigned, false, FileSizeParser>
MFS("max-file-size", cl::desc("Maximum file size to accept"),
    cl::value_desc("size"));

```

Which adds this to the output of our program:

```

OPTIONS:
  -help                - display available options (-help-hidden for more)
  ...
  -max-file-size=<size> - Maximum file size to accept

```

And we can test that our parse works correctly now (the test program just prints out the max-file-size argument value):

```

$ ./test
MFS: 0
$ ./test -max-file-size=123MB
MFS: 128974848
$ ./test -max-file-size=3G
MFS: 3221225472
$ ./test -max-file-size=dog
-max-file-size option: 'dog' value invalid for file size argument!

```

It looks like it works. The error message that we get is nice and helpful, and we seem to accept reasonable file sizes. This wraps up the "custom parser" tutorial.

Exploiting external storage

Several of the LLVM libraries define static `cl::opt` instances that will automatically be included in any program that links with that library. This is a feature. However, sometimes it is necessary to know the value of the command line option outside of the library. In these cases the library does or should provide an external storage location that is accessible to users of the library. Examples of this include the `llvm::DebugFlag` exported by the `lib/Support/Debug.cpp` file and the `llvm::TimePassesIsEnabled` flag exported by the `lib/IR/PassManager.cpp` file.

Dynamically adding command line options

3.5 Extending LLVM: Adding instructions, intrinsics, types, etc.

3.5.1 Introduction and Warning

During the course of using LLVM, you may wish to customize it for your research project or for experimentation. At this point, you may realize that you need to add something to LLVM, whether it be a new fundamental type, a new intrinsic function, or a whole new instruction.

When you come to this realization, stop and think. Do you really need to extend LLVM? Is it a new fundamental capability that LLVM does not support at its current incarnation or can it be synthesized from already pre-existing LLVM elements? If you are not sure, ask on the [LLVM-dev](#) list. The reason is that extending LLVM will get involved as you need to update all the different passes that you intend to use with your extension, and there are many LLVM analyses and transformations, so it may be quite a bit of work.

Adding an *intrinsic function* is far easier than adding an instruction, and is transparent to optimization passes. If your added functionality can be expressed as a function call, an intrinsic function is the method of choice for LLVM extension.

Before you invest a significant amount of effort into a non-trivial extension, **ask on the list** if what you are looking to do can be done with already-existing infrastructure, or if maybe someone else is already working on it. You will save yourself a lot of time and effort by doing so.

3.5.2 Adding a new intrinsic function

Adding a new intrinsic function to LLVM is much easier than adding a new instruction. Almost all extensions to LLVM should start as an intrinsic function and then be turned into an instruction if warranted.

1. `llvm/docs/LangRef.html`:

Document the intrinsic. Decide whether it is code generator specific and what the restrictions are. Talk to other people about it so that you are sure it's a good idea.

2. `llvm/include/llvm/IR/Intrinsics*.td`:

Add an entry for your intrinsic. Describe its memory access characteristics for optimization (this controls whether it will be DCE'd, CSE'd, etc). If any arguments need to be immediates, these must be indicated with the `ImmArg` property. Note that any intrinsic using one of the `llvm_any*_ty` types for an argument or return type will be deemed by `tblgen` as overloaded and the corresponding suffix will be required on the intrinsic's name.

3. `llvm/lib/Analysis/ConstantFolding.cpp`:

If it is possible to constant fold your intrinsic, add support to it in the `canConstantFoldCallTo` and `ConstantFoldCall` functions.

4. `llvm/test/*:`

Add test cases for your test cases to the test suite

Once the intrinsic has been added to the system, you must add code generator support for it. Generally you must do the following steps:

Add support to the `.td` file for the target(s) of your choice in `lib/Target/*/*.td`.

This is usually a matter of adding a pattern to the `.td` file that matches the intrinsic, though it may obviously require adding the instructions you want to generate as well. There are lots of examples in the PowerPC and X86 backend to follow.

3.5.3 Adding a new SelectionDAG node

As with intrinsics, adding a new SelectionDAG node to LLVM is much easier than adding a new instruction. New nodes are often added to help represent instructions common to many targets. These nodes often map to an LLVM instruction (add, sub) or intrinsic (byteswap, population count). In other cases, new nodes have been added to allow many targets to perform a common task (converting between floating point and integer representation) or capture more complicated behavior in a single node (rotate).

1. `include/llvm/CodeGen/ISDOpcodes.h:`

Add an enum value for the new SelectionDAG node.

2. `lib/CodeGen/SelectionDAG/SelectionDAG.cpp:`

Add code to print the node to `getOperationName`. If your new node can be evaluated at compile time when given constant arguments (such as an add of a constant with another constant), find the `getNode` method that takes the appropriate number of arguments, and add a case for your node to the switch statement that performs constant folding for nodes that take the same number of arguments as your new node.

3. `lib/CodeGen/SelectionDAG/LegalizedAG.cpp:`

Add code to **legalize, promote, and expand** the node as necessary. At a minimum, you will need to add a case statement for your node in `LegalizeOp` which calls `LegalizeOp` on the node's operands, and returns a new node if any of the operands changed as a result of being legalized. It is likely that not all targets supported by the SelectionDAG framework will natively support the new node. In this case, you must also add code in your node's case statement in `LegalizeOp` to Expand your node into simpler, legal operations. The case for `ISD::UREM` for expanding a remainder into a divide, multiply, and a subtract is a good example.

4. `lib/CodeGen/SelectionDAG/LegalizedAG.cpp:`

If targets may support the new node being added only at certain sizes, you will also need to add code to your node's case statement in `LegalizeOp` to Promote your node's operands to a larger size, and perform the correct operation. You will also need to add code to `PromoteOp` to do this as well. For a good example, see `ISD::BSWAP`, which promotes its operand to a wider size, performs the byteswap, and then shifts the correct bytes right to emulate the narrower byteswap in the wider type.

5. `lib/CodeGen/SelectionDAG/LegalizedAG.cpp:`

Add a case for your node in `ExpandOp` to teach the legalizer how to perform the action represented by the new node on a value that has been split into high and low halves. This case will be used to support your node with a 64 bit operand on a 32 bit target.

6. `lib/CodeGen/SelectionDAG/DAGCombiner.cpp:`

If your node can be combined with itself, or other existing nodes in a peephole-like fashion, add a visit function for it, and call that function from. There are several good examples for simple combines you can do; `visitFABS` and `visitSRL` are good starting places.

7. `lib/Target/PowerPC/PPCISelLowering.cpp`:

Each target has an implementation of the `TargetLowering` class, usually in its own file (although some targets include it in the same file as the `DAGToDAGISel`). The default behavior for a target is to assume that your new node is legal for all types that are legal for that target. If this target does not natively support your node, then tell the target to either Promote it (if it is supported at a larger type) or Expand it. This will cause the code you wrote in `LegalizeOp` above to decompose your new node into other legal nodes for this target.

8. `lib/Target/TargetSelectionDAG.td`:

Most current targets supported by LLVM generate code using the DAGToDAG method, where `SelectionDAG` nodes are pattern matched to target-specific nodes, which represent individual instructions. In order for the targets to match an instruction to your new node, you must add a def for that node to the list in this file, with the appropriate type constraints. Look at `add`, `bswap`, and `fadd` for examples.

9. `lib/Target/PowerPC/PPCInstrInfo.td`:

Each target has a `tablegen` file that describes the target's instruction set. For targets that use the DAGToDAG instruction selection framework, add a pattern for your new node that uses one or more target nodes. Documentation for this is a bit sparse right now, but there are several decent examples. See the patterns for `rotl` in `PPCInstrInfo.td`.

10. TODO: document complex patterns.

11. `llvm/test/CodeGen/*`:

Add test cases for your new node to the test suite. `llvm/test/CodeGen/X86/bswap.ll` is a good example.

3.5.4 Adding a new instruction

Warning: Adding instructions changes the bitcode format, and it will take some effort to maintain compatibility with the previous version. Only add an instruction if it is absolutely necessary.

1. `llvm/include/llvm/IR/Instruction.def`:

add a number for your instruction and an enum name

2. `llvm/include/llvm/IR/Instructions.h`:

add a definition for the class that will represent your instruction

3. `llvm/include/llvm/IR/InstVisitor.h`:

add a prototype for a visitor to your new instruction type

4. `llvm/lib/AsmParser/LLLexer.cpp`:

add a new token to parse your instruction from assembly text file

5. `llvm/lib/AsmParser/LLParser.cpp`:

add the grammar on how your instruction can be read and what it will construct as a result

6. `llvm/lib/Bitcode/Reader/BitcodeReader.cpp`:

add a case for your instruction and how it will be parsed from bitcode

7. `llvm/lib/Bitcode/Writer/BitcodeWriter.cpp`:

add a case for your instruction and how it will be parsed from bitcode

8. `llvm/lib/IR/Instruction.cpp`:
add a case for how your instruction will be printed out to assembly
9. `llvm/lib/IR/Instructions.cpp`:
implement the class you defined in `llvm/include/llvm/Instructions.h`
10. Test your instruction
11. `llvm/lib/Target/*`:
add support for your instruction to code generators, or add a lowering pass.
12. `llvm/test/*`:
add your test cases to the test suite.

Also, you need to implement (or modify) any analyses or passes that you want to understand this new instruction.

3.5.5 Adding a new type

Warning: Adding new types changes the bitcode format, and will break compatibility with currently-existing LLVM installations. Only add new types if it is absolutely necessary.

Adding a fundamental type

1. `llvm/include/llvm/IR/Type.h`:
add enum for the new type; add static `Type*` for this type
2. `llvm/lib/IR/Type.cpp` and `llvm/lib/IR/ValueTypes.cpp`:
add mapping from `TypeID => Type*`; initialize the static `Type*`
3. `llvm/llvm-llvm-c/Core.cpp`:
add enum `LLVMTypeKind` and modify `LLVMTypeKind LLVMGetTypeKind(LLVMTypeRef Ty)` for the new type
4. `llvm/lib/AsmParser/Lexer.cpp`:
add ability to parse in the type from text assembly
5. `llvm/lib/AsmParser/LLParser.cpp`:
add a token for that type
6. `llvm/lib/Bitcode/Writer/BitcodeWriter.cpp`:
modify `static void WriteTypeTable(const ValueEnumerator &VE, BitstreamWriter &Stream)` to serialize your type
7. `llvm/lib/Bitcode/Reader/BitcodeReader.cpp`:
modify `bool BitcodeReader::ParseTypeType()` to read your data type
8. `include/llvm/Bitcode/LLVMBitCodes.h`:
add enum `TypeCodes` for the new type

Adding a derived type

1. `llvm/include/llvm/IR/Type.h`:
add enum for the new type; add a forward declaration of the type also
2. `llvm/include/llvm/IR/DerivedTypes.h`:
add new class to represent new class in the hierarchy; add forward declaration to the `TypeMap` value type
3. `llvm/lib/IR/Type.cpp` and `llvm/lib/IR/ValueTypes.cpp`:
add support for derived type, notably *enum TypeID* and *is, get* methods.
4. `llvm/llvm/llvm-c/Core.cpp`:
add enum `LLVMTypeKind` and modify *LLVMTypeKind LLVMGetTypeKind(LLVMTypeRefTy)* for the new type
5. `llvm/lib/AsmParser/LLLexer.cpp`:
modify `lltok::Kind LLLexer::LexIdentifier()` to add ability to parse in the type from text assembly
6. `llvm/lib/Bitcode/Writer/BitcodeWriter.cpp`:
modify `static void WriteTypeTable(const ValueEnumerator &VE, BitstreamWriter &Stream)` to serialize your type
7. `llvm/lib/Bitcode/Reader/BitcodeReader.cpp`:
modify `bool BitcodeReader::ParseTypeType()` to read your data type
8. `include/llvm/Bitcode/LLVMBitCodes.h`:
add enum `TypeCodes` for the new type
9. `llvm/lib/IR/AsmWriter.cpp`:
modify `void TypePrinting::print(Type *Ty, raw_ostream &OS)` to output the new derived type

3.6 How to set up LLVM-style RTTI for your class hierarchy

Contents

- *How to set up LLVM-style RTTI for your class hierarchy*
 - *Background*
 - *Basic Setup*
 - *Concrete Bases and Deeper Hierarchies*
 - * *A Bug to be Aware Of*
 - * *The Contract of `classof`*
 - *Rules of Thumb*

3.6.1 Background

LLVM avoids using C++'s built in RTTI. Instead, it pervasively uses its own hand-rolled form of RTTI which is much more efficient and flexible, although it requires a bit more work from you as a class author.

A description of how to use LLVM-style RTTI from a client's perspective is given in the [Programmer's Manual](#). This document, in contrast, discusses the steps you need to take as a class hierarchy author to make LLVM-style RTTI available to your clients.

Before diving in, make sure that you are familiar with the Object Oriented Programming concept of "is-a".

3.6.2 Basic Setup

This section describes how to set up the most basic form of LLVM-style RTTI (which is sufficient for 99.9% of the cases). We will set up LLVM-style RTTI for this class hierarchy:

```
class Shape {
public:
    Shape() {}
    virtual double computeArea() = 0;
};

class Square : public Shape {
    double SideLength;
public:
    Square(double S) : SideLength(S) {}
    double computeArea() override;
};

class Circle : public Shape {
    double Radius;
public:
    Circle(double R) : Radius(R) {}
    double computeArea() override;
};
```

The most basic working setup for LLVM-style RTTI requires the following steps:

1. In the header where you declare Shape, you will want to `#include "llvm/Support/Casting.h"`, which declares LLVM's RTTI templates. That way your clients don't even have to think about it.

```
#include "llvm/Support/Casting.h"
```

2. In the base class, introduce an enum which discriminates all of the different concrete classes in the hierarchy, and stash the enum value somewhere in the base class.

Here is the code after introducing this change:

```
class Shape {
public:
+   /// Discriminator for LLVM-style RTTI (dyn_cast<> et al.)
+   enum ShapeKind {
+       SK_Square,
+       SK_Circle
+   };
+private:
+   const ShapeKind Kind;
```

(continues on next page)

(continued from previous page)

```
+public:
+ ShapeKind getKind() const { return Kind; }
+
+   Shape() {}
+   virtual double computeArea() = 0;
+};
```

You will usually want to keep the `Kind` member encapsulated and private, but let the enum `ShapeKind` be public along with providing a `getKind()` method. This is convenient for clients so that they can do a `switch` over the enum.

A common naming convention is that these enums are "kind"s, to avoid ambiguity with the words "type" or "class" which have overloaded meanings in many contexts within LLVM. Sometimes there will be a natural name for it, like "opcode". Don't bikeshed over this; when in doubt use `Kind`.

You might wonder why the `Kind` enum doesn't have an entry for `Shape`. The reason for this is that since `Shape` is abstract (`computeArea() = 0;`), you will never actually have non-derived instances of exactly that class (only subclasses). See *Concrete Bases and Deeper Hierarchies* for information on how to deal with non-abstract bases. It's worth mentioning here that unlike `dynamic_cast<>`, LLVM-style RTTI can be used (and is often used) for classes that don't have v-tables.

3. Next, you need to make sure that the `Kind` gets initialized to the value corresponding to the dynamic type of the class. Typically, you will want to have it be an argument to the constructor of the base class, and then pass in the respective `XXXXKind` from subclass constructors.

Here is the code after that change:

```
class Shape {
public:
    /// Discriminator for LLVM-style RTTI (dyn_cast<> et al.)
    enum ShapeKind {
        SK_Square,
        SK_Circle
    };
private:
    const ShapeKind Kind;
public:
    ShapeKind getKind() const { return Kind; }

-   Shape() {}
+   Shape(ShapeKind K) : Kind(K) {}
    virtual double computeArea() = 0;
};

class Square : public Shape {
    double SideLength;
public:
-   Square(double S) : SideLength(S) {}
+   Square(double S) : Shape(SK_Square), SideLength(S) {}
    double computeArea() override;
};

class Circle : public Shape {
    double Radius;
public:
-   Circle(double R) : Radius(R) {}
+   Circle(double R) : Shape(SK_Circle), Radius(R) {}
```

(continues on next page)

(continued from previous page)

```
double computeArea() override;
};
```

4. Finally, you need to inform LLVM's RTTI templates how to dynamically determine the type of a class (i.e. whether the `isa<>/dyn_cast<>` should succeed). The default "99.9% of use cases" way to accomplish this is through a small static member function `classof`. In order to have proper context for an explanation, we will display this code first, and then below describe each part:

```
class Shape {
public:
    /// Discriminator for LLVM-style RTTI (dyn_cast<> et al.)
    enum ShapeKind {
        SK_Square,
        SK_Circle
    };
private:
    const ShapeKind Kind;
public:
    ShapeKind getKind() const { return Kind; }

    Shape(ShapeKind K) : Kind(K) {}
    virtual double computeArea() = 0;
};

class Square : public Shape {
    double SideLength;
public:
    Square(double S) : Shape(SK_Square), SideLength(S) {}
    double computeArea() override;
+
+ static bool classof(const Shape *S) {
+     return S->getKind() == SK_Square;
+ }
};

class Circle : public Shape {
    double Radius;
public:
    Circle(double R) : Shape(SK_Circle), Radius(R) {}
    double computeArea() override;
+
+ static bool classof(const Shape *S) {
+     return S->getKind() == SK_Circle;
+ }
};
```

The job of `classof` is to dynamically determine whether an object of a base class is in fact of a particular derived class. In order to downcast a type `Base` to a type `Derived`, there needs to be a `classof` in `Derived` which will accept an object of type `Base`.

To be concrete, consider the following code:

```
Shape *S = ...;
if (isa<Circle>(S)) {
    /* do something ... */
}
```

The code of the `isa<>` test in this code will eventually boil down---after template instantiation and some other machinery---to a check roughly like `Circle::classof(S)`. For more information, see [The Contract of `classof`](#).

The argument to `classof` should always be an *ancestor* class because the implementation has logic to allow and optimize away upcasts/up-`isa<>`'s automatically. It is as though every class `Foo` automatically has a `classof` like:

```
class Foo {
    [...]
    template <class T>
    static bool classof(const T *,
                       ::std::enable_if<
                           ::std::is_base_of<Foo, T>::value
                           >::type* = 0) { return true; }
    [...]
};
```

Note that this is the reason that we did not need to introduce a `classof` into `Shape`: all relevant classes derive from `Shape`, and `Shape` itself is abstract (has no entry in the `Kind` enum), so this notional inferred `classof` is all we need. See [Concrete Bases and Deeper Hierarchies](#) for more information about how to extend this example to more general hierarchies.

Although for this small example setting up LLVM-style RTTI seems like a lot of "boilerplate", if your classes are doing anything interesting then this will end up being a tiny fraction of the code.

3.6.3 Concrete Bases and Deeper Hierarchies

For concrete bases (i.e. non-abstract interior nodes of the inheritance tree), the `Kind` check inside `classof` needs to be a bit more complicated. The situation differs from the example above in that

- Since the class is concrete, it must itself have an entry in the `Kind` enum because it is possible to have objects with this class as a dynamic type.
- Since the class has children, the check inside `classof` must take them into account.

Say that `SpecialSquare` and `OtherSpecialSquare` derive from `Square`, and so `ShapeKind` becomes:

```
enum ShapeKind {
    SK_Square,
+   SK_SpecialSquare,
+   SK_OtherSpecialSquare,
    SK_Circle
}
```

Then in `Square`, we would need to modify the `classof` like so:

```
- static bool classof(const Shape *S) {
-     return S->getKind() == SK_Square;
- }
+ static bool classof(const Shape *S) {
+     return S->getKind() >= SK_Square &&
+           S->getKind() <= SK_OtherSpecialSquare;
+ }
```

The reason that we need to test a range like this instead of just equality is that both `SpecialSquare` and `OtherSpecialSquare` "is-a" `Square`, and so `classof` needs to return true for them.

This approach can be made to scale to arbitrarily deep hierarchies. The trick is that you arrange the enum values so that they correspond to a preorder traversal of the class hierarchy tree. With that arrangement, all subclass tests can be done with two comparisons as shown above. If you just list the class hierarchy like a list of bullet points, you'll get the ordering right:

```
| Shape
|   Square
|     SpecialSquare
|     OtherSpecialSquare
|   Circle
```

A Bug to be Aware Of

The example just given opens the door to bugs where the `classofs` are not updated to match the `Kind` enum when adding (or removing) classes to (from) the hierarchy.

Continuing the example above, suppose we add a `SomewhatSpecialSquare` as a subclass of `Square`, and update the `ShapeKind` enum like so:

```
enum ShapeKind {
    SK_Square,
    SK_SpecialSquare,
    SK_OtherSpecialSquare,
+   SK_SomewhatSpecialSquare,
    SK_Circle
}
```

Now, suppose that we forget to update `Square::classof()`, so it still looks like:

```
static bool classof(const Shape *S) {
    // BUG: Returns false when S->getKind() == SK_SomewhatSpecialSquare,
    // even though SomewhatSpecialSquare "is a" Square.
    return S->getKind() >= SK_Square &&
           S->getKind() <= SK_OtherSpecialSquare;
}
```

As the comment indicates, this code contains a bug. A straightforward and non-clever way to avoid this is to introduce an explicit `SK_LastSquare` entry in the enum when adding the first subclass(es). For example, we could rewrite the example at the beginning of *Concrete Bases and Deeper Hierarchies* as:

```
enum ShapeKind {
    SK_Square,
+   SK_SpecialSquare,
+   SK_OtherSpecialSquare,
+   SK_LastSquare,
    SK_Circle
}
...
// Square::classof()
- static bool classof(const Shape *S) {
-     return S->getKind() == SK_Square;
- }
+ static bool classof(const Shape *S) {
+     return S->getKind() >= SK_Square &&
+           S->getKind() <= SK_LastSquare;
+ }
```

Then, adding new subclasses is easy:

```
enum ShapeKind {
    SK_Square,
    SK_SpecialSquare,
    SK_OtherSpecialSquare,
+   SK_SomewhatSpecialSquare,
    SK_LastSquare,
    SK_Circle
}
```

Notice that `Square::classof` does not need to be changed.

The Contract of `classof`

To be more precise, let `classof` be inside a class `C`. Then the contract for `classof` is "return `true` if the dynamic type of the argument is-a `C`". As long as your implementation fulfills this contract, you can tweak and optimize it as much as you want.

For example, LLVM-style RTTI can work fine in the presence of multiple-inheritance by defining an appropriate `classof`. An example of this in practice is `Decl` vs. `DeclContext` inside Clang. The `Decl` hierarchy is done very similarly to the example setup demonstrated in this tutorial. The key part is how to then incorporate `DeclContext`: all that is needed is in `bool DeclContext::classof(const Decl *)`, which asks the question "Given a `Decl`, how can I determine if it is-a `DeclContext`?". It answers this with a simple switch over the set of `Decl` "kinds", and returning `true` for ones that are known to be `DeclContext`'s.

3.6.4 Rules of Thumb

1. The `Kind` enum should have one entry per concrete class, ordered according to a preorder traversal of the inheritance tree.
2. The argument to `classof` should be a `const Base *`, where `Base` is some ancestor in the inheritance hierarchy. The argument should *never* be a derived class or the class itself: the template machinery for `isa<>` already handles this case and optimizes it.
3. For each class in the hierarchy that has no children, implement a `classof` that checks only against its `Kind`.
4. For each class in the hierarchy that has children, implement a `classof` that checks a range of the first child's `Kind` and the last child's `Kind`.

3.7.1 Introduction

This document is meant to highlight some of the important classes and interfaces available in the LLVM source-base. This manual is not intended to explain what LLVM is, how it works, and what LLVM code looks like. It assumes that you know the basics of LLVM and are interested in writing transformations or otherwise analyzing or manipulating the code.

This document should get you oriented so that you can find your way in the continuously growing source code that makes up the LLVM infrastructure. Note that this manual is not intended to serve as a replacement for reading the source code, so if you think there should be a method in one of these classes to do something, but it's not listed, check the source. Links to the [doxygen](#) sources are provided to make this as easy as possible.

The first section of this document describes general information that is useful to know when working in the LLVM infrastructure, and the second describes the Core LLVM classes. In the future this manual will be extended with information describing how to use extension libraries, such as dominator information, CFG traversal routines, and useful utilities like the `InstVisitor` ([doxygen](#)) template.

3.7.2 General Information

This section contains general information that is useful if you are working in the LLVM source-base, but that isn't specific to any particular API.

The C++ Standard Template Library

LLVM makes heavy use of the C++ Standard Template Library (STL), perhaps much more than you are used to, or have seen before. Because of this, you might want to do a little background reading in the techniques used and capabilities of the library. There are many good pages that discuss the STL, and several books on the subject that you can get, so it will not be discussed in this document.

Here are some useful links:

1. [cppreference.com](#) - an excellent reference for the STL and other parts of the standard C++ library.
2. [C++ In a Nutshell](#) - This is an O'Reilly book in the making. It has a decent Standard Library Reference that rivals Dinkumware's, and is unfortunately no longer free since the book has been published.
3. [C++ Frequently Asked Questions](#).
4. [SGI's STL Programmer's Guide](#) - Contains a useful Introduction to the STL.
5. [Bjarne Stroustrup's C++ Page](#).
6. [Bruce Eckel's Thinking in C++, 2nd ed. Volume 2 Revision 4.0](#) (even better, [get the book](#)).

You are also encouraged to take a look at the [LLVM Coding Standards](#) guide which focuses on how to write maintainable code more than where to put your curly braces.

Other useful references

1. [Using static and shared libraries across platforms](#)

3.7.3 Important and useful LLVM APIs

Here we highlight some LLVM APIs that are generally useful and good to know about when writing transformations.

The `isa<>`, `cast<>` and `dyn_cast<>` templates

The LLVM source-base makes extensive use of a custom form of RTTI. These templates have many similarities to the C++ `dynamic_cast<>` operator, but they don't have some drawbacks (primarily stemming from the fact that `dynamic_cast<>` only works on classes that have a v-table). Because they are used so often, you must know what they do and how they work. All of these templates are defined in the `llvm/Support/Casting.h` ([doxygen](#)) file (note that you very rarely have to include this file directly).

`isa<>`: The `isa<>` operator works exactly like the Java "instanceof" operator. It returns true or false depending on whether a reference or pointer points to an instance of the specified class. This can be very useful for constraint checking of various sorts (example below).

`cast<>`: The `cast<>` operator is a "checked cast" operation. It converts a pointer or reference from a base class to a derived class, causing an assertion failure if it is not really an instance of the right type. This should be used in cases where you have some information that makes you believe that something is of the right type. An example of the `isa<>` and `cast<>` template is:

```
static bool isLoopInvariant(const Value *V, const Loop *L) {
    if (isa<Constant>(V) || isa<Argument>(V) || isa<GlobalValue>(V))
        return true;

    // Otherwise, it must be an instruction...
    return !L->contains(cast<Instruction>(V)->getParent());
}
```

Note that you should **not** use an `isa<>` test followed by a `cast<>`, for that use the `dyn_cast<>` operator.

`dyn_cast<>`: The `dyn_cast<>` operator is a "checking cast" operation. It checks to see if the operand is of the specified type, and if so, returns a pointer to it (this operator does not work with references). If the operand is not of the correct type, a null pointer is returned. Thus, this works very much like the `dynamic_cast<>` operator in C++, and should be used in the same circumstances. Typically, the `dyn_cast<>` operator is used in an `if` statement or some other flow control statement like this:

```
if (auto *AI = dyn_cast<AllocationInst>(Val)) {
    // ...
}
```

This form of the `if` statement effectively combines together a call to `isa<>` and a call to `cast<>` into one statement, which is very convenient.

Note that the `dyn_cast<>` operator, like C++'s `dynamic_cast<>` or Java's `instanceof` operator, can be abused. In particular, you should not use big chained `if/then/else` blocks to check for lots of different variants of classes. If you find yourself wanting to do this, it is much cleaner and more efficient to use the `InstVisitor` class to dispatch over the instruction type directly.

`isa_and_nonnull<>`: The `isa_and_nonnull<>` operator works just like the `isa<>` operator, except that it allows for a null pointer as an argument (which it then returns false). This can sometimes be useful, allowing you to combine several null checks into one.

cast_or_null<>: The `cast_or_null<>` operator works just like the `cast<>` operator, except that it allows for a null pointer as an argument (which it then propagates). This can sometimes be useful, allowing you to combine several null checks into one.

dyn_cast_or_null<>: The `dyn_cast_or_null<>` operator works just like the `dyn_cast<>` operator, except that it allows for a null pointer as an argument (which it then propagates). This can sometimes be useful, allowing you to combine several null checks into one.

These five templates can be used with any classes, whether they have a v-table or not. If you want to add support for these templates, see the document *How to set up LLVM-style RTTI for your class hierarchy*

Passing strings (the `StringRef` and `Twine` classes)

Although LLVM generally does not do much string manipulation, we do have several important APIs which take strings. Two important examples are the `Value` class -- which has names for instructions, functions, etc. -- and the `StringMap` class which is used extensively in LLVM and Clang.

These are generic classes, and they need to be able to accept strings which may have embedded null characters. Therefore, they cannot simply take a `const char *`, and taking a `const std::string&` requires clients to perform a heap allocation which is usually unnecessary. Instead, many LLVM APIs use a `StringRef` or a `const Twine&` for passing strings efficiently.

The `StringRef` class

The `StringRef` data type represents a reference to a constant string (a character array and a length) and supports the common operations available on `std::string`, but does not require heap allocation.

It can be implicitly constructed using a C style null-terminated string, an `std::string`, or explicitly with a character pointer and length. For example, the `StringRef` `find` function is declared as:

```
iterator find(StringRef Key);
```

and clients can call it using any one of:

```
Map.find("foo");           // Lookup "foo"
Map.find(std::string("bar")); // Lookup "bar"
Map.find(StringRef("\0baz", 4)); // Lookup "\0baz"
```

Similarly, APIs which need to return a string may return a `StringRef` instance, which can be used directly or converted to an `std::string` using the `str` member function. See `llvm/ADT/StringRef.h` ([doxygen](#)) for more information.

You should rarely use the `StringRef` class directly, because it contains pointers to external memory it is not generally safe to store an instance of the class (unless you know that the external storage will not be freed). `StringRef` is small and pervasive enough in LLVM that it should always be passed by value.

The Twine class

The `Twine` ([doxygen](#)) class is an efficient way for APIs to accept concatenated strings. For example, a common LLVM paradigm is to name one instruction based on the name of another instruction with a suffix, for example:

```
New = CmpInst::Create(..., SO->getName() + ".cmp");
```

The `Twine` class is effectively a lightweight [rope](#) which points to temporary (stack allocated) objects. Twines can be implicitly constructed as the result of the plus operator applied to strings (i.e., a C strings, an `std::string`, or a `StringRef`). The `twine` delays the actual concatenation of strings until it is actually required, at which point it can be efficiently rendered directly into a character array. This avoids unnecessary heap allocation involved in constructing the temporary results of string concatenation. See `llvm/ADT/Twine.h` ([doxygen](#)) and [here](#) for more information.

As with a `StringRef`, `Twine` objects point to external memory and should almost never be stored or mentioned directly. They are intended solely for use when defining a function which should be able to efficiently accept concatenated strings.

Formatting strings (the `formatv` function)

While LLVM doesn't necessarily do a lot of string manipulation and parsing, it does do a lot of string formatting. From diagnostic messages, to `llvm` tool outputs such as `llvm-readobj` to printing verbose disassembly listings and LLDB runtime logging, the need for string formatting is pervasive.

The `formatv` is similar in spirit to `printf`, but uses a different syntax which borrows heavily from Python and C#. Unlike `printf` it deduces the type to be formatted at compile time, so it does not need a format specifier such as `%d`. This reduces the mental overhead of trying to construct portable format strings, especially for platform-specific types like `size_t` or pointer types. Unlike both `printf` and Python, it additionally fails to compile if LLVM does not know how to format the type. These two properties ensure that the function is both safer and simpler to use than traditional formatting methods such as the `printf` family of functions.

Simple formatting

A call to `formatv` involves a single **format string** consisting of 0 or more **replacement sequences**, followed by a variable length list of **replacement values**. A replacement sequence is a string of the form `{N[, align]:style]}`.

`N` refers to the 0-based index of the argument from the list of replacement values. Note that this means it is possible to reference the same parameter multiple times, possibly with different style and/or alignment options, in any order.

`align` is an optional string specifying the width of the field to format the value into, and the alignment of the value within the field. It is specified as an optional **alignment style** followed by a positive integral **field width**. The alignment style can be one of the characters `-` (left align), `=` (center align), or `+` (right align). The default is right aligned.

`style` is an optional string consisting of a type specific that controls the formatting of the value. For example, to format a floating point value as a percentage, you can use the style option `P`.

Custom formatting

There are two ways to customize the formatting behavior for a type.

1. Provide a template specialization of `llvm::format_provider<T>` for your type `T` with the appropriate static format method.

```
namespace llvm {
    template<>
    struct format_provider<MyFooBar> {
        static void format(const MyFooBar &V, raw_ostream &Stream,StringRef_
→Style) {
            // Do whatever is necessary to format `V` into `Stream`
        }
    };
    void foo() {
        MyFooBar X;
        std::string S = formatv("{0}", X);
    }
}
```

This is a useful extensibility mechanism for adding support for formatting your own custom types with your own custom Style options. But it does not help when you want to extend the mechanism for formatting a type that the library already knows how to format. For that, we need something else.

2. Provide a **format adapter** inheriting from `llvm::FormatAdapter<T>`.

```
namespace anything {
    struct format_int_custom : public llvm::FormatAdapter<int> {
        explicit format_int_custom(int N) : llvm::FormatAdapter<int>(N) {}
        void format(llvm::raw_ostream &Stream, StringRef Style) override {
            // Do whatever is necessary to format ``this->Item`` into ``Stream``
        }
    };
}
namespace llvm {
    void foo() {
        std::string S = formatv("{0}", anything::format_int_custom(42));
    }
}
```

If the type is detected to be derived from `FormatAdapter<T>`, `formatv` will call the `format` method on the argument passing in the specified style. This allows one to provide custom formatting of any type, including one which already has a builtin format provider.

formatv Examples

Below is intended to provide an incomplete set of examples demonstrating the usage of `formatv`. More information can be found by reading the doxygen documentation or by looking at the unit test suite.

```
std::string S;
// Simple formatting of basic types and implicit string conversion.
S = formatv("{0} ({1:P})", 7, 0.35); // S == "7 (35.00%)"

// Out-of-order referencing and multi-referencing
outs() << formatv("{0} {2} {1} {0}", 1, "test", 3); // prints "1 3 test 1"
```

(continues on next page)

(continued from previous page)

```
// Left, right, and center alignment
S = formatv("{0,7}", 'a'); // S == "      a";
S = formatv("{0,-7}", 'a'); // S == "a      ";
S = formatv("{0,=7}", 'a'); // S == "   a   ";
S = formatv("{0,+7}", 'a'); // S == "   a   ";

// Custom styles
S = formatv("{0:N} - {0:x} - {1:E}", 12345, 123908342); // S == "12,345 - 0x3039 - 1.
↪24E8"

// Adapters
S = formatv("{0}", fmt_align(42, AlignStyle::Center, 7)); // S == "   42   "
S = formatv("{0}", fmt_repeat("hi", 3)); // S == "hihihi"
S = formatv("{0}", fmt_pad("hi", 2, 6)); // S == "   hi   "

// Ranges
std::vector<int> V = {8, 9, 10};
S = formatv("{0}", make_range(V.begin(), V.end())); // S == "8, 9, 10"
S = formatv("{0:$[+]}", make_range(V.begin(), V.end())); // S == "8+9+10"
S = formatv("{0:$[ + ]@[x]}", make_range(V.begin(), V.end())); // S == "0x8 + 0x9 +
↪0xA"
```

Error handling

Proper error handling helps us identify bugs in our code, and helps end-users understand errors in their tool usage. Errors fall into two broad categories: *programmatic* and *recoverable*, with different strategies for handling and reporting.

Programmatic Errors

Programmatic errors are violations of program invariants or API contracts, and represent bugs within the program itself. Our aim is to document invariants, and to abort quickly at the point of failure (providing some basic diagnostic) when invariants are broken at runtime.

The fundamental tools for handling programmatic errors are assertions and the `llvm_unreachable` function. Assertions are used to express invariant conditions, and should include a message describing the invariant:

```
assert(isPhysReg(R) && "All virt regs should have been allocated already.");
```

The `llvm_unreachable` function can be used to document areas of control flow that should never be entered if the program invariants hold:

```
enum { Foo, Bar, Baz } X = foo();

switch (X) {
  case Foo: /* Handle Foo */; break;
  case Bar: /* Handle Bar */; break;
  default:
    llvm_unreachable("X should be Foo or Bar here");
}
```

Recoverable Errors

Recoverable errors represent an error in the program's environment, for example a resource failure (a missing file, a dropped network connection, etc.), or malformed input. These errors should be detected and communicated to a level of the program where they can be handled appropriately. Handling the error may be as simple as reporting the issue to the user, or it may involve attempts at recovery.

Note: While it would be ideal to use this error handling scheme throughout LLVM, there are places where this hasn't been practical to apply. In situations where you absolutely must emit a non-programmatic error and the `Error` model isn't workable you can call `report_fatal_error`, which will call installed error handlers, print a message, and exit the program.

Recoverable errors are modeled using LLVM's `Error` scheme. This scheme represents errors using function return values, similar to classic C integer error codes, or C++'s `std::error_code`. However, the `Error` class is actually a lightweight wrapper for user-defined error types, allowing arbitrary information to be attached to describe the error. This is similar to the way C++ exceptions allow throwing of user-defined types.

Success values are created by calling `Error::success()`, E.g.:

```
Error foo() {
    // Do something.
    // Return success.
    return Error::success();
}
```

Success values are very cheap to construct and return - they have minimal impact on program performance.

Failure values are constructed using `make_error<T>`, where `T` is any class that inherits from the `ErrorInfo` utility, E.g.:

```
class BadFileFormat : public ErrorInfo<BadFileFormat> {
public:
    static char ID;
    std::string Path;

    BadFileFormat(StringRef Path) : Path(Path.str()) {}

    void log(raw_ostream &OS) const override {
        OS << Path << " is malformed";
    }

    std::error_code convertToErrorCode() const override {
        return make_error_code(object_error::parse_failed);
    }
};

char BadFileFormat::ID; // This should be declared in the C++ file.

Error printFormattedFile(StringRef Path) {
    if (<check for valid format>)
        return make_error<BadFileFormat>(Path);
    // print file contents.
    return Error::success();
}
```

Error values can be implicitly converted to `bool`: true for error, false for success, enabling the following idiom:

```
Error mayFail();

Error foo() {
    if (auto Err = mayFail())
        return Err;
    // Success! We can proceed.
    ...
}
```

For functions that can fail but need to return a value the `Expected<T>` utility can be used. Values of this type can be constructed with either a `T`, or an `Error`. `Expected<T>` values are also implicitly convertible to boolean, but with the opposite convention to `Error`: true for success, false for error. If success, the `T` value can be accessed via the dereference operator. If failure, the `Error` value can be extracted using the `takeError()` method. Idiomatic usage looks like:

```
Expected<FormattedFile> openFormattedFile(StringRef Path) {
    // If badly formatted, return an error.
    if (auto Err = checkFormat(Path))
        return std::move(Err);
    // Otherwise return a FormattedFile instance.
    return FormattedFile(Path);
}

Error processFormattedFile(StringRef Path) {
    // Try to open a formatted file
    if (auto FileOrErr = openFormattedFile(Path)) {
        // On success, grab a reference to the file and continue.
        auto &File = *FileOrErr;
        ...
    } else
        // On error, extract the Error value and return it.
        return FileOrErr.takeError();
}
```

If an `Expected<T>` value is in success mode then the `takeError()` method will return a success value. Using this fact, the above function can be rewritten as:

```
Error processFormattedFile(StringRef Path) {
    // Try to open a formatted file
    auto FileOrErr = openFormattedFile(Path);
    if (auto Err = FileOrErr.takeError())
        // On error, extract the Error value and return it.
        return Err;
    // On success, grab a reference to the file and continue.
    auto &File = *FileOrErr;
    ...
}
```

This second form is often more readable for functions that involve multiple `Expected<T>` values as it limits the indentation required.

All `Error` instances, whether success or failure, must be either checked or moved from (via `std::move` or a `return`) before they are destructed. Accidentally discarding an unchecked error will cause a program abort at the point where the unchecked value's destructor is run, making it easy to identify and fix violations of this rule.

Success values are considered checked once they have been tested (by invoking the boolean conversion operator):

```
if (auto Err = mayFail(...))
    return Err; // Failure value - move error to caller.

// Safe to continue: Err was checked.
```

In contrast, the following code will always cause an abort, even if `mayFail` returns a success value:

```
mayFail();
// Program will always abort here, even if mayFail() returns Success, since
// the value is not checked.
```

Failure values are considered checked once a handler for the error type has been activated:

```
handleErrors(
    processFormattedFile(...),
    [](const BadFileFormat &BFF) {
        report("Unable to process " + BFF.Path + ": bad format");
    },
    [](const FileNotFound &FNF) {
        report("File not found " + FNF.Path);
    });
```

The `handleErrors` function takes an error as its first argument, followed by a variadic list of "handlers", each of which must be a callable type (a function, lambda, or class with a call operator) with one argument. The `handleErrors` function will visit each handler in the sequence and check its argument type against the dynamic type of the error, running the first handler that matches. This is the same decision process that is used to decide which catch clause to run for a C++ exception.

Since the list of handlers passed to `handleErrors` may not cover every error type that can occur, the `handleErrors` function also returns an `Error` value that must be checked or propagated. If the error value that is passed to `handleErrors` does not match any of the handlers it will be returned from `handleErrors`. Idiomatic use of `handleErrors` thus looks like:

```
if (auto Err =
    handleErrors(
        processFormattedFile(...),
        [](const BadFileFormat &BFF) {
            report("Unable to process " + BFF.Path + ": bad format");
        },
        [](const FileNotFound &FNF) {
            report("File not found " + FNF.Path);
        }))
    return Err;
```

In cases where you truly know that the handler list is exhaustive the `handleAllErrors` function can be used instead. This is identical to `handleErrors` except that it will terminate the program if an unhandled error is passed in, and can therefore return void. The `handleAllErrors` function should generally be avoided: the introduction of a new error type elsewhere in the program can easily turn a formerly exhaustive list of errors into a non-exhaustive list, risking unexpected program termination. Where possible, use `handleErrors` and propagate unknown errors up the stack instead.

For tool code, where errors can be handled by printing an error message then exiting with an error code, the [ExitOnError](#) utility may be a better choice than `handleErrors`, as it simplifies control flow when calling fallible functions.

In situations where it is known that a particular call to a fallible function will always succeed (for example, a call to a function that can only fail on a subset of inputs with an input that is known to be safe) the [cantFail](#) functions can be used to remove the error type, simplifying control flow.

StringError

Many kinds of errors have no recovery strategy, the only action that can be taken is to report them to the user so that the user can attempt to fix the environment. In this case representing the error as a string makes perfect sense. LLVM provides the `StringError` class for this purpose. It takes two arguments: A string error message, and an equivalent `std::error_code` for interoperability. It also provides a `createStringError` function to simplify common usage of this class:

```
// These two lines of code are equivalent:
make_error<StringError>("Bad executable", errc::executable_format_error);
createStringError(errc::executable_format_error, "Bad executable");
```

If you're certain that the error you're building will never need to be converted to a `std::error_code` you can use the `inconvertibleErrorCode()` function:

```
createStringError(inconvertibleErrorCode(), "Bad executable");
```

This should be done only after careful consideration. If any attempt is made to convert this error to a `std::error_code` it will trigger immediate program termination. Unless you are certain that your errors will not need interoperability you should look for an existing `std::error_code` that you can convert to, and even (as painful as it is) consider introducing a new one as a stopgap measure.

`createStringError` can take `printf` style format specifiers to provide a formatted message:

```
createStringError(errc::executable_format_error,
                  "Bad executable: %s", FileName);
```

Interoperability with `std::error_code` and `ErrorOr`

Many existing LLVM APIs use `std::error_code` and its partner `ErrorOr<T>` (which plays the same role as `Expected<T>`, but wraps a `std::error_code` rather than an `Error`). The infectious nature of error types means that an attempt to change one of these functions to return `Error` or `Expected<T>` instead often results in an avalanche of changes to callers, callers of callers, and so on. (The first such attempt, returning an `Error` from `MachObjectFile`'s constructor, was abandoned after the diff reached 3000 lines, impacted half a dozen libraries, and was still growing).

To solve this problem, the `Error/std::error_code` interoperability requirement was introduced. Two pairs of functions allow any `Error` value to be converted to a `std::error_code`, any `Expected<T>` to be converted to an `ErrorOr<T>`, and vice versa:

```
std::error_code errorToErrorCode(Error Err);
Error errorCodeToError(std::error_code EC);

template <typename T> ErrorOr<T> expectedToErrorOr(Expected<T> TOrErr);
template <typename T> Expected<T> errorOrToExpected(ErrorOr<T> TOrEC);
```

Using these APIs it is easy to make surgical patches that update individual functions from `std::error_code` to `Error`, and from `ErrorOr<T>` to `Expected<T>`.

Returning Errors from error handlers

Error recovery attempts may themselves fail. For that reason, `handleErrors` actually recognises three different forms of handler signature:

```
// Error must be handled, no new errors produced:
void(UserDefinedError &E);

// Error must be handled, new errors can be produced:
Error(UserDefinedError &E);

// Original error can be inspected, then re-wrapped and returned (or a new
// error can be produced):
Error(std::unique_ptr<UserDefinedError> E);
```

Any error returned from a handler will be returned from the `handleErrors` function so that it can be handled itself, or propagated up the stack.

Using `ExitOnError` to simplify tool code

Library code should never call `exit` for a recoverable error, however in tool code (especially command line tools) this can be a reasonable approach. Calling `exit` upon encountering an error dramatically simplifies control flow as the error no longer needs to be propagated up the stack. This allows code to be written in straight-line style, as long as each fallible call is wrapped in a check and call to `exit`. The `ExitOnError` class supports this pattern by providing call operators that inspect `Error` values, stripping the error away in the success case and logging to `stderr` then exiting in the failure case.

To use this class, declare a global `ExitOnError` variable in your program:

```
ExitOnError ExitOnErr;
```

Calls to fallible functions can then be wrapped with a call to `ExitOnErr`, turning them into non-failing calls:

```
Error mayFail();
Expected<int> mayFail2();

void foo() {
    ExitOnErr(mayFail());
    int X = ExitOnErr(mayFail2());
}
```

On failure, the error's log message will be written to `stderr`, optionally preceded by a string "banner" that can be set by calling the `setBanner` method. A mapping can also be supplied from `Error` values to exit codes using the `setExitCodeMapper` method:

```
int main(int argc, char *argv[]) {
    ExitOnErr.setBanner(std::string(argv[0]) + " error:");
    ExitOnErr.setExitCodeMapper(
        [] (const Error &Err) {
            if (Err.isA<BadFileFormat>())
                return 2;
            return 1;
        });
}
```

Use `ExitOnError` in your tool code where possible as it can greatly improve readability.

Using cantFail to simplify safe callsites

Some functions may only fail for a subset of their inputs, so calls using known safe inputs can be assumed to succeed.

The cantFail functions encapsulate this by wrapping an assertion that their argument is a success value and, in the case of Expected<T>, unwrapping the T value:

```
Error onlyFailsForSomeXValues(int X);
Expected<int> onlyFailsForSomeXValues2(int X);

void foo() {
    cantFail(onlyFailsForSomeXValues(KnownSafeValue));
    int Y = cantFail(onlyFailsForSomeXValues2(KnownSafeValue));
    ...
}
```

Like the ExitOnError utility, cantFail simplifies control flow. Their treatment of error cases is very different however: Where ExitOnError is guaranteed to terminate the program on an error input, cantFail simply asserts that the result is success. In debug builds this will result in an assertion failure if an error is encountered. In release builds the behavior of cantFail for failure values is undefined. As such, care must be taken in the use of cantFail: clients must be certain that a cantFail wrapped call really can not fail with the given arguments.

Use of the cantFail functions should be rare in library code, but they are likely to be of more use in tool and unit-test code where inputs and/or mocked-up classes or functions may be known to be safe.

Fallible constructors

Some classes require resource acquisition or other complex initialization that can fail during construction. Unfortunately constructors can't return errors, and having clients test objects after they're constructed to ensure that they're valid is error prone as it's all too easy to forget the test. To work around this, use the named constructor idiom and return an Expected<T>:

```
class Foo {
public:

    static Expected<Foo> Create(Resource R1, Resource R2) {
        Error Err;
        Foo F(R1, R2, Err);
        if (Err)
            return std::move(Err);
        return std::move(F);
    }

private:

    Foo(Resource R1, Resource R2, Error &Err) {
        ErrorAsOutParameter EAO(&Err);
        if (auto Err2 = R1.acquire()) {
            Err = std::move(Err2);
            return;
        }
        Err = R2.acquire();
    }
};
```

Here, the named constructor passes an Error by reference into the actual constructor, which the constructor can then use to return errors. The ErrorAsOutParameter utility sets the Error value's checked flag on entry to the

constructor so that the error can be assigned to, then resets it on exit to force the client (the named constructor) to check the error.

By using this idiom, clients attempting to construct a Foo receive either a well-formed Foo or an Error, never an object in an invalid state.

Propagating and consuming errors based on types

In some contexts, certain types of error are known to be benign. For example, when walking an archive, some clients may be happy to skip over badly formatted object files rather than terminating the walk immediately. Skipping badly formatted objects could be achieved using an elaborate handler method, but the Error.h header provides two utilities that make this idiom much cleaner: the type inspection method, `isA`, and the `consumeError` function:

```
Error walkArchive(Archive A) {
    for (unsigned I = 0; I != A.numMembers(); ++I) {
        auto ChildOrErr = A.getMember(I);
        if (auto Err = ChildOrErr.takeError()) {
            if (Err.isA<BadFileFormat>())
                consumeError(std::move(Err))
            else
                return Err;
        }
        auto &Child = *ChildOrErr;
        // Use Child
        ...
    }
    return Error::success();
}
```

Concatenating Errors with joinErrors

In the archive walking example above `BadFileFormat` errors are simply consumed and ignored. If the client had wanted report these errors after completing the walk over the archive they could use the `joinErrors` utility:

```
Error walkArchive(Archive A) {
    Error DeferredErrs = Error::success();
    for (unsigned I = 0; I != A.numMembers(); ++I) {
        auto ChildOrErr = A.getMember(I);
        if (auto Err = ChildOrErr.takeError())
            if (Err.isA<BadFileFormat>())
                DeferredErrs = joinErrors(std::move(DeferredErrs), std::move(Err));
            else
                return Err;
        auto &Child = *ChildOrErr;
        // Use Child
        ...
    }
    return DeferredErrs;
}
```

The `joinErrors` routine builds a special error type called `ErrorList`, which holds a list of user defined errors. The `handleErrors` routine recognizes this type and will attempt to handle each of the contained errors in order. If all contained errors can be handled, `handleErrors` will return `Error::success()`, otherwise `handleErrors` will concatenate the remaining errors and return the resulting `ErrorList`.

Building fallible iterators and iterator ranges

The archive walking examples above retrieve archive members by index, however this requires considerable boilerplate for iteration and error checking. We can clean this up by using the "fallible iterator" pattern, which supports the following natural iteration idiom for fallible containers like Archive:

```
Error Err;
for (auto &Child : Ar->children(Err)) {
    // Use Child - only enter the loop when it's valid

    // Allow early exit from the loop body, since we know that Err is success
    // when we're inside the loop.
    if (BailOutOn(Child))
        return;

    ...
}
// Check Err after the loop to ensure it didn't break due to an error.
if (Err)
    return Err;
```

To enable this idiom, iterators over fallible containers are written in a natural style, with their ++ and -- operators replaced with fallible `Error inc()` and `Error dec()` functions. E.g.:

```
class FallibleChildIterator {
public:
    FallibleChildIterator(Archive &A, unsigned ChildIdx);
    Archive::Child &operator*();
    friend bool operator==(const ArchiveIterator &LHS,
                           const ArchiveIterator &RHS);

    // operator++/operator-- replaced with fallible increment / decrement:
    Error inc() {
        if (!A.childValid(ChildIdx + 1))
            return make_error<BadArchiveMember>(...);
        ++ChildIdx;
        return Error::success();
    }

    Error dec() { ... }
};
```

Instances of this kind of fallible iterator interface are then wrapped with the `fallible_iterator` utility which provides `operator++` and `operator--`, returning any errors via a reference passed in to the wrapper at construction time. The `fallible_iterator` wrapper takes care of (a) jumping to the end of the range on error, and (b) marking the error as checked whenever an iterator is compared to end and found to be unequal (in particular: this marks the error as checked throughout the body of a range-based for loop), enabling early exit from the loop without redundant error checking.

Instances of the fallible iterator interface (e.g. `FallibleChildIterator` above) are wrapped using the `make_fallible_itr` and `make_fallible_end` functions. E.g.:

```
class Archive {
public:
    using child_iterator = fallible_iterator<FallibleChildIterator>;

    child_iterator child_begin(Error &Err) {
```

(continues on next page)

(continued from previous page)

```

    return make_fallible_itr(FallibleChildIterator(*this, 0), Err);
}

child_iterator child_end() {
    return make_fallible_end(FallibleChildIterator(*this, size()));
}

iterator_range<child_iterator> children(Error &Err) {
    return make_range(child_begin(Err), child_end());
}
};

```

Using the `fallible_iterator` utility allows for both natural construction of fallible iterators (using failing `inc` and `dec` operations) and relatively natural use of c++ iterator/loop idioms.

More information on `Error` and its related utilities can be found in the `Error.h` header file.

Passing functions and other callable objects

Sometimes you may want a function to be passed a callback object. In order to support lambda expressions and other function objects, you should not use the traditional C approach of taking a function pointer and an opaque cookie:

```
void takeCallback(bool (*Callback)(Function *, void *), void *Cookie);
```

Instead, use one of the following approaches:

Function template

If you don't mind putting the definition of your function into a header file, make it a function template that is templated on the callable type.

```

template<typename Callable>
void takeCallback(Callable Callback) {
    Callback(1, 2, 3);
}

```

The `function_ref` class template

The `function_ref` (doxygen) class template represents a reference to a callable object, templated over the type of the callable. This is a good choice for passing a callback to a function, if you don't need to hold onto the callback after the function returns. In this way, `function_ref` is to `std::function` as `StringRef` is to `std::string`.

`function_ref<Ret(Param1, Param2, ...)>` can be implicitly constructed from any callable object that can be called with arguments of type `Param1`, `Param2`, ..., and returns a value that can be converted to type `Ret`. For example:

```

void visitBasicBlocks(Function *F, function_ref<bool (BasicBlock*)> Callback) {
    for (BasicBlock &BB : *F)
        if (Callback(&BB))
            return;
}

```

can be called using:

```
visitBasicBlocks(F, [&](BasicBlock *BB) {  
    if (process(BB))  
        return isEmpty(BB);  
    return false;  
});
```

Note that a `function_ref` object contains pointers to external memory, so it is not generally safe to store an instance of the class (unless you know that the external storage will not be freed). If you need this ability, consider using `std::function`. `function_ref` is small enough that it should always be passed by value.

The `LLVM_DEBUG()` macro and `-debug` option

Often when working on your pass you will put a bunch of debugging printouts and other code into your pass. After you get it working, you want to remove it, but you may need it again in the future (to work out new bugs that you run across).

Naturally, because of this, you don't want to delete the debug printouts, but you don't want them to always be noisy. A standard compromise is to comment them out, allowing you to enable them if you need them in the future.

The `llvm/Support/Debug.h` (doxygen) file provides a macro named `LLVM_DEBUG()` that is a much nicer solution to this problem. Basically, you can put arbitrary code into the argument of the `LLVM_DEBUG` macro, and it is only executed if 'opt' (or any other tool) is run with the `-debug` command line argument:

```
LLVM_DEBUG(dbgs() << "I am here!\n");
```

Then you can run your pass like this:

```
$ opt < a.bc > /dev/null -mypass  
<no output>  
$ opt < a.bc > /dev/null -mypass -debug  
I am here!
```

Using the `LLVM_DEBUG()` macro instead of a home-brewed solution allows you to not have to create "yet another" command line option for the debug output for your pass. Note that `LLVM_DEBUG()` macros are disabled for non-asserts builds, so they do not cause a performance impact at all (for the same reason, they should also not contain side-effects!).

One additional nice thing about the `LLVM_DEBUG()` macro is that you can enable or disable it directly in gdb. Just use `"set DebugFlag=0"` or `"set DebugFlag=1"` from the gdb if the program is running. If the program hasn't been started yet, you can always just run it with `-debug`.

Fine grained debug info with `DEBUG_TYPE` and the `-debug-only` option

Sometimes you may find yourself in a situation where enabling `-debug` just turns on **too much** information (such as when working on the code generator). If you want to enable debug information with more fine-grained control, you should define the `DEBUG_TYPE` macro and use the `-debug-only` option as follows:

```
#define DEBUG_TYPE "foo"  
LLVM_DEBUG(dbgs() << "'foo' debug type\n");  
#undef DEBUG_TYPE  
#define DEBUG_TYPE "bar"  
LLVM_DEBUG(dbgs() << "'bar' debug type\n");  
#undef DEBUG_TYPE
```

Then you can run your pass like this:

```
$ opt < a.bc > /dev/null -mypass
<no output>
$ opt < a.bc > /dev/null -mypass -debug
'foo' debug type
'bar' debug type
$ opt < a.bc > /dev/null -mypass -debug-only=foo
'foo' debug type
$ opt < a.bc > /dev/null -mypass -debug-only=bar
'bar' debug type
$ opt < a.bc > /dev/null -mypass -debug-only=foo,bar
'foo' debug type
'bar' debug type
```

Of course, in practice, you should only set `DEBUG_TYPE` at the top of a file, to specify the debug type for the entire module. Be careful that you only do this after including `Debug.h` and not around any `#include` of headers. Also, you should use names more meaningful than "foo" and "bar", because there is no system in place to ensure that names do not conflict. If two different modules use the same string, they will all be turned on when the name is specified. This allows, for example, all debug information for instruction scheduling to be enabled with `-debug-only=InstrSched`, even if the source lives in multiple files. The name must not include a comma (,) as that is used to separate the arguments of the `-debug-only` option.

For performance reasons, `-debug-only` is not available in optimized build (`--enable-optimized`) of LLVM.

The `DEBUG_WITH_TYPE` macro is also available for situations where you would like to set `DEBUG_TYPE`, but only for one specific `DEBUG` statement. It takes an additional first parameter, which is the type to use. For example, the preceding example could be written as:

```
DEBUG_WITH_TYPE("foo", dbgs() << "'foo' debug type\n");
DEBUG_WITH_TYPE("bar", dbgs() << "'bar' debug type\n");
```

The `Statistic` class & `-stats` option

The `llvm/ADT/Statistic.h` (doxygen) file provides a class named `Statistic` that is used as a unified way to keep track of what the LLVM compiler is doing and how effective various optimizations are. It is useful to see what optimizations are contributing to making a particular program run faster.

Often you may run your pass on some big program, and you're interested to see how many times it makes a certain transformation. Although you can do this with hand inspection, or some ad-hoc method, this is a real pain and not very useful for big programs. Using the `Statistic` class makes it very easy to keep track of this information, and the calculated information is presented in a uniform manner with the rest of the passes being executed.

There are many examples of `Statistic` uses, but the basics of using it are as follows:

Define your statistic like this:

```
#define DEBUG_TYPE "mypassname" // This goes before any #includes.
STATISTIC(NumXForms, "The # of times I did stuff");
```

The `STATISTIC` macro defines a static variable, whose name is specified by the first argument. The pass name is taken from the `DEBUG_TYPE` macro, and the description is taken from the second argument. The variable defined ("NumXForms" in this case) acts like an unsigned integer.

Whenever you make a transformation, bump the counter:

```
++NumXForms; // I did stuff!
```

That's all you have to do. To get 'opt' to print out the statistics gathered, use the `'-stats'` option:

```
$ opt -stats -mypassname < program.bc > /dev/null
... statistics output ...
```

Note that in order to use the '-stats' option, LLVM must be compiled with assertions enabled.

When running `opt` on a C file from the SPEC benchmark suite, it gives a report that looks like this:

```
7646 bitcodewriter - Number of normal instructions
725 bitcodewriter - Number of oversized instructions
129996 bitcodewriter - Number of bitcode bytes written
2817 raise - Number of insts DCEd or constprop'd
3213 raise - Number of cast-of-self removed
5046 raise - Number of expression trees converted
75 raise - Number of other getelementptr's formed
138 raise - Number of load/store peepholes
42 deadtypeelim - Number of unused typenames removed from symtab
392 funcresolve - Number of varargs functions resolved
27 globaldce - Number of global variables removed
2 adce - Number of basic blocks removed
134 cee - Number of branches revectorized
49 cee - Number of setcc instruction eliminated
532 gcse - Number of loads removed
2919 gcse - Number of instructions removed
86 indvars - Number of canonical indvars added
87 indvars - Number of aux indvars removed
25 instcombine - Number of dead inst eliminate
434 instcombine - Number of insts combined
248 licm - Number of load insts hoisted
1298 licm - Number of insts hoisted to a loop pre-header
3 licm - Number of insts hoisted to multiple loop preds (bad, no loop_
↳pre-header)
75 mem2reg - Number of alloca's promoted
1444 cfgsimplify - Number of blocks simplified
```

Obviously, with so many optimizations, having a unified framework for this stuff is very nice. Making your pass fit well into the framework makes it more maintainable and useful.

Adding debug counters to aid in debugging your code

Sometimes, when writing new passes, or trying to track down bugs, it is useful to be able to control whether certain things in your pass happen or not. For example, there are times the minimization tooling can only easily give you large testcases. You would like to narrow your bug down to a specific transformation happening or not happening, automatically, using bisection. This is where debug counters help. They provide a framework for making parts of your code only execute a certain number of times.

The `llvm/Support/DebugCounter.h` (doxygen) file provides a class named `DebugCounter` that can be used to create command line counter options that control execution of parts of your code.

Define your `DebugCounter` like this:

```
DEBUG_COUNTER(DeleteAnInstruction, "passname-delete-instruction",
              "Controls which instructions get delete");
```

The `DEBUG_COUNTER` macro defines a static variable, whose name is specified by the first argument. The name of the counter (which is used on the command line) is specified by the second argument, and the description used in the help is specified by the third argument.

Whatever code you want that control, use `DebugCounter::shouldExecute` to control it.

```
if (DebugCounter::shouldExecute(DeleteAnInstruction))
    I->eraseFromParent();
```

That's all you have to do. Now, using `opt`, you can control when this code triggers using the `'--debug-counter'` option. There are two counters provided, `skip` and `count`. `skip` is the number of times to skip execution of the codepath. `count` is the number of times, once we are done skipping, to execute the codepath.

```
$ opt --debug-counter=passname-delete-instruction-skip=1,passname-delete-instruction-
↪count=2 -passname
```

This will skip the above code the first time we hit it, then execute it twice, then skip the rest of the executions.

So if executed on the following code:

```
%1 = add i32 %a, %b
%2 = add i32 %a, %b
%3 = add i32 %a, %b
%4 = add i32 %a, %b
```

It would delete number `%2` and `%3`.

A utility is provided in `utils/bisect-skip-count` to binary search skip and count arguments. It can be used to automatically minimize the skip and count for a debug-counter variable.

Viewing graphs while debugging code

Several of the important data structures in LLVM are graphs: for example CFGs made out of LLVM *BasicBlocks*, CFGs made out of LLVM *MachineBasicBlocks*, and *Instruction Selection DAGs*. In many cases, while debugging various parts of the compiler, it is nice to instantly visualize these graphs.

LLVM provides several callbacks that are available in a debug build to do exactly that. If you call the `Function::viewCFG()` method, for example, the current LLVM tool will pop up a window containing the CFG for the function where each basic block is a node in the graph, and each node contains the instructions in the block. Similarly, there also exists `Function::viewCFGOnly()` (does not include the instructions), the `MachineFunction::viewCFG()` and `MachineFunction::viewCFGOnly()`, and the `SelectionDAG::viewGraph()` methods. Within GDB, for example, you can usually use something like `call DAG.viewGraph()` to pop up a window. Alternatively, you can sprinkle calls to these functions in your code in places you want to debug.

Getting this to work requires a small amount of setup. On Unix systems with X11, install the [graphviz](#) toolkit, and make sure `'dot'` and `'gv'` are in your path. If you are running on macOS, download and install the macOS [Graphviz program](#) and add `/Applications/Graphviz.app/Contents/MacOS/` (or wherever you install it) to your path. The programs need not be present when configuring, building or running LLVM and can simply be installed when needed during an active debug session.

`SelectionDAG` has been extended to make it easier to locate *interesting* nodes in large complex graphs. From `gdb`, if you call `DAG.setGraphColor(node, "color")`, then the next call `DAG.viewGraph()` would highlight the node in the specified color (choices of colors can be found at [colors](#).) More complex node attributes can be provided with call `DAG.setGraphAttrs(node, "attributes")` (choices can be found at [Graph attributes](#).) If you want to restart and clear all the current graph attributes, then you can call `DAG.clearGraphAttrs()`.

Note that graph visualization features are compiled out of Release builds to reduce file size. This means that you need a Debug+Asserts or Release+Asserts build to use these features.

3.7.4 Picking the Right Data Structure for a Task

LLVM has a plethora of data structures in the `llvm/ADT/` directory, and we commonly use STL data structures. This section describes the trade-offs you should consider when you pick one.

The first step is to choose your own adventure: do you want a sequential container, a set-like container, or a map-like container? The most important thing when choosing a container is the algorithmic properties of how you plan to access the container. Based on that, you should use:

- a *map-like* container if you need efficient look-up of a value based on another value. Map-like containers also support efficient queries for containment (whether a key is in the map). Map-like containers generally do not support efficient reverse mapping (values to keys). If you need that, use two maps. Some map-like containers also support efficient iteration through the keys in sorted order. Map-like containers are the most expensive sort, only use them if you need one of these capabilities.
- a *set-like* container if you need to put a bunch of stuff into a container that automatically eliminates duplicates. Some set-like containers support efficient iteration through the elements in sorted order. Set-like containers are more expensive than sequential containers.
- a *sequential* container provides the most efficient way to add elements and keeps track of the order they are added to the collection. They permit duplicates and support efficient iteration, but do not support efficient look-up based on a key.
- a *string* container is a specialized sequential container or reference structure that is used for character or byte arrays.
- a *bit* container provides an efficient way to store and perform set operations on sets of numeric id's, while automatically eliminating duplicates. Bit containers require a maximum of 1 bit for each identifier you want to store.

Once the proper category of container is determined, you can fine tune the memory use, constant factors, and cache behaviors of access by intelligently picking a member of the category. Note that constant factors and cache behavior can be a big deal. If you have a vector that usually only contains a few elements (but could contain many), for example, it's much better to use *SmallVector* than *vector*. Doing so avoids (relatively) expensive malloc/free calls, which dwarf the cost of adding the elements to the container.

Sequential Containers (`std::vector`, `std::list`, etc)

There are a variety of sequential containers available for you, based on your needs. Pick the first in this section that will do what you want.

`llvm/ADT/ArrayRef.h`

The `llvm::ArrayRef` class is the preferred class to use in an interface that accepts a sequential list of elements in memory and just reads from them. By taking an `ArrayRef`, the API can be passed a fixed size array, an `std::vector`, an `llvm::SmallVector` and anything else that is contiguous in memory.

Fixed Size Arrays

Fixed size arrays are very simple and very fast. They are good if you know exactly how many elements you have, or you have a (low) upper bound on how many you have.

Heap Allocated Arrays

Heap allocated arrays (`new[] + delete[]`) are also simple. They are good if the number of elements is variable, if you know how many elements you will need before the array is allocated, and if the array is usually large (if not, consider a *SmallVector*). The cost of a heap allocated array is the cost of the `new/delete` (aka `malloc/free`). Also note that if you are allocating an array of a type with a constructor, the constructor and destructors will be run for every element in the array (re-sizable vectors only construct those elements actually used).

llvm/ADT/TinyPtrVector.h

`TinyPtrVector<Type>` is a highly specialized collection class that is optimized to avoid allocation in the case when a vector has zero or one elements. It has two major restrictions: 1) it can only hold values of pointer type, and 2) it cannot hold a null pointer.

Since this container is highly specialized, it is rarely used.

llvm/ADT/SmallVector.h

`SmallVector<Type, N>` is a simple class that looks and smells just like `vector<Type>`: it supports efficient iteration, lays out elements in memory order (so you can do pointer arithmetic between elements), supports efficient `push_back/pop_back` operations, supports efficient random access to its elements, etc.

The main advantage of `SmallVector` is that it allocates space for some number of elements (`N`) **in the object itself**. Because of this, if the `SmallVector` is dynamically smaller than `N`, no `malloc` is performed. This can be a big win in cases where the `malloc/free` call is far more expensive than the code that fiddles around with the elements.

This is good for vectors that are "usually small" (e.g. the number of predecessors/successors of a block is usually less than 8). On the other hand, this makes the size of the `SmallVector` itself large, so you don't want to allocate lots of them (doing so will waste a lot of space). As such, `SmallVectors` are most useful when on the stack.

`SmallVector` also provides a nice portable and efficient replacement for `alloca`.

`SmallVector` has grown a few other minor advantages over `std::vector`, causing `SmallVector<Type, 0>` to be preferred over `std::vector<Type>`.

1. `std::vector` is exception-safe, and some implementations have pessimizations that copy elements when `SmallVector` would move them.
2. `SmallVector` understands `llvm::is_trivially_copyable<Type>` and uses `realloc` aggressively.
3. Many LLVM APIs take a `SmallVectorImpl` as an out parameter (see the note below).
4. `SmallVector` with `N` equal to 0 is smaller than `std::vector` on 64-bit platforms, since it uses `unsigned` (instead of `void*`) for its size and capacity.

Note: Prefer to use `SmallVectorImpl<T>` as a parameter type.

In APIs that don't care about the "small size" (most?), prefer to use the `SmallVectorImpl<T>` class, which is basically just the "vector header" (and methods) without the elements allocated after it. Note that `SmallVector<T, N>` inherits from `SmallVectorImpl<T>` so the conversion is implicit and costs nothing. E.g.

```
// BAD: Clients cannot pass e.g. SmallVector<Foo, 4>.
hardcodedSmallSize(SmallVector<Foo, 2> &Out);
// GOOD: Clients can pass any SmallVector<Foo, N>.
allowsAnySmallSize(SmallVectorImpl<Foo> &Out);

void someFunc() {
    SmallVector<Foo, 8> Vec;
    hardcodedSmallSize(Vec); // Error.
    allowsAnySmallSize(Vec); // Works.
}
```

Even though it has "Impl" in the name, this is so widely used that it really isn't "private to the implementation" anymore. A name like `SmallVectorHeader` would be more appropriate.

<vector>

`std::vector<T>` is well loved and respected. However, `SmallVector<T, 0>` is often a better option due to the advantages listed above. `std::vector` is still useful when you need to store more than `UINT32_MAX` elements or when interfacing with code that expects vectors :).

One worthwhile note about `std::vector`: avoid code like this:

```
for ( ... ) {
    std::vector<foo> V;
    // make use of V.
}
```

Instead, write this as:

```
std::vector<foo> V;
for ( ... ) {
    // make use of V.
    V.clear();
}
```

Doing so will save (at least) one heap allocation and free per iteration of the loop.

<deque>

`std::deque` is, in some senses, a generalized version of `std::vector`. Like `std::vector`, it provides constant time random access and other similar properties, but it also provides efficient access to the front of the list. It does not guarantee continuity of elements within memory.

In exchange for this extra flexibility, `std::deque` has significantly higher constant factor costs than `std::vector`. If possible, use `std::vector` or something cheaper.

<list>

`std::list` is an extremely inefficient class that is rarely useful. It performs a heap allocation for every element inserted into it, thus having an extremely high constant factor, particularly for small data types. `std::list` also only supports bidirectional iteration, not random access iteration.

In exchange for this high cost, `std::list` supports efficient access to both ends of the list (like `std::deque`, but unlike `std::vector` or `SmallVector`). In addition, the iterator invalidation characteristics of `std::list` are stronger than that of a vector class: inserting or removing an element into the list does not invalidate iterator or pointers to other elements in the list.

llvm/ADT/ilist.h

`ilist<T>` implements an 'intrusive' doubly-linked list. It is intrusive, because it requires the element to store and provide access to the prev/next pointers for the list.

`ilist` has the same drawbacks as `std::list`, and additionally requires an `ilist_traits` implementation for the element type, but it provides some novel characteristics. In particular, it can efficiently store polymorphic objects, the traits class is informed when an element is inserted or removed from the list, and `ilists` are guaranteed to support a constant-time splice operation.

These properties are exactly what we want for things like Instructions and basic blocks, which is why these are implemented with `ilists`.

Related classes of interest are explained in the following subsections:

- [*ilist_traits*](#)
- [*iplist*](#)
- [*llvm/ADT/ilist_node.h*](#)
- [*Sentinels*](#)

llvm/ADT/PackedVector.h

Useful for storing a vector of values using only a few number of bits for each value. Apart from the standard operations of a vector-like container, it can also perform an 'or' set operation.

For example:

```
enum State {
    None = 0x0,
    FirstCondition = 0x1,
    SecondCondition = 0x2,
    Both = 0x3
};

State get() {
    PackedVector<State, 2> Vec1;
    Vec1.push_back(FirstCondition);

    PackedVector<State, 2> Vec2;
    Vec2.push_back(SecondCondition);

    Vec1 |= Vec2;
```

(continues on next page)

(continued from previous page)

```
    return Vec1[0]; // returns 'Both'.  
}
```

ilist_traits

`ilist_traits<T>` is `ilist<T>`'s customization mechanism. `iplist<T>` (and consequently `ilist<T>`) publicly derive from this traits class.

iplist

`iplist<T>` is `ilist<T>`'s base and as such supports a slightly narrower interface. Notably, inserters from `T&` are absent.

`ilist_traits<T>` is a public base of this class and can be used for a wide variety of customizations.

llvm/ADT/ilist_node.h

`ilist_node<T>` implements the forward and backward links that are expected by the `ilist<T>` (and analogous containers) in the default manner.

`ilist_node<T>`s are meant to be embedded in the node type `T`, usually `T` publicly derives from `ilist_node<T>`.

Sentinels

`ilists` have another specialty that must be considered. To be a good citizen in the C++ ecosystem, it needs to support the standard container operations, such as `begin` and `end` iterators, etc. Also, the `operator--` must work correctly on the `end` iterator in the case of non-empty `ilists`.

The only sensible solution to this problem is to allocate a so-called *sentinel* along with the intrusive list, which serves as the `end` iterator, providing the back-link to the last element. However conforming to the C++ convention it is illegal to `operator++` beyond the sentinel and it also must not be dereferenced.

These constraints allow for some implementation freedom to the `ilist` how to allocate and store the sentinel. The corresponding policy is dictated by `ilist_traits<T>`. By default a `T` gets heap-allocated whenever the need for a sentinel arises.

While the default policy is sufficient in most cases, it may break down when `T` does not provide a default constructor. Also, in the case of many instances of `ilists`, the memory overhead of the associated sentinels is wasted. To alleviate the situation with numerous and voluminous `T`-sentinels, sometimes a trick is employed, leading to *ghostly sentinels*.

Ghostly sentinels are obtained by specially-crafted `ilist_traits<T>` which superpose the sentinel with the `ilist` instance in memory. Pointer arithmetic is used to obtain the sentinel, which is relative to the `ilist`'s `this` pointer. The `ilist` is augmented by an extra pointer, which serves as the back-link of the sentinel. This is the only field in the ghostly sentinel which can be legally accessed.

Other Sequential Container options

Other STL containers are available, such as `std::string`.

There are also various STL adapter classes such as `std::queue`, `std::priority_queue`, `std::stack`, etc. These provide simplified access to an underlying container but don't affect the cost of the container itself.

String-like containers

There are a variety of ways to pass around and use strings in C and C++, and LLVM adds a few new options to choose from. Pick the first option on this list that will do what you need, they are ordered according to their relative cost.

Note that it is generally preferred to *not* pass strings around as `const char*`'s. These have a number of problems, including the fact that they cannot represent embedded nul ("0") characters, and do not have a length available efficiently. The general replacement for `'const char*'` is `StringRef`.

For more information on choosing string containers for APIs, please see [Passing Strings](#).

llvm/ADT/StringRef.h

The `StringRef` class is a simple value class that contains a pointer to a character and a length, and is quite related to the [ArrayRef](#) class (but specialized for arrays of characters). Because `StringRef` carries a length with it, it safely handles strings with embedded nul characters in it, getting the length does not require a `strlen` call, and it even has very convenient APIs for slicing and dicing the character range that it represents.

`StringRef` is ideal for passing simple strings around that are known to be live, either because they are C string literals, `std::string`, a C array, or a `SmallVector`. Each of these cases has an efficient implicit conversion to `StringRef`, which doesn't result in a dynamic `strlen` being executed.

`StringRef` has a few major limitations which make more powerful string containers useful:

1. You cannot directly convert a `StringRef` to a `'const char*'` because there is no way to add a trailing nul (unlike the `.c_str()` method on various stronger classes).
2. `StringRef` doesn't own or keep alive the underlying string bytes. As such it can easily lead to dangling pointers, and is not suitable for embedding in datastructures in most cases (instead, use an `std::string` or something like that).
3. For the same reason, `StringRef` cannot be used as the return value of a method if the method "computes" the result string. Instead, use `std::string`.
4. `StringRef`'s do not allow you to mutate the pointed-to string bytes and it doesn't allow you to insert or remove bytes from the range. For editing operations like this, it interoperates with the [Twine](#) class.

Because of its strengths and limitations, it is very common for a function to take a `StringRef` and for a method on an object to return a `StringRef` that points into some string that it owns.

llvm/ADT/Twine.h

The Twine class is used as an intermediary datatype for APIs that want to take a string that can be constructed inline with a series of concatenations. Twine works by forming recursive instances of the Twine datatype (a simple value object) on the stack as temporary objects, linking them together into a tree which is then linearized when the Twine is consumed. Twine is only safe to use as the argument to a function, and should always be a const reference, e.g.:

```
void foo(const Twine &T);
...
StringRef X = ...
unsigned i = ...
foo(X + "." + Twine(i));
```

This example forms a string like "blarg.42" by concatenating the values together, and does not form intermediate strings containing "blarg" or "blarg.".

Because Twine is constructed with temporary objects on the stack, and because these instances are destroyed at the end of the current statement, it is an inherently dangerous API. For example, this simple variant contains undefined behavior and will probably crash:

```
void foo(const Twine &T);
...
StringRef X = ...
unsigned i = ...
const Twine &Tmp = X + "." + Twine(i);
foo(Tmp);
```

... because the temporaries are destroyed before the call. That said, Twine's are much more efficient than intermediate std::string temporaries, and they work really well with StringRef. Just be aware of their limitations.

llvm/ADT/SmallString.h

SmallString is a subclass of *SmallVector* that adds some convenience APIs like += that takes StringRef's. SmallString avoids allocating memory in the case when the preallocated space is enough to hold its data, and it calls back to general heap allocation when required. Since it owns its data, it is very safe to use and supports full mutation of the string.

Like SmallVector's, the big downside to SmallString is their sizeof. While they are optimized for small strings, they themselves are not particularly small. This means that they work great for temporary scratch buffers on the stack, but should not generally be put into the heap: it is very rare to see a SmallString as the member of a frequently-allocated heap data structure or returned by-value.

std::string

The standard C++ std::string class is a very general class that (like SmallString) owns its underlying data. sizeof(std::string) is very reasonable so it can be embedded into heap data structures and returned by-value. On the other hand, std::string is highly inefficient for inline editing (e.g. concatenating a bunch of stuff together) and because it is provided by the standard library, its performance characteristics depend a lot of the host standard library (e.g. libc++ and MSVC provide a highly optimized string class, GCC contains a really slow implementation).

The major disadvantage of std::string is that almost every operation that makes them larger can allocate memory, which is slow. As such, it is better to use SmallVector or Twine as a scratch buffer, but then use std::string to persist the result.

Set-Like Containers (`std::set`, `SmallSet`, `SetVector`, etc)

Set-like containers are useful when you need to canonicalize multiple values into a single representation. There are several different choices for how to do this, providing various trade-offs.

A sorted 'vector'

If you intend to insert a lot of elements, then do a lot of queries, a great approach is to use an `std::vector` (or other sequential container) with `std::sort+std::unique` to remove duplicates. This approach works really well if your usage pattern has these two distinct phases (insert then query), and can be coupled with a good choice of *sequential container*.

This combination provides the several nice properties: the result data is contiguous in memory (good for cache locality), has few allocations, is easy to address (iterators in the final vector are just indices or pointers), and can be efficiently queried with a standard binary search (e.g. `std::lower_bound`; if you want the whole range of elements comparing equal, use `std::equal_range`).

llvm/ADT/SmallSet.h

If you have a set-like data structure that is usually small and whose elements are reasonably small, a `SmallSet<Type, N>` is a good choice. This set has space for `N` elements in place (thus, if the set is dynamically smaller than `N`, no malloc traffic is required) and accesses them with a simple linear search. When the set grows beyond `N` elements, it allocates a more expensive representation that guarantees efficient access (for most types, it falls back to *std::set*, but for pointers it uses something far better, *SmallPtrSet*).

The magic of this class is that it handles small sets extremely efficiently, but gracefully handles extremely large sets without loss of efficiency.

llvm/ADT/SmallPtrSet.h

`SmallPtrSet` has all the advantages of `SmallSet` (and a `SmallSet` of pointers is transparently implemented with a `SmallPtrSet`). If more than `N` insertions are performed, a single quadratically probed hash table is allocated and grows as needed, providing extremely efficient access (constant time insertion/deleting/queries with low constant factors) and is very stingy with malloc traffic.

Note that, unlike *std::set*, the iterators of `SmallPtrSet` are invalidated whenever an insertion occurs. Also, the values visited by the iterators are not visited in sorted order.

llvm/ADT/StringSet.h

`StringSet` is a thin wrapper around *StringMap<char>*, and it allows efficient storage and retrieval of unique strings.

Functionally analogous to `SmallSet<StringRef>`, `StringSet` also supports iteration. (The iterator dereferences to a `StringMapEntry<char>`, so you need to call `i->getKey()` to access the item of the `StringSet`.) On the other hand, `StringSet` doesn't support range-insertion and copy-construction, which *SmallSet* and *SmallPtrSet* do support.

llvm/ADT/DenseSet.h

DenseSet is a simple quadratically probed hash table. It excels at supporting small values: it uses a single allocation to hold all of the pairs that are currently inserted in the set. DenseSet is a great way to unique small values that are not simple pointers (use *SmallPtrSet* for pointers). Note that DenseSet has the same requirements for the value type that *DenseMap* has.

llvm/ADT/SparseSet.h

SparseSet holds a small number of objects identified by unsigned keys of moderate size. It uses a lot of memory, but provides operations that are almost as fast as a vector. Typical keys are physical registers, virtual registers, or numbered basic blocks.

SparseSet is useful for algorithms that need very fast clear/find/insert/erase and fast iteration over small sets. It is not intended for building composite data structures.

llvm/ADT/SparseMultiSet.h

SparseMultiSet adds multiset behavior to SparseSet, while retaining SparseSet's desirable attributes. Like SparseSet, it typically uses a lot of memory, but provides operations that are almost as fast as a vector. Typical keys are physical registers, virtual registers, or numbered basic blocks.

SparseMultiSet is useful for algorithms that need very fast clear/find/insert/erase of the entire collection, and iteration over sets of elements sharing a key. It is often a more efficient choice than using composite data structures (e.g. vector-of-vectors, map-of-vectors). It is not intended for building composite data structures.

llvm/ADT/FoldingSet.h

FoldingSet is an aggregate class that is really good at uniquing expensive-to-create or polymorphic objects. It is a combination of a chained hash table with intrusive links (uniqued objects are required to inherit from FoldingSetNode) that uses *SmallVector* as part of its ID process.

Consider a case where you want to implement a "getOrCreateFoo" method for a complex object (for example, a node in the code generator). The client has a description of **what** it wants to generate (it knows the opcode and all the operands), but we don't want to 'new' a node, then try inserting it into a set only to find out it already exists, at which point we would have to delete it and return the node that already exists.

To support this style of client, FoldingSet perform a query with a FoldingSetNodeID (which wraps SmallVector) that can be used to describe the element that we want to query for. The query either returns the element matching the ID or it returns an opaque ID that indicates where insertion should take place. Construction of the ID usually does not require heap traffic.

Because FoldingSet uses intrusive links, it can support polymorphic objects in the set (for example, you can have SDNode instances mixed with LoadSDNodes). Because the elements are individually allocated, pointers to the elements are stable: inserting or removing elements does not invalidate any pointers to other elements.

<set>

`std::set` is a reasonable all-around set class, which is decent at many things but great at nothing. `std::set` allocates memory for each element inserted (thus it is very malloc intensive) and typically stores three pointers per element in the set (thus adding a large amount of per-element space overhead). It offers guaranteed $\log(n)$ performance, which is not particularly fast from a complexity standpoint (particularly if the elements of the set are expensive to compare, like strings), and has extremely high constant factors for lookup, insertion and removal.

The advantages of `std::set` are that its iterators are stable (deleting or inserting an element from the set does not affect iterators or pointers to other elements) and that iteration over the set is guaranteed to be in sorted order. If the elements in the set are large, then the relative overhead of the pointers and malloc traffic is not a big deal, but if the elements of the set are small, `std::set` is almost never a good choice.

llvm/ADT/SetVector.h

LLVM's `SetVector<Type>` is an adapter class that combines your choice of a set-like container along with a *Sequential Container*. The important property that this provides is efficient insertion with uniquing (duplicate elements are ignored) with iteration support. It implements this by inserting elements into both a set-like container and the sequential container, using the set-like container for uniquing and the sequential container for iteration.

The difference between `SetVector` and other sets is that the order of iteration is guaranteed to match the order of insertion into the `SetVector`. This property is really important for things like sets of pointers. Because pointer values are non-deterministic (e.g. vary across runs of the program on different machines), iterating over the pointers in the set will not be in a well-defined order.

The drawback of `SetVector` is that it requires twice as much space as a normal set and has the sum of constant factors from the set-like container and the sequential container that it uses. Use it **only** if you need to iterate over the elements in a deterministic order. `SetVector` is also expensive to delete elements out of (linear time), unless you use its "pop_back" method, which is faster.

`SetVector` is an adapter class that defaults to using `std::vector` and a size 16 `SmallSet` for the underlying containers, so it is quite expensive. However, "llvm/ADT/SetVector.h" also provides a `SmallSetVector` class, which defaults to using a `SmallVector` and `SmallSet` of a specified size. If you use this, and if your sets are dynamically smaller than N, you will save a lot of heap traffic.

llvm/ADT/UniqueVector.h

`UniqueVector` is similar to *SetVector* but it retains a unique ID for each element inserted into the set. It internally contains a map and a vector, and it assigns a unique ID for each value inserted into the set.

`UniqueVector` is very expensive: its cost is the sum of the cost of maintaining both the map and vector, it has high complexity, high constant factors, and produces a lot of malloc traffic. It should be avoided.

llvm/ADT/ImmutableSet.h

`ImmutableSet` is an immutable (functional) set implementation based on an AVL tree. Adding or removing elements is done through a Factory object and results in the creation of a new `ImmutableSet` object. If an `ImmutableSet` already exists with the given contents, then the existing one is returned; equality is compared with a `FoldingSetNodeID`. The time and space complexity of add or remove operations is logarithmic in the size of the original set.

There is no method for returning an element of the set, you can only check for membership.

Other Set-Like Container Options

The STL provides several other options, such as `std::multiset` and the various "hash_set" like containers (whether from C++ TR1 or from the SGI library). We never use `hash_set` and `unordered_set` because they are generally very expensive (each insertion requires a malloc) and very non-portable.

`std::multiset` is useful if you're not interested in elimination of duplicates, but has all the drawbacks of *`std::set`*. A sorted vector (where you don't delete duplicate entries) or some other approach is almost always better.

Map-Like Containers (`std::map`, `DenseMap`, etc)

Map-like containers are useful when you want to associate data to a key. As usual, there are a lot of different ways to do this. :)

A sorted 'vector'

If your usage pattern follows a strict insert-then-query approach, you can trivially use the same approach as *`sorted vectors for set-like containers`*. The only difference is that your query function (which uses `std::lower_bound` to get efficient $\log(n)$ lookup) should only compare the key, not both the key and value. This yields the same advantages as sorted vectors for sets.

llvm/ADT/StringMap.h

Strings are commonly used as keys in maps, and they are difficult to support efficiently: they are variable length, inefficient to hash and compare when long, expensive to copy, etc. `StringMap` is a specialized container designed to cope with these issues. It supports mapping an arbitrary range of bytes to an arbitrary other object.

The `StringMap` implementation uses a quadratically-probed hash table, where the buckets store a pointer to the heap allocated entries (and some other stuff). The entries in the map must be heap allocated because the strings are variable length. The string data (key) and the element object (value) are stored in the same allocation with the string data immediately after the element object. This container guarantees the `(char*) (&Value+1)` points to the key string for a value.

The `StringMap` is very fast for several reasons: quadratic probing is very cache efficient for lookups, the hash value of strings in buckets is not recomputed when looking up an element, `StringMap` rarely has to touch the memory for unrelated objects when looking up a value (even when hash collisions happen), hash table growth does not recompute the hash values for strings already in the table, and each pair in the map is store in a single allocation (the string data is stored in the same allocation as the Value of a pair).

`StringMap` also provides query methods that take byte ranges, so it only ever copies a string if a value is inserted into the table.

`StringMap` iteration order, however, is not guaranteed to be deterministic, so any uses which require that should instead use a `std::map`.

llvm/ADT/IndexedMap.h

IndexedMap is a specialized container for mapping small dense integers (or values that can be mapped to small dense integers) to some other type. It is internally implemented as a vector with a mapping function that maps the keys to the dense integer range.

This is useful for cases like virtual registers in the LLVM code generator: they have a dense mapping that is offset by a compile-time constant (the first virtual register ID).

llvm/ADT/DenseMap.h

DenseMap is a simple quadratically probed hash table. It excels at supporting small keys and values: it uses a single allocation to hold all of the pairs that are currently inserted in the map. DenseMap is a great way to map pointers to pointers, or map other small types to each other.

There are several aspects of DenseMap that you should be aware of, however. The iterators in a DenseMap are invalidated whenever an insertion occurs, unlike map. Also, because DenseMap allocates space for a large number of key/value pairs (it starts with 64 by default), it will waste a lot of space if your keys or values are large. Finally, you must implement a partial specialization of DenseMapInfo for the key that you want, if it isn't already supported. This is required to tell DenseMap about two special marker values (which can never be inserted into the map) that it needs internally.

DenseMap's find_as() method supports lookup operations using an alternate key type. This is useful in cases where the normal key type is expensive to construct, but cheap to compare against. The DenseMapInfo is responsible for defining the appropriate comparison and hashing methods for each alternate key type used.

llvm/IR/ValueMap.h

ValueMap is a wrapper around a *DenseMap* mapping `Value*s` (or subclasses) to another type. When a Value is deleted or RAUW'ed, ValueMap will update itself so the new version of the key is mapped to the same value, just as if the key were a WeakVH. You can configure exactly how this happens, and what else happens on these two events, by passing a `Config` parameter to the ValueMap template.

llvm/ADT/IntervalMap.h

IntervalMap is a compact map for small keys and values. It maps key intervals instead of single keys, and it will automatically coalesce adjacent intervals. When the map only contains a few intervals, they are stored in the map object itself to avoid allocations.

The IntervalMap iterators are quite big, so they should not be passed around as STL iterators. The heavyweight iterators allow a smaller data structure.

<map>

`std::map` has similar characteristics to *std::set*: it uses a single allocation per pair inserted into the map, it offers $\log(n)$ lookup with an extremely large constant factor, imposes a space penalty of 3 pointers per pair in the map, etc.

`std::map` is most useful when your keys or values are very large, if you need to iterate over the collection in sorted order, or if you need stable iterators into the map (i.e. they don't get invalidated if an insertion or deletion of another element takes place).

llvm/ADT/MapVector.h

`MapVector<KeyT, ValueT>` provides a subset of the `DenseMap` interface. The main difference is that the iteration order is guaranteed to be the insertion order, making it an easy (but somewhat expensive) solution for non-deterministic iteration over maps of pointers.

It is implemented by mapping from key to an index in a vector of key,value pairs. This provides fast lookup and iteration, but has two main drawbacks: the key is stored twice and removing elements takes linear time. If it is necessary to remove elements, it's best to remove them in bulk using `remove_if()`.

llvm/ADT/IntEqClasses.h

`IntEqClasses` provides a compact representation of equivalence classes of small integers. Initially, each integer in the range $0..n-1$ has its own equivalence class. Classes can be joined by passing two class representatives to the `join(a, b)` method. Two integers are in the same class when `findLeader()` returns the same representative.

Once all equivalence classes are formed, the map can be compressed so each integer $0..n-1$ maps to an equivalence class number in the range $0..m-1$, where m is the total number of equivalence classes. The map must be uncompressed before it can be edited again.

llvm/ADT/ImmutableMap.h

`ImmutableMap` is an immutable (functional) map implementation based on an AVL tree. Adding or removing elements is done through a `Factory` object and results in the creation of a new `ImmutableMap` object. If an `ImmutableMap` already exists with the given key set, then the existing one is returned; equality is compared with a `FoldingSetNodeID`. The time and space complexity of add or remove operations is logarithmic in the size of the original map.

Other Map-Like Container Options

The STL provides several other options, such as `std::multimap` and the various "hash_map" like containers (whether from C++ TR1 or from the SGI library). We never use `hash_set` and `unordered_set` because they are generally very expensive (each insertion requires a malloc) and very non-portable.

`std::multimap` is useful if you want to map a key to multiple values, but has all the drawbacks of `std::map`. A sorted vector or some other approach is almost always better.

Bit storage containers (`BitVector`, `SparseBitVector`)

Unlike the other containers, there are only two bit storage containers, and choosing when to use each is relatively straightforward.

One additional option is `std::vector<bool>`: we discourage its use for two reasons 1) the implementation in many common compilers (e.g. commonly available versions of GCC) is extremely inefficient and 2) the C++ standards committee is likely to deprecate this container and/or change it significantly somehow. In any case, please don't use it.

BitVector

The BitVector container provides a dynamic size set of bits for manipulation. It supports individual bit setting/testing, as well as set operations. The set operations take time $O(\text{size of bitvector})$, but operations are performed one word at a time, instead of one bit at a time. This makes the BitVector very fast for set operations compared to other containers. Use the BitVector when you expect the number of set bits to be high (i.e. a dense set).

SmallBitVector

The SmallBitVector container provides the same interface as BitVector, but it is optimized for the case where only a small number of bits, less than 25 or so, are needed. It also transparently supports larger bit counts, but slightly less efficiently than a plain BitVector, so SmallBitVector should only be used when larger counts are rare.

At this time, SmallBitVector does not support set operations (and, or, xor), and its operator[] does not provide an assignable lvalue.

SparseBitVector

The SparseBitVector container is much like BitVector, with one major difference: Only the bits that are set, are stored. This makes the SparseBitVector much more space efficient than BitVector when the set is sparse, as well as making set operations $O(\text{number of set bits})$ instead of $O(\text{size of universe})$. The downside to the SparseBitVector is that setting and testing of random bits is $O(N)$, and on large SparseBitVectors, this can be slower than BitVector. In our implementation, setting or testing bits in sorted order (either forwards or reverse) is $O(1)$ worst case. Testing and setting bits within 128 bits (depends on size) of the current bit is also $O(1)$. As a general statement, testing/setting bits in a SparseBitVector is $O(\text{distance away from last set bit})$.

3.7.5 Debugging

A handful of [GDB pretty printers](#) are provided for some of the core LLVM libraries. To use them, execute the following (or add it to your `~/ .gdbinit`):

```
source /path/to/llvm/src/utils/gdb-scripts/prettyprinters.py
```

It also might be handy to enable the [print pretty](#) option to avoid data structures being printed as a big block of text.

3.7.6 Helpful Hints for Common Operations

This section describes how to perform some very simple transformations of LLVM code. This is meant to give examples of common idioms used, showing the practical side of LLVM transformations.

Because this is a "how-to" section, you should also read about the main classes that you will be working with. The [Core LLVM Class Hierarchy Reference](#) contains details and descriptions of the main classes that you should know about.

Basic Inspection and Traversal Routines

The LLVM compiler infrastructure have many different data structures that may be traversed. Following the example of the C++ standard template library, the techniques used to traverse these various data structures are all basically the same. For an enumerable sequence of values, the `XXXbegin()` function (or method) returns an iterator to the start of the sequence, the `XXXend()` function returns an iterator pointing to one past the last valid element of the sequence, and there is some `XXXiterator` data type that is common between the two operations.

Because the pattern for iteration is common across many different aspects of the program representation, the standard template library algorithms may be used on them, and it is easier to remember how to iterate. First we show a few common examples of the data structures that need to be traversed. Other data structures are traversed in very similar ways.

Iterating over the `BasicBlock` in a `Function`

It's quite common to have a `Function` instance that you'd like to transform in some way; in particular, you'd like to manipulate its `BasicBlocks`. To facilitate this, you'll need to iterate over all of the `BasicBlocks` that constitute the `Function`. The following is an example that prints the name of a `BasicBlock` and the number of `Instructions` it contains:

```
Function &Func = ...
for (BasicBlock &BB : Func)
    // Print out the name of the basic block if it has one, and then the
    // number of instructions that it contains
    errs() << "Basic block (name=" << BB.getName() << ") has "
            << BB.size() << " instructions.\n";
```

Iterating over the `Instruction` in a `BasicBlock`

Just like when dealing with `BasicBlocks` in `Functions`, it's easy to iterate over the individual instructions that make up `BasicBlocks`. Here's a code snippet that prints out each instruction in a `BasicBlock`:

```
BasicBlock& BB = ...
for (Instruction &I : BB)
    // The next statement works since operator<<(ostream&,...)
    // is overloaded for Instruction&
    errs() << I << "\n";
```

However, this isn't really the best way to print out the contents of a `BasicBlock`! Since the ostream operators are overloaded for virtually anything you'll care about, you could have just invoked the print routine on the basic block itself: `errs() << BB << "\n";`.

Iterating over the `Instruction` in a `Function`

If you're finding that you commonly iterate over a `Function`'s `BasicBlocks` and then that `BasicBlock`'s `Instructions`, `InstIterator` should be used instead. You'll need to include `llvm/IR/InstIterator.h` ([doxygen](#)) and then instantiate `InstIterators` explicitly in your code. Here's a small example that shows how to dump all instructions in a function to the standard error stream:

```
#include "llvm/IR/InstIterator.h"

// F is a pointer to a Function instance
```

(continues on next page)

(continued from previous page)

```
for (inst_iterator I = inst_begin(F), E = inst_end(F); I != E; ++I)
    errs() << *I << "\n";
```

Easy, isn't it? You can also use `InstIterators` to fill a work list with its initial contents. For example, if you wanted to initialize a work list to contain all instructions in a `Function F`, all you would need to do is something like:

```
std::set<Instruction*> worklist;
// or better yet, SmallPtrSet<Instruction*, 64> worklist;

for (inst_iterator I = inst_begin(F), E = inst_end(F); I != E; ++I)
    worklist.insert(&*I);
```

The STL set `worklist` would now contain all instructions in the `Function` pointed to by `F`.

Turning an iterator into a class pointer (and vice-versa)

Sometimes, it'll be useful to grab a reference (or pointer) to a class instance when all you've got at hand is an iterator. Well, extracting a reference or a pointer from an iterator is very straight-forward. Assuming that `i` is a `BasicBlock::iterator` and `j` is a `BasicBlock::const_iterator`:

```
Instruction& inst = *i;    // Grab reference to instruction reference
Instruction* pinst = &*i; // Grab pointer to instruction reference
const Instruction& inst = *j;
```

However, the iterators you'll be working with in the LLVM framework are special: they will automatically convert to a `ptr-to-instance` type whenever they need to. Instead of dereferencing the iterator and then taking the address of the result, you can simply assign the iterator to the proper pointer type and you get the dereference and address-of operation as a result of the assignment (behind the scenes, this is a result of overloading casting mechanisms). Thus the second line of the last example,

```
Instruction *pinst = &*i;
```

is semantically equivalent to

```
Instruction *pinst = i;
```

It's also possible to turn a class pointer into the corresponding iterator, and this is a constant time operation (very efficient). The following code snippet illustrates use of the conversion constructors provided by LLVM iterators. By using these, you can explicitly grab the iterator of something without actually obtaining it via iteration over some structure:

```
void printNextInstruction(Instruction* inst) {
    BasicBlock::iterator it(inst);
    ++it; // After this line, it refers to the instruction after *inst
    if (it != inst->getParent()->end()) errs() << *it << "\n";
}
```

Unfortunately, these implicit conversions come at a cost; they prevent these iterators from conforming to standard iterator conventions, and thus from being usable with standard algorithms and containers. For example, they prevent the following code, where `B` is a `BasicBlock`, from compiling:

```
llvm::SmallVector<llvm::Instruction *, 16>(B->begin(), B->end());
```

Because of this, these implicit conversions may be removed some day, and `operator*` changed to return a pointer instead of a reference.

Finding call sites: a slightly more complex example

Say that you're writing a `FunctionPass` and would like to count all the locations in the entire module (that is, across every `Function`) where a certain function (i.e., some `Function *`) is already in scope. As you'll learn later, you may want to use an `InstVisitor` to accomplish this in a much more straight-forward manner, but this example will allow us to explore how you'd do it if you didn't have `InstVisitor` around. In pseudo-code, this is what we want to do:

```
initialize callCounter to zero
for each Function f in the Module
  for each BasicBlock b in f
    for each Instruction i in b
      if (i is a CallInst and calls the given function)
        increment callCounter
```

And the actual code is (remember, because we're writing a `FunctionPass`, our `FunctionPass`-derived class simply has to override the `runOnFunction` method):

```
Function* targetFunc = ...;

class OurFunctionPass : public FunctionPass {
public:
    OurFunctionPass(): callCounter(0) { }

    virtual runOnFunction(Function& F) {
        for (BasicBlock &B : F) {
            for (Instruction &I : B) {
                if (auto *CallInst = dyn_cast<CallInst>(&I)) {
                    // We know we've encountered a call instruction, so we
                    // need to determine if it's a call to the
                    // function pointed to by m_func or not.
                    if (CallInst->getCalledFunction() == targetFunc)
                        ++callCounter;
                }
            }
        }
    }

private:
    unsigned callCounter;
};
```

Treating calls and invokes the same way

You may have noticed that the previous example was a bit oversimplified in that it did not deal with call sites generated by 'invoke' instructions. In this, and in other situations, you may find that you want to treat `CallInsts` and `InvokeInsts` the same way, even though their most-specific common base class is `Instruction`, which includes lots of less closely-related things. For these cases, LLVM provides a handy wrapper class called `CallSite` (doxygen). It is essentially a wrapper around an `Instruction` pointer, with some methods that provide functionality common to `CallInsts` and `InvokeInsts`.

This class has "value semantics": it should be passed by value, not by reference and it should not be dynamically allocated or deallocated using `operator new` or `operator delete`. It is efficiently copyable, assignable and constructable, with costs equivalents to that of a bare pointer. If you look at its definition, it has only a single pointer member.

Iterating over def-use & use-def chains

Frequently, we might have an instance of the `Value` class (doxygen) and we want to determine which `Users` use the `Value`. The list of all `Users` of a particular `Value` is called a *def-use* chain. For example, let's say we have a `Function*` named `F` to a particular function `foo`. Finding all of the instructions that *use* `foo` is as simple as iterating over the *def-use* chain of `F`:

```
Function *F = ...;

for (User *U : F->users()) {
    if (Instruction *Inst = dyn_cast<Instruction>(U)) {
        errs() << "F is used in instruction:\n";
        errs() << *Inst << "\n";
    }
}
```

Alternatively, it's common to have an instance of the `User` Class (doxygen) and need to know what `Values` are used by it. The list of all `Values` used by a `User` is known as a *use-def* chain. Instances of class `Instruction` are common `User`s, so we might want to iterate over all of the values that a particular instruction uses (that is, the operands of the particular `Instruction`):

```
Instruction *pi = ...;

for (Use &U : pi->operands()) {
    Value *v = U.get();
    // ...
}
```

Declaring objects as `const` is an important tool of enforcing mutation free algorithms (such as analyses, etc.). For this purpose above iterators come in constant flavors as `Value::const_use_iterator` and `Value::const_op_iterator`. They automatically arise when calling `use/op_begin()` on `const Value*s` or `const User*s` respectively. Upon dereferencing, they return `const Use*s`. Otherwise the above patterns remain unchanged.

Iterating over predecessors & successors of blocks

Iterating over the predecessors and successors of a block is quite easy with the routines defined in "llvm/IR/CFG.h". Just use code like this to iterate over all predecessors of BB:

```
#include "llvm/IR/CFG.h"
BasicBlock *BB = ...;

for (BasicBlock *Pred : predecessors(BB)) {
    // ...
}
```

Similarly, to iterate over successors use `successors`.

Making simple changes

There are some primitive transformation operations present in the LLVM infrastructure that are worth knowing about. When performing transformations, it's fairly common to manipulate the contents of basic blocks. This section describes some of the common methods for doing so and gives example code.

Creating and inserting new Instructions

Instantiating Instructions

Creation of Instructions is straight-forward: simply call the constructor for the kind of instruction to instantiate and provide the necessary parameters. For example, an `AllocaInst` only *requires* a (const-`ptr-to`) `Type`. Thus:

```
auto *ai = new AllocaInst(Type::Int32Ty);
```

will create an `AllocaInst` instance that represents the allocation of one integer in the current stack frame, at run time. Each `Instruction` subclass is likely to have varying default parameters which change the semantics of the instruction, so refer to the [doxygen documentation for the subclass of `Instruction`](#) that you're interested in instantiating.

Naming values

It is very useful to name the values of instructions when you're able to, as this facilitates the debugging of your transformations. If you end up looking at generated LLVM machine code, you definitely want to have logical names associated with the results of instructions! By supplying a value for the `Name` (default) parameter of the `Instruction` constructor, you associate a logical name with the result of the instruction's execution at run time. For example, say that I'm writing a transformation that dynamically allocates space for an integer on the stack, and that integer is going to be used as some kind of index by some other code. To accomplish this, I place an `AllocaInst` at the first point in the first `BasicBlock` of some `Function`, and I'm intending to use it within the same `Function`. I might do:

```
auto *pa = new AllocaInst(Type::Int32Ty, 0, "indexLoc");
```

where `indexLoc` is now the logical name of the instruction's execution value, which is a pointer to an integer on the run time stack.

Inserting instructions

There are essentially three ways to insert an `Instruction` into an existing sequence of instructions that form a `BasicBlock`:

- Insertion into an explicit instruction list

Given a `BasicBlock*` `pb`, an `Instruction*` `pi` within that `BasicBlock`, and a newly-created instruction we wish to insert before `*pi`, we do the following:

```
BasicBlock *pb = ...;
Instruction *pi = ...;
auto *newInst = new Instruction(...);

pb->getInstList().insert(pi, newInst); // Inserts newInst before pi in pb
```

Appending to the end of a `BasicBlock` is so common that the `Instruction` class and `Instruction`-derived classes provide constructors which take a pointer to a `BasicBlock` to be appended to. For example code that looked like:

```
BasicBlock *pb = ...;
auto *newInst = new Instruction(...);

pb->getInstList().push_back(newInst); // Appends newInst to pb
```

becomes:

```
BasicBlock *pb = ...;
auto *newInst = new Instruction(..., pb);
```

which is much cleaner, especially if you are creating long instruction streams.

- Insertion into an implicit instruction list

`Instruction` instances that are already in `BasicBlocks` are implicitly associated with an existing instruction list: the instruction list of the enclosing basic block. Thus, we could have accomplished the same thing as the above code without being given a `BasicBlock` by doing:

```
Instruction *pi = ...;
auto *newInst = new Instruction(...);

pi->getParent()->getInstList().insert(pi, newInst);
```

In fact, this sequence of steps occurs so frequently that the `Instruction` class and `Instruction`-derived classes provide constructors which take (as a default parameter) a pointer to an `Instruction` which the newly-created `Instruction` should precede. That is, `Instruction` constructors are capable of inserting the newly-created instance into the `BasicBlock` of a provided instruction, immediately before that instruction. Using an `Instruction` constructor with a `insertBefore` (default) parameter, the above code becomes:

```
Instruction* pi = ...;
auto *newInst = new Instruction(..., pi);
```

which is much cleaner, especially if you're creating a lot of instructions and adding them to `BasicBlocks`.

- Insertion using an instance of `IRBuilder`

Inserting several `Instructions` can be quite laborious using the previous methods. The `IRBuilder` is a convenience class that can be used to add several instructions to the end of a `BasicBlock` or before a particular `Instruction`. It also supports constant folding and renaming named registers (see `IRBuilder`'s template arguments).

The example below demonstrates a very simple use of the `IRBuilder` where three instructions are inserted before the instruction `pi`. The first two instructions are `Call` instructions and third instruction multiplies the return value of the two calls.

```
Instruction *pi = ...;
IRBuilder<> Builder(pi);
CallInst* callOne = Builder.CreateCall(...);
```

(continues on next page)

(continued from previous page)

```
CallInst* callTwo = Builder.CreateCall(...);
Value* result = Builder.CreateMul(callOne, callTwo);
```

The example below is similar to the above example except that the created `IRBuilder` inserts instructions at the end of the `BasicBlock` `pb`.

```
BasicBlock *pb = ...;
IRBuilder<> Builder(pb);
CallInst* callOne = Builder.CreateCall(...);
CallInst* callTwo = Builder.CreateCall(...);
Value* result = Builder.CreateMul(callOne, callTwo);
```

See *Kaleidoscope: Code generation to LLVM IR* for a practical use of the `IRBuilder`.

Deleting Instructions

Deleting an instruction from an existing sequence of instructions that form a *BasicBlock* is very straight-forward: just call the instruction's `eraseFromParent()` method. For example:

```
Instruction *I = .. ;
I->eraseFromParent();
```

This unlinks the instruction from its containing basic block and deletes it. If you'd just like to unlink the instruction from its containing basic block but not delete it, you can use the `removeFromParent()` method.

Replacing an Instruction with another Value

Replacing individual instructions

Including `"llvm/Transforms/Utils/BasicBlockUtils.h"` permits use of two very useful replace functions: `ReplaceInstWithValue` and `ReplaceInstWithInst`.

Deleting Instructions

- `ReplaceInstWithValue`

This function replaces all uses of a given instruction with a value, and then removes the original instruction. The following example illustrates the replacement of the result of a particular `AllocaInst` that allocates memory for a single integer with a null pointer to an integer.

```
AllocaInst* instToReplace = ...;
BasicBlock::iterator ii(instToReplace);

ReplaceInstWithValue(instToReplace->getParent()->getInstList(), ii,
    Constant::getNullValue(PointerTy::getUnqual(Type::Int32Ty)));
```

- `ReplaceInstWithInst`

This function replaces a particular instruction with another instruction, inserting the new instruction into the basic block at the location where the old instruction was, and replacing any uses of the old instruction with the new instruction. The following example illustrates the replacement of one `AllocaInst` with another.

```

AllocaInst* instToReplace = ...;
BasicBlock::iterator ii(instToReplace);

ReplaceInstWithInst(instToReplace->getParent()->getInstList(), ii,
                    new AllocaInst(Type::Int32Ty, 0, "ptrToReplacedInt"));

```

Replacing multiple uses of Users and Values

You can use `Value::replaceAllUsesWith` and `User::replaceAllUsesOfWith` to change more than one use at a time. See the doxygen documentation for the [Value Class](#) and [User Class](#), respectively, for more information.

Deleting Global Variables

Deleting a global variable from a module is just as easy as deleting an Instruction. First, you must have a pointer to the global variable that you wish to delete. You use this pointer to erase it from its parent, the module. For example:

```

GlobalVariable *GV = .. ;

GV->eraseFromParent();

```

3.7.7 Threads and LLVM

This section describes the interaction of the LLVM APIs with multithreading, both on the part of client applications, and in the JIT, in the hosted application.

Note that LLVM's support for multithreading is still relatively young. Up through version 2.5, the execution of threaded hosted applications was supported, but not threaded client access to the APIs. While this use case is now supported, clients *must* adhere to the guidelines specified below to ensure proper operation in multithreaded mode.

Note that, on Unix-like platforms, LLVM requires the presence of GCC's atomic intrinsics in order to support threaded operation. If you need a multithreading-capable LLVM on a platform without a suitably modern system compiler, consider compiling LLVM and LLVM-GCC in single-threaded mode, and using the resultant compiler to build a copy of LLVM with multithreading support.

Ending Execution with `llvm_shutdown()`

When you are done using the LLVM APIs, you should call `llvm_shutdown()` to deallocate memory used for internal structures.

Lazy Initialization with `ManagedStatic`

`ManagedStatic` is a utility class in LLVM used to implement static initialization of static resources, such as the global type tables. In a single-threaded environment, it implements a simple lazy initialization scheme. When LLVM is compiled with support for multi-threading, however, it uses double-checked locking to implement thread-safe lazy initialization.

Achieving Isolation with `LLVMContext`

`LLVMContext` is an opaque class in the LLVM API which clients can use to operate multiple, isolated instances of LLVM concurrently within the same address space. For instance, in a hypothetical compile-server, the compilation of an individual translation unit is conceptually independent from all the others, and it would be desirable to be able to compile incoming translation units concurrently on independent server threads. Fortunately, `LLVMContext` exists to enable just this kind of scenario!

Conceptually, `LLVMContext` provides isolation. Every LLVM entity (Modules, Values, Types, Constants, etc.) in LLVM's in-memory IR belongs to an `LLVMContext`. Entities in different contexts *cannot* interact with each other: Modules in different contexts cannot be linked together, Functions cannot be added to Modules in different contexts, etc. What this means is that is safe to compile on multiple threads simultaneously, as long as no two threads operate on entities within the same context.

In practice, very few places in the API require the explicit specification of a `LLVMContext`, other than the Type creation/lookup APIs. Because every Type carries a reference to its owning context, most other entities can determine what context they belong to by looking at their own Type. If you are adding new entities to LLVM IR, please try to maintain this interface design.

Threads and the JIT

LLVM's "eager" JIT compiler is safe to use in threaded programs. Multiple threads can call `ExecutionEngine::getPointerToFunction()` or `ExecutionEngine::runFunction()` concurrently, and multiple threads can run code output by the JIT concurrently. The user must still ensure that only one thread accesses IR in a given `LLVMContext` while another thread might be modifying it. One way to do that is to always hold the JIT lock while accessing IR outside the JIT (the JIT *modifies* the IR by adding `CallbackVHs`). Another way is to only call `getPointerToFunction()` from the `LLVMContext`'s thread.

When the JIT is configured to compile lazily (using `ExecutionEngine::DisableLazyCompilation(false)`), there is currently a [race condition](#) in updating call sites after a function is lazily-jitted. It's still possible to use the lazy JIT in a threaded program if you ensure that only one thread at a time can call any particular lazy stub and that the JIT lock guards any IR access, but we suggest using only the eager JIT in threaded programs.

3.7.8 Advanced Topics

This section describes some of the advanced or obscure API's that most clients do not need to be aware of. These API's tend manage the inner workings of the LLVM system, and only need to be accessed in unusual circumstances.

The `ValueSymbolTable` class

The `ValueSymbolTable` ([doxygen](#)) class provides a symbol table that the `Function` and `Module` classes use for naming value definitions. The symbol table can provide a name for any `Value`.

Note that the `SymbolTable` class should not be directly accessed by most clients. It should only be used when iteration over the symbol table names themselves are required, which is very special purpose. Note that not all LLVM `Values` have names, and those without names (i.e. they have an empty name) do not exist in the symbol table.

Symbol tables support iteration over the values in the symbol table with `begin/end/iterator` and supports querying to see if a specific name is in the symbol table (with `lookup`). The `ValueSymbolTable` class exposes no public mutator methods, instead, simply call `setName` on a value, which will autoinsert it into the appropriate symbol table.

The User and owned Use classes' memory layout

The `User (doxygen)` class provides a basis for expressing the ownership of `User` towards other `Value` instances. The `Use (doxygen)` helper class is employed to do the bookkeeping and to facilitate $O(1)$ addition and removal.

Interaction and relationship between User and Use objects

A subclass of `User` can choose between incorporating its `Use` objects or refer to them out-of-line by means of a pointer. A mixed variant (some `Use` s inline others hung off) is impractical and breaks the invariant that the `Use` objects belonging to the same `User` form a contiguous array.

We have 2 different layouts in the `User` (sub)classes:

- Layout a)
The `Use` object(s) are inside (resp. at fixed offset) of the `User` object and there are a fixed number of them.
- Layout b)
The `Use` object(s) are referenced by a pointer to an array from the `User` object and there may be a variable number of them.

As of v2.4 each layout still possesses a direct pointer to the start of the array of `Uses`. Though not mandatory for layout a), we stick to this redundancy for the sake of simplicity. The `User` object also stores the number of `Use` objects it has. (Theoretically this information can also be calculated given the scheme presented below.)

Special forms of allocation operators (`operator new`) enforce the following memory layouts:

- Layout a) is modelled by prepending the `User` object by the `Use[]` array.

- Layout b) is modelled by pointing at the `Use []` array.

(In the above figures 'P' stands for the Use** that is stored in each Use object in the member Use::Prev)

The waymarking algorithm

Since the `Use` objects are deprived of the direct (back)pointer to their `User` objects, there must be a fast and exact method to recover it. This is accomplished by the following scheme:

A bit-encoding in the 2 LSBits (least significant bits) of the `Use::Prev` allows to find the start of the `User` object:

- 00 --- binary digit 0
- 01 --- binary digit 1
- 10 --- stop and calculate (s)

- 11 --- full stop (S)

Given a `Use*`, all we have to do is to walk till we get a stop and we either have a `User` immediately behind or we have to walk to the next stop picking up digits and calculating the offset:

Only the significant number of bits need to be stored between the stops, so that the *worst case* is 20 memory accesses when there are 1000 `Use` objects associated with a `User`.

Reference implementation

The following literate Haskell fragment demonstrates the concept:

```
> import Test.QuickCheck
>
> digits :: Int -> [Char] -> [Char]
> digits 0 acc = '0' : acc
> digits 1 acc = '1' : acc
> digits n acc = digits (n `div` 2) $ digits (n `mod` 2) acc
>
> dist :: Int -> [Char] -> [Char]
> dist 0 [] = ['S']
> dist 0 acc = acc
> dist 1 acc = let r = dist 0 acc in 's' : digits (length r) r
> dist n acc = dist (n - 1) $ dist 1 acc
>
> takeLast n ss = reverse $ take n $ reverse ss
>
> test = takeLast 40 $ dist 20 []
>
```

Printing <test> gives: "1s100000s11010s10100s1111s1010s110s11s1S"

The reverse algorithm computes the length of the string just by examining a certain prefix:

```
> pref :: [Char] -> Int
> pref "S" = 1
> pref ('s': '1': rest) = decode 2 1 rest
> pref (_: rest) = 1 + pref rest
>
> decode walk acc ('0': rest) = decode (walk + 1) (acc * 2) rest
> decode walk acc ('1': rest) = decode (walk + 1) (acc * 2 + 1) rest
> decode walk acc _ = walk + acc
>
```

Now, as expected, printing <pref test> gives 40.

We can *quickCheck* this with following property:

```
> testcase = dist 2000 []
> testcaseLength = length testcase
>
> identityProp n = n > 0 && n <= testcaseLength ==> length arr == pref arr
>   where arr = takeLast n testcase
>
```

As expected <quickCheck identityProp> gives:

```
*Main> quickCheck identityProp
OK, passed 100 tests.
```

Let's be a bit more exhaustive:

```
>
> deepCheck p = check (defaultConfig { configMaxTest = 500 }) p
>
```

And here is the result of <deepCheck identityProp>:

```
*Main> deepCheck identityProp
OK, passed 500 tests.
```

Tagging considerations

To maintain the invariant that the 2 LSBits of each `Use**` in `Use` never change after being set up, setters of `Use::Prev` must re-tag the new `Use**` on every modification. Accordingly getters must strip the tag bits.

For layout b) instead of the `User` we find a pointer (`User*` with LSBit set). Following this pointer brings us to the `User`. A portable trick ensures that the first bytes of `User` (if interpreted as a pointer) never has the LSBit set. (Portability is relying on the fact that all known compilers place the `vptr` in the first word of the instances.)

Designing Type Hierarchies and Polymorphic Interfaces

There are two different design patterns that tend to result in the use of virtual dispatch for methods in a type hierarchy in C++ programs. The first is a genuine type hierarchy where different types in the hierarchy model a specific subset of the functionality and semantics, and these types nest strictly within each other. Good examples of this can be seen in the `Value` or `Type` type hierarchies.

A second is the desire to dispatch dynamically across a collection of polymorphic interface implementations. This latter use case can be modeled with virtual dispatch and inheritance by defining an abstract interface base class which all implementations derive from and override. However, this implementation strategy forces an "is-a" relationship to exist that is not actually meaningful. There is often not some nested hierarchy of useful generalizations which code might interact with and move up and down. Instead, there is a singular interface which is dispatched across a range of implementations.

The preferred implementation strategy for the second use case is that of generic programming (sometimes called "compile-time duck typing" or "static polymorphism"). For example, a template over some type parameter `T` can be instantiated across any particular implementation that conforms to the interface or *concept*. A good example here is the highly generic properties of any type which models a node in a directed graph. LLVM models these primarily through templates and generic programming. Such templates include the `LoopInfoBase` and `DominatorTreeBase`. When this type of polymorphism truly needs **dynamic** dispatch you can generalize it using a technique called *concept-based polymorphism*. This pattern emulates the interfaces and behaviors of templates using a very limited form of virtual dispatch for type erasure inside its implementation. You can find examples of this technique in the

`PassManager.h` system, and there is a more detailed introduction to it by Sean Parent in several of his talks and papers:

1. [Inheritance Is The Base Class of Evil](#) - The GoingNative 2013 talk describing this technique, and probably the best place to start.
2. [Value Semantics and Concepts-based Polymorphism](#) - The C++Now! 2012 talk describing this technique in more detail.
3. [Sean Parent's Papers and Presentations](#) - A Github project full of links to slides, video, and sometimes code.

When deciding between creating a type hierarchy (with either tagged or virtual dispatch) and using templates or concepts-based polymorphism, consider whether there is some refinement of an abstract base class which is a semantically meaningful type on an interface boundary. If anything more refined than the root abstract interface is meaningless to talk about as a partial extension of the semantic model, then your use case likely fits better with polymorphism and you should avoid using virtual dispatch. However, there may be some exigent circumstances that require one technique or the other to be used.

If you do need to introduce a type hierarchy, we prefer to use explicitly closed type hierarchies with manual tagged dispatch and/or RTTI rather than the open inheritance model and virtual dispatch that is more common in C++ code. This is because LLVM rarely encourages library consumers to extend its core types, and leverages the closed and tag-dispatched nature of its hierarchies to generate significantly more efficient code. We have also found that a large amount of our usage of type hierarchies fits better with tag-based pattern matching rather than dynamic dispatch across a common interface. Within LLVM we have built custom helpers to facilitate this design. See this document's section on *isa and dyn_cast* and our *detailed document* which describes how you can implement this pattern for use with the LLVM helpers.

ABI Breaking Checks

Checks and asserts that alter the LLVM C++ ABI are predicated on the preprocessor symbol `LLVM_ENABLE_ABI_BREAKING_CHECKS` -- LLVM libraries built with `LLVM_ENABLE_ABI_BREAKING_CHECKS` are not ABI compatible LLVM libraries built without it defined. By default, turning on assertions also turns on `LLVM_ENABLE_ABI_BREAKING_CHECKS` so a default `+Asserts` build is not ABI compatible with a default `-Asserts` build. Clients that want ABI compatibility between `+Asserts` and `-Asserts` builds should use the CMake build system to set `LLVM_ENABLE_ABI_BREAKING_CHECKS` independently of `LLVM_ENABLE_ASSERTIONS`.

3.7.9 The Core LLVM Class Hierarchy Reference

```
#include "llvm/IR/Type.h"
```

header source: [Type.h](#)

doxygen info: [Type Clases](#)

The Core LLVM classes are the primary means of representing the program being inspected or transformed. The core LLVM classes are defined in header files in the `include/llvm/IR` directory, and implemented in the `lib/IR` directory. It's worth noting that, for historical reasons, this library is called `libLLVMCore.so`, not `libLLVMIR.so` as you might expect.

The Type class and Derived Types

`Type` is a superclass of all type classes. Every `Value` has a `Type`. `Type` cannot be instantiated directly but only through its subclasses. Certain primitive types (`VoidType`, `LabelType`, `FloatType` and `DoubleType`) have hidden subclasses. They are hidden because they offer no useful functionality beyond what the `Type` class offers except to distinguish themselves from other subclasses of `Type`.

All other types are subclasses of `DerivedType`. Types can be named, but this is not a requirement. There exists exactly one instance of a given shape at any one time. This allows type equality to be performed with address equality of the `Type` Instance. That is, given two `Type*` values, the types are identical if the pointers are identical.

Important Public Methods

- `bool isIntegerTy() const`: Returns true for any integer type.
- `bool isFloatingPointTy()`: Return true if this is one of the five floating point types.
- `bool isSized()`: Return true if the type has known size. Things that don't have a size are abstract types, labels and void.

Important Derived Types

IntegerType Subclass of `DerivedType` that represents integer types of any bit width. Any bit width between `IntegerType::MIN_INT_BITS` (1) and `IntegerType::MAX_INT_BITS` (~8 million) can be represented.

- `static const IntegerType* get(unsigned NumBits)`: get an integer type of a specific bit width.
- `unsigned getBitWidth() const`: Get the bit width of an integer type.

SequentialType This is subclassed by `ArrayType` and `VectorType`.

- `const Type * getElementTy() const`: Returns the type of each of the elements in the sequential type.
- `uint64_t getNumElements() const`: Returns the number of elements in the sequential type.

ArrayType This is a subclass of `SequentialType` and defines the interface for array types.

PointerType Subclass of `Type` for pointer types.

VectorType Subclass of `SequentialType` for vector types. A vector type is similar to an `ArrayType` but is distinguished because it is a first class type whereas `ArrayType` is not. Vector types are used for vector operations and are usually small vectors of an integer or floating point type.

StructType Subclass of `DerivedTypes` for struct types.

FunctionType Subclass of `DerivedTypes` for function types.

- `bool isVarArg() const`: Returns true if it's a vararg function.
- `const Type * getReturnTy() const`: Returns the return type of the function.
- `const Type * getParamTy(unsigned i)`: Returns the type of the *i*th parameter.
- `const unsigned getNumParams() const`: Returns the number of formal parameters.

The Module class

#include "llvm/IR/Module.h"

header source: [Module.h](#)

doxygen info: [Module Class](#)

The `Module` class represents the top level structure present in LLVM programs. An LLVM module is effectively either a translation unit of the original program or a combination of several translation units merged by the linker. The `Module` class keeps track of a list of [Functions](#), a list of [GlobalVariables](#), and a [SymbolTable](#). Additionally, it contains a few helpful member functions that try to make common operations easy.

Important Public Members of the Module class

- `Module::Module(std::string name = "")`

Constructing a [Module](#) is easy. You can optionally provide a name for it (probably based on the name of the translation unit).

- `Module::iterator` - Typedef for function list iterator
`Module::const_iterator` - Typedef for const_iterator.
`begin()`, `end()`, `size()`, `empty()`

These are forwarding methods that make it easy to access the contents of a `Module` object's [Function](#) list.

- `Module::FunctionListType &getFunctionList()`

Returns the list of [Functions](#). This is necessary to use when you need to update the list or perform a complex action that doesn't have a forwarding method.

- `Module::global_iterator` - Typedef for global variable list iterator
`Module::const_global_iterator` - Typedef for const_iterator.
`global_begin()`, `global_end()`, `global_size()`, `global_empty()`

These are forwarding methods that make it easy to access the contents of a `Module` object's [GlobalVariable](#) list.

- `Module::GlobalListType &getGlobalList()`

Returns the list of [GlobalVariables](#). This is necessary to use when you need to update the list or perform a complex action that doesn't have a forwarding method.

- `SymbolTable *getSymbolTable()`

Return a reference to the [SymbolTable](#) for this `Module`.

- `Function *getFunction(StringRef Name) const`

Look up the specified function in the `Module` [SymbolTable](#). If it does not exist, return null.

- `FunctionCallee getOrInsertFunction(const std::string &Name, const FunctionType *T)`

Look up the specified function in the `Module` [SymbolTable](#). If it does not exist, add an external declaration for the function and return it. Note that the function signature already present may not match the requested

signature. Thus, in order to enable the common usage of passing the result directly to `EmitCall`, the return type is a struct of `{FunctionType *T, Constant *FunctionPtr}`, rather than simply the `Function*` with potentially an unexpected signature.

- `std::string getTypeName(const Type *Ty)`

If there is at least one entry in the *SymbolTable* for the specified *Type*, return it. Otherwise return the empty string.

- `bool addTypeName(const std::string &Name, const Type *Ty)`

Insert an entry in the *SymbolTable* mapping `Name` to `Ty`. If there is already an entry for this name, `true` is returned and the *SymbolTable* is not modified.

The Value class

```
#include "llvm/IR/Value.h"
```

header source: [Value.h](#)

doxygen info: [Value Class](#)

The `Value` class is the most important class in the LLVM Source base. It represents a typed value that may be used (among other things) as an operand to an instruction. There are many different types of `Values`, such as *Constants*, *Arguments*. Even *Instructions* and *Functions* are `Values`.

A particular `Value` may be used many times in the LLVM representation for a program. For example, an incoming argument to a function (represented with an instance of the *Argument* class) is "used" by every instruction in the function that references the argument. To keep track of this relationship, the `Value` class keeps a list of all of the `Users` that is using it (the *User* class is a base class for all nodes in the LLVM graph that can refer to `Values`). This use list is how LLVM represents def-use information in the program, and is accessible through the `use_*` methods, shown below.

Because LLVM is a typed representation, every LLVM `Value` is typed, and this *Type* is available through the `getType()` method. In addition, all LLVM values can be named. The "name" of the `Value` is a symbolic string printed in the LLVM code:

```
%foo = add i32 1, 2
```

The name of this instruction is "foo". **NOTE** that the name of any value may be missing (an empty string), so names should **ONLY** be used for debugging (making the source code easier to read, debugging printouts), they should not be used to keep track of values or map between them. For this purpose, use a `std::map` of pointers to the `Value` itself instead.

One important aspect of LLVM is that there is no distinction between an SSA variable and the operation that produces it. Because of this, any reference to the value produced by an instruction (or the value available as an incoming argument, for example) is represented as a direct pointer to the instance of the class that represents this value. Although this may take some getting used to, it simplifies the representation and makes it easier to manipulate.

Important Public Members of the `Value` class

- `Value::use_iterator` - Typedef for iterator over the use-list
- `Value::const_use_iterator` - Typedef for `const_iterator` over the use-list
- `unsigned use_size()` - Returns the number of users of the value.
- `bool use_empty()` - Returns true if there are no users.
- `use_iterator use_begin()` - Get an iterator to the start of the use-list.
- `use_iterator use_end()` - Get an iterator to the end of the use-list.
- `User *use_back()` - Returns the last element in the list.

These methods are the interface to access the def-use information in LLVM. As with all other iterators in LLVM, the naming conventions follow the conventions defined by the *STL*.

- `Type *getType() const` This method returns the Type of the Value.
- `bool hasName() const`
• `std::string getName() const`
• `void setName(const std::string &Name)`

This family of methods is used to access and assign a name to a Value, be aware of the *precaution above*.

- `void replaceAllUsesWith(Value *V)`

This method traverses the use list of a Value changing all *Users* of the current value to refer to "V" instead. For example, if you detect that an instruction always produces a constant value (for example through constant folding), you can replace all uses of the instruction with the constant like this:

```
Inst->replaceAllUsesWith(ConstVal);
```

The `User` class

```
#include "llvm/IR/User.h"
```

header source: [User.h](#)

doxygen info: [User Class](#)

Superclass: [Value](#)

The `User` class is the common base class of all LLVM nodes that may refer to Values. It exposes a list of "Operands" that are all of the Values that the User is referring to. The `User` class itself is a subclass of `Value`.

The operands of a `User` point directly to the LLVM Value that it refers to. Because LLVM uses Static Single Assignment (SSA) form, there can only be one definition referred to, allowing this direct connection. This connection provides the use-def information in LLVM.

Important Public Members of the `User` class

The `User` class exposes the operand list in two ways: through an index access interface and through an iterator based interface.

- `Value *getOperand(unsigned i)`
• `unsigned getNumOperands()`

These two methods expose the operands of the `User` in a convenient form for direct access.

- `User::op_iterator` - Typedef for iterator over the operand list

`op_iterator op_begin()` - Get an iterator to the start of the operand list.

`op_iterator op_end()` - Get an iterator to the end of the operand list.

Together, these methods make up the iterator based interface to the operands of a `User`.

The Instruction class

`#include "llvm/IR/Instruction.h"`

header source: [Instruction.h](#)

doxygen info: [Instruction Class](#)

Superclasses: [User](#), [Value](#)

The `Instruction` class is the common base class for all LLVM instructions. It provides only a few methods, but is a very commonly used class. The primary data tracked by the `Instruction` class itself is the opcode (instruction type) and the parent [BasicBlock](#) the `Instruction` is embedded into. To represent a specific type of instruction, one of many subclasses of `Instruction` are used.

Because the `Instruction` class subclasses the [User](#) class, its operands can be accessed in the same way as for other `Users` (with the `getOperand()`/`getNumOperands()` and `op_begin()`/`op_end()` methods). An important file for the `Instruction` class is the `llvm/Instruction.def` file. This file contains some meta-data about the various different types of instructions in LLVM. It describes the enum values that are used as opcodes (for example `Instruction::Add` and `Instruction::ICmp`), as well as the concrete sub-classes of `Instruction` that implement the instruction (for example [BinaryOperator](#) and [CmpInst](#)). Unfortunately, the use of macros in this file confuses doxygen, so these enum values don't show up correctly in the [doxygen output](#).

Important Subclasses of the Instruction class

- `BinaryOperator`

This subclasses represents all two operand instructions whose operands must be the same type, except for the comparison instructions.

- `CastInst` This subclass is the parent of the 12 casting instructions. It provides common operations on cast instructions.

- `CmpInst`

This subclass represents the two comparison instructions, [ICmpInst](#) (integer operands), and [FCmpInst](#) (floating point operands).

Important Public Members of the Instruction class

- `BasicBlock *getParent()`

Returns the [BasicBlock](#) that this `Instruction` is embedded into.

- `bool mayWriteToMemory()`

Returns true if the instruction writes to memory, i.e. it is a call, free, invoke, or store.

- `unsigned getOpcode()`

Returns the opcode for the `Instruction`.

- `Instruction *clone() const`

Returns another instance of the specified instruction, identical in all ways to the original except that the instruction has no parent (i.e. it's not embedded into a *BasicBlock*), and it has no name.

The Constant class and subclasses

Constant represents a base class for different types of constants. It is subclassed by ConstantInt, ConstantArray, etc. for representing the various types of Constants. *GlobalValue* is also a subclass, which represents the address of a global variable or function.

Important Subclasses of Constant

- ConstantInt : This subclass of Constant represents an integer constant of any width.
 - `const APInt& getValue() const`: Returns the underlying value of this constant, an APInt value.
 - `int64_t getSExtValue() const`: Converts the underlying APInt value to an int64_t via sign extension. If the value (not the bit width) of the APInt is too large to fit in an int64_t, an assertion will result. For this reason, use of this method is discouraged.
 - `uint64_t getZExtValue() const`: Converts the underlying APInt value to a uint64_t via zero extension. IF the value (not the bit width) of the APInt is too large to fit in a uint64_t, an assertion will result. For this reason, use of this method is discouraged.
 - `static ConstantInt* get(const APInt& Val)`: Returns the ConstantInt object that represents the value provided by Val. The type is implied as the IntegerType that corresponds to the bit width of Val.
 - `static ConstantInt* get(const Type *Ty, uint64_t Val)`: Returns the ConstantInt object that represents the value provided by Val for integer type Ty.
- ConstantFP : This class represents a floating point constant.
 - `double getValue() const`: Returns the underlying value of this constant.
- ConstantArray : This represents a constant array.
 - `const std::vector<Use> &getValues() const`: Returns a vector of component constants that makeup this array.
- ConstantStruct : This represents a constant struct.
 - `const std::vector<Use> &getValues() const`: Returns a vector of component constants that makeup this array.
- GlobalValue : This represents either a global variable or a function. In either case, the value is a constant fixed address (after linking).

The GlobalValue class

#include "llvm/IR/GlobalValue.h"

header source: [GlobalValue.h](#)

doxygen info: [GlobalValue Class](#)

Superclasses: [Constant](#), [User](#), [Value](#)

Global values ([GlobalVariables](#) or [Functions](#)) are the only LLVM values that are visible in the bodies of all [Functions](#). Because they are visible at global scope, they are also subject to linking with other globals defined in different translation units. To control the linking process, GlobalValues know their linkage rules. Specifically, GlobalValues know whether they have internal or external linkage, as defined by the [LinkageTypes](#) enumeration.

If a GlobalValue has internal linkage (equivalent to being `static` in C), it is not visible to code outside the current translation unit, and does not participate in linking. If it has external linkage, it is visible to external code, and does participate in linking. In addition to linkage information, GlobalValues keep track of which [Module](#) they are currently part of.

Because GlobalValues are memory objects, they are always referred to by their **address**. As such, the [Type](#) of a global is always a pointer to its contents. It is important to remember this when using the `GetElementPtrInst` instruction because this pointer must be dereferenced first. For example, if you have a [GlobalVariable](#) (a subclass of [GlobalValue](#)) that is an array of 24 ints, type `[24 x i32]`, then the [GlobalVariable](#) is a pointer to that array. Although the address of the first element of this array and the value of the [GlobalVariable](#) are the same, they have different types. The [GlobalVariable](#)'s type is `[24 x i32]`. The first element's type is `i32`. Because of this, accessing a global value requires you to dereference the pointer with `GetElementPtrInst` first, then its elements can be accessed. This is explained in the [LLVM Language Reference Manual](#).

Important Public Members of the GlobalValue class

- `bool hasInternalLinkage() const`
`bool hasExternalLinkage() const`
`void setInternalLinkage(bool HasInternalLinkage)`
 These methods manipulate the linkage characteristics of the [GlobalValue](#).
- `Module *getParent()`
 This returns the [Module](#) that the [GlobalValue](#) is currently embedded into.

The Function class

#include "llvm/IR/Function.h"

header source: [Function.h](#)

doxygen info: [Function Class](#)

Superclasses: [GlobalValue](#), [Constant](#), [User](#), [Value](#)

The [Function](#) class represents a single procedure in LLVM. It is actually one of the more complex classes in the LLVM hierarchy because it must keep track of a large amount of data. The [Function](#) class keeps track of a list of [BasicBlocks](#), a list of formal [Arguments](#), and a [SymbolTable](#).

The list of [BasicBlocks](#) is the most commonly used part of [Function](#) objects. The list imposes an implicit ordering of the blocks in the function, which indicate how the code will be laid out by the backend. Additionally, the first [BasicBlock](#) is the implicit entry node for the [Function](#). It is not legal in LLVM to explicitly branch to this initial block. There are no implicit exit nodes, and in fact there may be multiple exit nodes from a single [Function](#). If the

BasicBlock list is empty, this indicates that the `Function` is actually a function declaration: the actual body of the function hasn't been linked in yet.

In addition to a list of *BasicBlocks*, the `Function` class also keeps track of the list of formal *Arguments* that the function receives. This container manages the lifetime of the *Argument* nodes, just like the *BasicBlock* list does for the *BasicBlocks*.

The *SymbolTable* is a very rarely used LLVM feature that is only used when you have to look up a value by name. Aside from that, the *SymbolTable* is used internally to make sure that there are not conflicts between the names of *Instructions*, *BasicBlocks*, or *Arguments* in the function body.

Note that `Function` is a *GlobalValue* and therefore also a *Constant*. The value of the function is its address (after linking) which is guaranteed to be constant.

Important Public Members of the `Function`

- `Function(const FunctionType *Ty, LinkageTypes Linkage, const std::string &N = "", Module* Parent = 0)`

Constructor used when you need to create new `Functions` to add the program. The constructor must specify the type of the function to create and what type of linkage the function should have. The *FunctionType* argument specifies the formal arguments and return value for the function. The same *FunctionType* value can be used to create multiple functions. The `Parent` argument specifies the `Module` in which the function is defined. If this argument is provided, the function will automatically be inserted into that module's list of functions.

- `bool isDeclaration()`

Return whether or not the `Function` has a body defined. If the function is "external", it does not have a body, and thus must be resolved by linking with a function defined in a different translation unit.

- `Function::iterator` - Typedef for basic block list iterator
`Function::const_iterator` - Typedef for const_iterator.
`begin()`, `end()`, `size()`, `empty()`

These are forwarding methods that make it easy to access the contents of a `Function` object's *BasicBlock* list.

- `Function::BasicBlockListType &getBasicBlockList()`

Returns the list of *BasicBlocks*. This is necessary to use when you need to update the list or perform a complex action that doesn't have a forwarding method.

- `Function::arg_iterator` - Typedef for the argument list iterator
`Function::const_arg_iterator` - Typedef for const_iterator.
`arg_begin()`, `arg_end()`, `arg_size()`, `arg_empty()`

These are forwarding methods that make it easy to access the contents of a `Function` object's *Argument* list.

- `Function::ArgumentListType &getArgumentList()`

Returns the list of *Argument*. This is necessary to use when you need to update the list or perform a complex action that doesn't have a forwarding method.

- `BasicBlock &getEntryBlock()`

Returns the entry *BasicBlock* for the function. Because the entry block for the function is always the first block, this returns the first block of the `Function`.

- `Type *getReturnType()`
`FunctionType *getFunctionType()`

This traverses the *Type* of the `Function` and returns the return type of the function, or the *FunctionType* of the actual function.

- `SymbolTable *getSymbolTable()`

Return a pointer to the *SymbolTable* for this `Function`.

The `GlobalVariable` class

#include "llvm/IR/GlobalVariable.h"

header source: `GlobalVariable.h`

doxygen info: [GlobalVariable Class](#)

Superclasses: *GlobalValue*, *Constant*, *User*, *Value*

Global variables are represented with the (surprise surprise) `GlobalVariable` class. Like functions, `GlobalVariables` are also subclasses of *GlobalValue*, and as such are always referenced by their address (global values must live in memory, so their "name" refers to their constant address). See *GlobalValue* for more on this. Global variables may have an initial value (which must be a *Constant*), and if they have an initializer, they may be marked as "constant" themselves (indicating that their contents never change at runtime).

Important Public Members of the `GlobalVariable` class

- `GlobalVariable(const Type *Ty, bool isConstant, LinkageTypes &Linkage, Constant *Initializer = 0, const std::string &Name = "", Module* Parent = 0)`

Create a new global variable of the specified type. If `isConstant` is true then the global variable will be marked as unchanging for the program. The `Linkage` parameter specifies the type of linkage (internal, external, weak, linkonce, appending) for the variable. If the linkage is `InternalLinkage`, `WeakAnyLinkage`, `WeakODRLinkage`, `LinkOnceAnyLinkage` or `LinkOnceODRLinkage`, then the resultant global variable will have internal linkage. `AppendingLinkage` concatenates together all instances (in different translation units) of the variable into a single variable but is only applicable to arrays. See the [LLVM Language Reference](#) for further details on linkage types. Optionally an initializer, a name, and the module to put the variable into may be specified for the global variable as well.

- `bool isConstant() const`

Returns true if this is a global variable that is known not to be modified at runtime.

- `bool hasInitializer()`

Returns true if this `GlobalVariable` has an initializer.

- `Constant *getInitializer()`

Returns the initial value for a `GlobalVariable`. It is not legal to call this method if there is no initializer.

The BasicBlock class

#include "llvm/IR/BasicBlock.h"

header source: [BasicBlock.h](#)

doxygen info: [BasicBlock Class](#)

Superclass: [Value](#)

This class represents a single entry single exit section of the code, commonly known as a basic block by the compiler community. The `BasicBlock` class maintains a list of [Instructions](#), which form the body of the block. Matching the language definition, the last element of this list of instructions is always a terminator instruction.

In addition to tracking the list of instructions that make up the block, the `BasicBlock` class also keeps track of the [Function](#) that it is embedded into.

Note that `BasicBlocks` themselves are [Values](#), because they are referenced by instructions like branches and can go in the switch tables. `BasicBlocks` have type `label`.

Important Public Members of the BasicBlock class

- `BasicBlock(const std::string &Name = "", Function *Parent = 0)`

The `BasicBlock` constructor is used to create new basic blocks for insertion into a function. The constructor optionally takes a name for the new block, and a [Function](#) to insert it into. If the `Parent` parameter is specified, the new `BasicBlock` is automatically inserted at the end of the specified [Function](#), if not specified, the `BasicBlock` must be manually inserted into the [Function](#).

- `BasicBlock::iterator` - Typedef for instruction list iterator
`BasicBlock::const_iterator` - Typedef for const_iterator.
`begin()`, `end()`, `front()`, `back()`, `size()`, `empty()` STL-style functions for accessing the instruction list.

These methods and typedefs are forwarding functions that have the same semantics as the standard library methods of the same names. These methods expose the underlying instruction list of a basic block in a way that is easy to manipulate. To get the full complement of container operations (including operations to update the list), you must use the `getInstList()` method.

- `BasicBlock::InstListType &getInstList()`

This method is used to get access to the underlying container that actually holds the `Instructions`. This method must be used when there isn't a forwarding function in the `BasicBlock` class for the operation that you would like to perform. Because there are no forwarding functions for "updating" operations, you need to use this if you want to update the contents of a `BasicBlock`.

- `Function *getParent()`

Returns a pointer to [Function](#) the block is embedded into, or a null pointer if it is homeless.

- `Instruction *getTerminator()`

Returns a pointer to the terminator instruction that appears at the end of the `BasicBlock`. If there is no terminator instruction, or if the last instruction in the block is not a terminator, then a null pointer is returned.

The Argument class

This subclass of Value defines the interface for incoming formal arguments to a function. A Function maintains a list of its formal arguments. An argument has a pointer to the parent Function.

3.8 LLVM Extensions

- *Introduction*

3.8.1 Introduction

This document describes extensions to tools and formats LLVM seeks compatibility with.

3.8.2 General Assembly Syntax

C99-style Hexadecimal Floating-point Constants

LLVM's assemblers allow floating-point constants to be written in C99's hexadecimal format instead of decimal if desired.

```
.section .data
.float 0x1c2.2ap3
```

3.8.3 Machine-specific Assembly Syntax

X86/COFF-Dependent

Relocations

The following additional relocation types are supported:

@IMGREL (AT&T syntax only) generates an image-relative relocation that corresponds to the COFF relocation types `IMAGE_REL_I386_DIR32NB` (32-bit) or `IMAGE_REL_AMD64_ADDR32NB` (64-bit).

```
.text
fun:
    mov foo@IMGREL(%ebx, %ecx, 4), %eax

.section .pdata
    .long fun@IMGREL
    .long (fun@imgrel + 0x3F)
    .long $unwind$fun@imgrel
```

.secrel32 generates a relocation that corresponds to the COFF relocation types `IMAGE_REL_I386_SECREL` (32-bit) or `IMAGE_REL_AMD64_SECREL` (64-bit).

.secidx relocation generates an index of the section that contains the target. It corresponds to the COFF relocation types `IMAGE_REL_I386_SECTION` (32-bit) or `IMAGE_REL_AMD64_SECTION` (64-bit).

```
.section .debug$$,"rn"
.long 4
.long 242
.long 40
.secrel32 _function_name + 0
.secdx    _function_name
...
```

.linkonce Directive

Syntax:

```
.linkonce [ comdat type ]
```

Supported COMDAT types:

discard Discards duplicate sections with the same COMDAT symbol. This is the default if no type is specified.

one_only If the symbol is defined multiple times, the linker issues an error.

same_size Duplicates are discarded, but the linker issues an error if any have different sizes.

same_contents Duplicates are discarded, but the linker issues an error if any duplicates do not have exactly the same content.

largest Links the largest section from among the duplicates.

newest Links the newest section from among the duplicates.

```
.section .text$foo
.linkonce
...
```

.section Directive

MC supports passing the information in `.linkonce` at the end of `.section`. For example, these two codes are equivalent

```
.section secName, "dr", discard, "Symbol1"
.globl Symbol1
Symbol1:
.long 1
```

```
.section secName, "dr"
.linkonce discard
.globl Symbol1
Symbol1:
.long 1
```

Note that in the combined form the COMDAT symbol is explicit. This extension exists to support multiple sections with the same name in different COMDATs:

```
.section secName, "dr", discard, "Symbol1"
.globl Symbol1
Symbol1:
.long 1
```

(continues on next page)

(continued from previous page)

```
.section secName, "dr", discard, "Symbol2"
.globl Symbol2
Symbol2:
.long 1
```

In addition to the types allowed with `.linkonce`, `.section` also accepts `associative`. The meaning is that the section is linked if a certain other COMDAT section is linked. This other section is indicated by the `comdat` symbol in this directive. It can be any symbol defined in the associated section, but is usually the associated section's `comdat`.

The following restrictions apply to the associated section:

1. It must be a COMDAT section.
2. It cannot be another associative COMDAT section.

In the following example the symbol `sym` is the `comdat` symbol of `.foo` and `.bar` is associated to `.foo`.

```
.section      .foo, "bw", discard, "sym"
.section      .bar, "rd", associative, "sym"
```

MC supports these flags in the COFF `.section` directive:

- `b`: BSS section (`IMAGE_SCN_CNT_INITIALIZED_DATA`)
- `d`: Data section (`IMAGE_SCN_CNT_UNINITIALIZED_DATA`)
- `n`: Section is not loaded (`IMAGE_SCN_LNK_REMOVE`)
- `r`: Read-only
- `s`: Shared section
- `w`: Writable
- `x`: Executable section
- `y`: Not readable
- `D`: Discardable (`IMAGE_SCN_MEM_DISCARDABLE`)

These flags are all compatible with `gas`, with the exception of the `D` flag, which `gnu as` does not support. For `gas` compatibility, sections with a name starting with `".debug"` are implicitly discardable.

ARM64/COFF-Dependent

Relocations

The following additional symbol variants are supported:

:secret_lo12: generates a relocation that corresponds to the COFF relocation types `IMAGE_REL_ARM64_SECRET_LOW12A` or `IMAGE_REL_ARM64_SECRET_LOW12L`.

:secret_hi12: generates a relocation that corresponds to the COFF relocation type `IMAGE_REL_ARM64_SECRET_HIGH12A`.

```
add x0, x0, :secret_hi12:symbol
ldr x0, [x0, :secret_lo12:symbol]

add x1, x1, :secret_hi12:symbol
```

(continues on next page)

(continued from previous page)

```
add x1, x1, :secret_lo12:symbol
...
```

ELF-Dependent

.section Directive

In order to support creating multiple sections with the same name and comdat, it is possible to add an unique number at the end of the `.section` directive. For example, the following code creates two sections named `.text`.

```
.section      .text,"ax",@progbits,unique,1
nop

.section      .text,"ax",@progbits,unique,2
nop
```

The unique number is not present in the resulting object at all. It is just used in the assembler to differentiate the sections.

The 'o' flag is mapped to SHF_LINK_ORDER. If it is present, a symbol must be given that identifies the section to be placed is the `.sh_link`.

```
.section .foo,"a",@progbits
.Ltmp:
.section .bar,"ao",@progbits,.Ltmp
```

which is equivalent to just

```
.section .foo,"a",@progbits
.section .bar,"ao",@progbits,.foo
```

.linker-options Section (linker options)

In order to support passing linker options from the frontend to the linker, a special section of type `SHT_LLVM_LINKER_OPTIONS` (usually named `.linker-options` though the name is not significant as it is identified by the type). The contents of this section is a simple pair-wise encoding of directives for consideration by the linker. The strings are encoded as standard null-terminated UTF-8 strings. They are emitted inline to avoid having the linker traverse the object file for retrieving the value. The linker is permitted to not honour the option and instead provide a warning/error to the user that the requested option was not honoured.

The section has type `SHT_LLVM_LINKER_OPTIONS` and has the `SHF_EXCLUDE` flag to ensure that the section is treated as opaque by linkers which do not support the feature and will not be emitted into the final linked binary.

This would be equivalent to the follow raw assembly:

```
.section ".linker-options","e",@llvm_linker_options
.asciz "option 1"
.asciz "value 1"
.asciz "option 2"
.asciz "value 2"
```

The following directives are specified:

- **lib**

The parameter identifies a library to be linked against. The library will be looked up in the default and any specified library search paths (specified to this point).

- **libpath**

The parameter identifies an additional library search path to be considered when looking up libraries after the inclusion of this option.

SHT_LLVM_DEPENDENT_LIBRARIES Section (Dependent Libraries)

This section contains strings specifying libraries to be added to the link by the linker.

The section should be consumed by the linker and not written to the output.

The strings are encoded as standard null-terminated UTF-8 strings.

For example:

```
.section ".deplibs", "MS", @llvm_dependent_libraries, 1
.asciz "library specifier 1"
.asciz "library specifier 2"
```

The interpretation of the library specifiers is defined by the consuming linker.

SHT_LLVM_CALL_GRAPH_PROFILE Section (Call Graph Profile)

This section is used to pass a call graph profile to the linker which can be used to optimize the placement of sections. It contains a sequence of (from symbol, to symbol, weight) tuples.

It shall have a type of `SHT_LLVM_CALL_GRAPH_PROFILE` (0x6fff4c02), shall have the `SHF_EXCLUDE` flag set, the `sh_link` member shall hold the section header index of the associated symbol table, and shall have a `sh_entsize` of 16. It should be named `.llvm.call-graph-profile`.

The contents of the section shall be a sequence of `Elf_CGProfile` entries.

```
typedef struct {
    Elf_Word cgp_from;
    Elf_Word cgp_to;
    Elf_Xword cgp_weight;
} Elf_CGProfile;
```

cgp_from The symbol index of the source of the edge.

cgp_to The symbol index of the destination of the edge.

cgp_weight The weight of the edge.

This is represented in assembly as:

```
.cg_profile from, to, 42
```

`.cg_profile` directives are processed at the end of the file. It is an error if either `from` or `to` are undefined temporary symbols. If either symbol is a temporary symbol, then the section symbol is used instead. If either symbol is undefined, then that symbol is defined as if `.weak symbol` has been written at the end of the file. This forces the symbol to show up in the symbol table.

SHT_LLVM_ADDRSIG Section (address-significance table)

This section is used to mark symbols as address-significant, i.e. the address of the symbol is used in a comparison or leaks outside the translation unit. It has the same meaning as the absence of the LLVM attributes `unnamed_addr` and `local_unnamed_addr`.

Any sections referred to by symbols that are not marked as address-significant in any object file may be safely merged by a linker without breaking the address uniqueness guarantee provided by the C and C++ language standards.

The contents of the section are a sequence of ULEB128-encoded integers referring to the symbol table indexes of the address-significant symbols.

There are two associated assembly directives:

```
.addrsig
```

This instructs the assembler to emit an address-significance table. Without this directive, all symbols are considered address-significant.

```
.addrsig_sym sym
```

This marks `sym` as address-significant.

SHT_LLVM_SYMPART Section (symbol partition specification)

This section is used to mark symbols with the `partition` that they belong to. An `.llvm_sympart` section consists of a null-terminated string specifying the name of the partition followed by a relocation referring to the symbol that belongs to the partition. It may be constructed as follows:

```
.section ".llvm_sympart", "", @llvm_sympart
.asciz "libpartition.so"
.word symbol_in_partition
```

CodeView-Dependent

.cv_file Directive

Syntax: `.cv_file` *FileNumber* *FileName* [*checksum*] [*checksumkind*]

.cv_func_id Directive

Introduces a function ID that can be used with `.cv_loc`.

Syntax: `.cv_func_id` *FunctionId*

.cv_inline_site_id Directive

Introduces a function ID that can be used with `.cv_loc`. Includes `inlined` at source location information for use in the line table of the caller, whether the caller is a real function or another inlined call site.

Syntax: `.cv_inline_site_id` *FunctionId* within *Function* `inlined_at` *FileNumber* *Line* [*Column*]

.cv_loc Directive

The first number is a file number, must have been previously assigned with a `.file` directive, the second number is the line number and optionally the third number is a column position (zero if not specified). The remaining optional items are `.loc` sub-directives.

Syntax: `.cv_loc` *FunctionId* *FileNumber* [*Line*] [*Column*] [*prologue_end*] [*is_stmt* *value*]

.cv_linetable Directive

Syntax: `.cv_linetable` *FunctionId* , *FunctionStart* , *FunctionEnd*

.cv_inline_linetable Directive

Syntax: `.cv_inline_linetable` *PrimaryFunctionId* , *FileNumber* *Line* *FunctionStart* *FunctionEnd*

.cv_def_range Directive

3.8.4 Target Specific Behaviour

X86

Relocations

@ABS8 can be applied to symbols which appear as immediate operands to instructions that have an 8-bit immediate form for that operand. It causes the assembler to use the 8-bit form and an 8-bit relocation (e.g. R_386_8 or R_X86_64_8) for the symbol.

For example:

```
cmpq $foo@ABS8, %rdi
```

This causes the assembler to select the form of the 64-bit `cmpq` instruction that takes an 8-bit immediate operand that is sign extended to 64 bits, as opposed to `cmpq $foo, %rdi` which takes a 32-bit immediate operand. This is also not the same as `cmpb $foo, %dil`, which is an 8-bit comparison.

Windows on ARM

Stack Probe Emission

The reference implementation (Microsoft Visual Studio 2012) emits stack probes in the following fashion:

```
movw r4, #constant
bl __chkstk
sub.w sp, sp, r4
```

However, this has the limitation of 32 MiB (± 16 MiB). In order to accommodate larger binaries, LLVM supports the use of `-mcode-model=large` to allow a 4GiB range via a slight deviation. It will generate an indirect jump as follows:

```
movw r4, #constant
movw r12, :lower16:__chkstk
movt r12, :upper16:__chkstk
blx r12
sub.w sp, sp, r4
```

Variable Length Arrays

The reference implementation (Microsoft Visual Studio 2012) does not permit the emission of Variable Length Arrays (VLAs).

The Windows ARM Itanium ABI extends the base ABI by adding support for emitting a dynamic stack allocation. When emitting a variable stack allocation, a call to `__chkstk` is emitted unconditionally to ensure that guard pages are setup properly. The emission of this stack probe emission is handled similar to the standard stack probe emission.

The MSVC environment does not emit code for VLAs currently.

Windows on ARM64

Stack Probe Emission

The reference implementation (Microsoft Visual Studio 2017) emits stack probes in the following fashion:

```
mov x15, #constant
bl __chkstk
sub sp, sp, x15, lsl #4
```

However, this has the limitation of 256 MiB (± 128 MiB). In order to accommodate larger binaries, LLVM supports the use of `-mcode-model=large` to allow a 8GiB (± 4 GiB) range via a slight deviation. It will generate an indirect jump as follows:

```
mov x15, #constant
adrp x16, __chkstk
add x16, x16, :lo12:__chkstk
blr x16
sub sp, sp, x15, lsl #4
```

3.9 libFuzzer – a library for coverage-guided fuzz testing.

- *Introduction*
- *Versions*
- *Getting Started*
- *Options*
- *Output*
- *Examples*
- *Advanced features*
- *Developing libFuzzer*
- *FAQ*
- *Trophies*

3.9.1 Introduction

LibFuzzer is in-process, coverage-guided, evolutionary fuzzing engine.

LibFuzzer is linked with the library under test, and feeds fuzzed inputs to the library via a specific fuzzing entrypoint (aka "target function"); the fuzzer then tracks which areas of the code are reached, and generates mutations on the corpus of input data in order to maximize the code coverage. The code coverage information for libFuzzer is provided by LLVM's `SanitizerCoverage` instrumentation.

Contact: [libfuzzer\(#\)googlegroups.com](mailto:libfuzzer@googlegroups.com)

3.9.2 Versions

LibFuzzer is under active development so you will need the current (or at least a very recent) version of the Clang compiler (see [building Clang from trunk](#))

Refer to <https://releases.llvm.org/5.0.0/docs/LibFuzzer.html> for documentation on the older version.

3.9.3 Getting Started

- *Fuzz Target*
- *Fuzzer Usage*
- *Corpus*
- *Running*
- *Parallel Fuzzing*
- *Fork mode*
- *Resuming merge*

Fuzz Target

The first step in using libFuzzer on a library is to implement a *fuzz target* -- a function that accepts an array of bytes and does something interesting with these bytes using the API under test. Like this:

```
// fuzz_target.cc
extern "C" int LLVMFuzzerTestOneInput(const uint8_t *Data, size_t Size) {
    DoSomethingInterestingWithMyAPI(Data, Size);
    return 0; // Non-zero return values are reserved for future use.
}
```

Note that this fuzz target does not depend on libFuzzer in any way and so it is possible and even desirable to use it with other fuzzing engines e.g. [AFL](#) and/or [Radamsa](#).

Some important things to remember about fuzz targets:

- The fuzzing engine will execute the fuzz target many times with different inputs in the same process.
- It must tolerate any kind of input (empty, huge, malformed, etc).
- It must not *exit()* on any input.
- It may use threads but ideally all threads should be joined at the end of the function.
- It must be as deterministic as possible. Non-determinism (e.g. random decisions not based on the input bytes) will make fuzzing inefficient.
- It must be fast. Try avoiding cubic or greater complexity, logging, or excessive memory consumption.
- Ideally, it should not modify any global state (although that's not strict).
- Usually, the narrower the target the better. E.g. if your target can parse several data formats, split it into several targets, one per format.

Fuzzer Usage

Recent versions of Clang (starting from 6.0) include libFuzzer, and no extra installation is necessary.

In order to build your fuzzer binary, use the `-fsanitize=fuzzer` flag during the compilation and linking. In most cases you may want to combine libFuzzer with [AddressSanitizer](#) (ASAN), [UndefinedBehaviorSanitizer](#) (UBSAN), or both. You can also build with [MemorySanitizer](#) (MSAN), but support is experimental:

```
clang -g -O1 -fsanitize=fuzzer                               mytarget.c # Builds the fuzz_
↳target w/o sanitizers
clang -g -O1 -fsanitize=fuzzer,address                     mytarget.c # Builds the fuzz_
↳target with ASAN
clang -g -O1 -fsanitize=fuzzer,signed-integer-overflow mytarget.c # Builds the fuzz_
↳target with a part of UBSAN
clang -g -O1 -fsanitize=fuzzer,memory                      mytarget.c # Builds the fuzz_
↳target with MSAN
```

This will perform the necessary instrumentation, as well as linking with the libFuzzer library. Note that `-fsanitize=fuzzer` links in the libFuzzer's `main()` symbol.

If modifying CFLAGS of a large project, which also compiles executables requiring their own `main` symbol, it may be desirable to request just the instrumentation without linking:

```
clang -fsanitize=fuzzer-no-link mytarget.c
```

Then libFuzzer can be linked to the desired driver by passing in `-fsanitize=fuzzer` during the linking stage.

Corpus

Coverage-guided fuzzers like libFuzzer rely on a corpus of sample inputs for the code under test. This corpus should ideally be seeded with a varied collection of valid and invalid inputs for the code under test; for example, for a graphics library the initial corpus might hold a variety of different small PNG/JPG/GIF files. The fuzzer generates random mutations based around the sample inputs in the current corpus. If a mutation triggers execution of a previously-uncovered path in the code under test, then that mutation is saved to the corpus for future variations.

LibFuzzer will work without any initial seeds, but will be less efficient if the library under test accepts complex, structured inputs.

The corpus can also act as a sanity/regression check, to confirm that the fuzzing entrypoint still works and that all of the sample inputs run through the code under test without problems.

If you have a large corpus (either generated by fuzzing or acquired by other means) you may want to minimize it while still preserving the full coverage. One way to do that is to use the `-merge=1` flag:

```
mkdir NEW_CORPUS_DIR # Store minimized corpus here.
./my_fuzzer -merge=1 NEW_CORPUS_DIR FULL_CORPUS_DIR
```

You may use the same flag to add more interesting items to an existing corpus. Only the inputs that trigger new coverage will be added to the first corpus.

```
./my_fuzzer -merge=1 CURRENT_CORPUS_DIR NEW_POTENTIALLY_INTERESTING_INPUTS_DIR
```

Running

To run the fuzzer, first create a *Corpus* directory that holds the initial "seed" sample inputs:

```
mkdir CORPUS_DIR
cp /some/input/samples/* CORPUS_DIR
```

Then run the fuzzer on the corpus directory:

```
./my_fuzzer CORPUS_DIR # -max_len=1000 -jobs=20 ...
```

As the fuzzer discovers new interesting test cases (i.e. test cases that trigger coverage of new paths through the code under test), those test cases will be added to the corpus directory.

By default, the fuzzing process will continue indefinitely – at least until a bug is found. Any crashes or sanitizer failures will be reported as usual, stopping the fuzzing process, and the particular input that triggered the bug will be written to disk (typically as `crash-<sha1>`, `leak-<sha1>`, or `timeout-<sha1>`).

Parallel Fuzzing

Each libFuzzer process is single-threaded, unless the library under test starts its own threads. However, it is possible to run multiple libFuzzer processes in parallel with a shared corpus directory; this has the advantage that any new inputs found by one fuzzer process will be available to the other fuzzer processes (unless you disable this with the `-reload=0` option).

This is primarily controlled by the `-jobs=N` option, which indicates that that *N* fuzzing jobs should be run to completion (i.e. until a bug is found or time/iteration limits are reached). These jobs will be run across a set of worker processes, by default using half of the available CPU cores; the count of worker processes can be overridden by the `-workers=N` option. For example, running with `-jobs=30` on a 12-core machine would run 6 workers by default, with each worker averaging 5 bugs by completion of the entire process.

Fork mode

Experimental mode `-fork=N` (where *N* is the number of parallel jobs) enables oom-, timeout-, and crash-resistant fuzzing with separate processes (using `fork-exec`, not just `fork`).

The top libFuzzer process will not do any fuzzing itself, but will spawn up to *N* concurrent child processes providing them small random subsets of the corpus. After a child exits, the top process merges the corpus generated by the child back to the main corpus.

Related flags:

-ignore_ooms True by default. If an OOM happens during fuzzing in one of the child processes, the reproducer is saved on disk, and fuzzing continues.

-ignore_timeouts True by default, same as `-ignore_ooms`, but for timeouts.

-ignore_crashes False by default, same as `-ignore_ooms`, but for all other crashes.

The plan is to eventually replace `-jobs=N` and `-workers=N` with `-fork=N`.

Resuming merge

Merging large corpora may be time consuming, and it is often desirable to do it on preemptable VMs, where the process may be killed at any time. In order to seamlessly resume the merge, use the `-merge_control_file` flag and use `killall -SIGUSR1 /path/to/fuzzer/binary` to stop the merge gracefully. Example:

```
% rm -f SomeLocalPath
% ./my_fuzzer CORPUS1 CORPUS2 -merge=1 -merge_control_file=SomeLocalPath
...
MERGE-INNER: using the control file 'SomeLocalPath'
...
# While this is running, do `killall -SIGUSR1 my_fuzzer` in another console
==9015== INFO: libFuzzer: exiting as requested

# This will leave the file SomeLocalPath with the partial state of the merge.
# Now, you can continue the merge by executing the same command. The merge
# will continue from where it has been interrupted.
% ./my_fuzzer CORPUS1 CORPUS2 -merge=1 -merge_control_file=SomeLocalPath
...
MERGE-OUTER: non-empty control file provided: 'SomeLocalPath'
MERGE-OUTER: control file ok, 32 files total, first not processed file 20
...
```

3.9.4 Options

To run the fuzzer, pass zero or more corpus directories as command line arguments. The fuzzer will read test inputs from each of these corpus directories, and any new test inputs that are generated will be written back to the first corpus directory:

```
./fuzzer [-flag1=val1 [-flag2=val2 ...] ] [dir1 [dir2 ...] ]
```

If a list of files (rather than directories) are passed to the fuzzer program, then it will re-run those files as test inputs but will not perform any fuzzing. In this mode the fuzzer binary can be used as a regression test (e.g. on a continuous integration system) to check the target function and saved inputs still work.

The most important command line options are:

- help** Print help message.
- seed** Random seed. If 0 (the default), the seed is generated.
- runs** Number of individual test runs, -1 (the default) to run indefinitely.
- max_len** Maximum length of a test input. If 0 (the default), libFuzzer tries to guess a good value based on the corpus (and reports it).
- len_control** Try generating small inputs first, then try larger inputs over time. Specifies the rate at which the length limit is increased (smaller == faster). Default is 100. If 0, immediately try inputs with size up to max_len.
- timeout** Timeout in seconds, default 1200. If an input takes longer than this timeout, the process is treated as a failure case.
- rss_limit_mb** Memory usage limit in Mb, default 2048. Use 0 to disable the limit. If an input requires more than this amount of RSS memory to execute, the process is treated as a failure case. The limit is checked in a separate thread every second. If running w/o ASAN/MSAN, you may use 'ulimit -v' instead.
- malloc_limit_mb** If non-zero, the fuzzer will exit if the target tries to allocate this number of Mb with one malloc call. If zero (default) same limit as rss_limit_mb is applied.

- timeout_exitcode** Exit code (default 77) used if libFuzzer reports a timeout.
- error_exitcode** Exit code (default 77) used if libFuzzer itself (not a sanitizer) reports a bug (leak, OOM, etc).
- max_total_time** If positive, indicates the maximum total time in seconds to run the fuzzer. If 0 (the default), run indefinitely.
- merge** If set to 1, any corpus inputs from the 2nd, 3rd etc. corpus directories that trigger new code coverage will be merged into the first corpus directory. Defaults to 0. This flag can be used to minimize a corpus.
- merge_control_file** Specify a control file used for the merge process. If a merge process gets killed it tries to leave this file in a state suitable for resuming the merge. By default a temporary file will be used.
- minimize_crash** If 1, minimizes the provided crash input. Use with `-runs=N` or `-max_total_time=N` to limit the number of attempts.
- reload** If set to 1 (the default), the corpus directory is re-read periodically to check for new inputs; this allows detection of new inputs that were discovered by other fuzzing processes.
- jobs** Number of fuzzing jobs to run to completion. Default value is 0, which runs a single fuzzing process until completion. If the value is ≥ 1 , then this number of jobs performing fuzzing are run, in a collection of parallel separate worker processes; each such worker process has its `stdout/stderr` redirected to `fuzz-<JOB>.log`.
- workers** Number of simultaneous worker processes to run the fuzzing jobs to completion in. If 0 (the default), `min(jobs, NumberOfCpuCores() / 2)` is used.
- dict** Provide a dictionary of input keywords; see [Dictionaries](#).
- use_counters** Use [coverage counters](#) to generate approximate counts of how often code blocks are hit; defaults to 1.
- reduce_inputs** Try to reduce the size of inputs while preserving their full feature sets; defaults to 1.
- use_value_profile** Use [value profile](#) to guide corpus expansion; defaults to 0.
- only_ascii** If 1, generate only ASCII (`isprint``+``isspace`) inputs. Defaults to 0.
- artifact_prefix** Provide a prefix to use when saving fuzzing artifacts (crash, timeout, or slow inputs) as `$(artifact_prefix)file`. Defaults to empty.
- exact_artifact_path** Ignored if empty (the default). If non-empty, write the single artifact on failure (crash, timeout) as `$(exact_artifact_path)`. This overrides `-artifact_prefix` and will not use checksum in the file name. Do not use the same path for several parallel processes.
- print_pcs** If 1, print out newly covered PCs. Defaults to 0.
- print_final_stats** If 1, print statistics at exit. Defaults to 0.
- detect_leaks** If 1 (default) and if LeakSanitizer is enabled try to detect memory leaks during fuzzing (i.e. not only at shut down).
- close_fd_mask** Indicate output streams to close at startup. Be careful, this will remove diagnostic output from target code (e.g. messages on assert failure).
 - 0 (default): close neither `stdout` nor `stderr`
 - 1: close `stdout`
 - 2: close `stderr`
 - 3: close both `stdout` and `stderr`.

For the full list of flags run the fuzzer binary with `-help=1`.

3.9.5 Output

During operation the fuzzer prints information to `stderr`, for example:

```
INFO: Seed: 1523017872
INFO: Loaded 1 modules (16 guards): [0x744e60, 0x744ea0),
INFO: -max_len is not provided, using 64
INFO: A corpus is not provided, starting from an empty corpus
#0  READ units: 1
#1  INITED cov: 3 ft: 2 corp: 1/1b exec/s: 0 rss: 24Mb
#3811 NEW    cov: 4 ft: 3 corp: 2/2b exec/s: 0 rss: 25Mb L: 1 MS: 5 ChangeBit-
      ↪ChangeByte-ChangeBit-ShuffleBytes-ChangeByte-
#3827 NEW    cov: 5 ft: 4 corp: 3/4b exec/s: 0 rss: 25Mb L: 2 MS: 1 CopyPart-
#3963 NEW    cov: 6 ft: 5 corp: 4/6b exec/s: 0 rss: 25Mb L: 2 MS: 2 ShuffleBytes-
      ↪ChangeBit-
#4167 NEW    cov: 7 ft: 6 corp: 5/9b exec/s: 0 rss: 25Mb L: 3 MS: 1 InsertByte-
...

```

The early parts of the output include information about the fuzzer options and configuration, including the current random seed (in the `Seed:` line; this can be overridden with the `-seed=N` flag).

Further output lines have the form of an event code and statistics. The possible event codes are:

READ The fuzzer has read in all of the provided input samples from the corpus directories.

INITED The fuzzer has completed initialization, which includes running each of the initial input samples through the code under test.

NEW The fuzzer has created a test input that covers new areas of the code under test. This input will be saved to the primary corpus directory.

REDUCE The fuzzer has found a better (smaller) input that triggers previously discovered features (set `-reduce_inputs=0` to disable).

pulse The fuzzer has generated 2ⁿ inputs (generated periodically to reassure the user that the fuzzer is still working).

DONE The fuzzer has completed operation because it has reached the specified iteration limit (`-runs`) or time limit (`-max_total_time`).

RELOAD The fuzzer is performing a periodic reload of inputs from the corpus directory; this allows it to discover any inputs discovered by other fuzzer processes (see [Parallel Fuzzing](#)).

Each output line also reports the following statistics (when non-zero):

cov: Total number of code blocks or edges covered by executing the current corpus.

ft: libFuzzer uses different signals to evaluate the code coverage: edge coverage, edge counters, value profiles, indirect caller/callee pairs, etc. These signals combined are called *features* (*ft:*).

corp: Number of entries in the current in-memory test corpus and its size in bytes.

lim: Current limit on the length of new entries in the corpus. Increases over time until the max length (`-max_len`) is reached.

exec/s: Number of fuzzer iterations per second.

rss: Current memory consumption.

For **NEW** events, the output line also includes information about the mutation operation that produced the new input:

L: Size of the new input in bytes.

MS: <n> <operations> Count and list of the mutation operations used to generate the input.

3.9.6 Examples

- *Toy example*
- *More examples*

Toy example

A simple function that does something interesting if it receives the input "HI!":

```
cat << EOF > test_fuzzer.cc
#include <stdint.h>
#include <stddef.h>
extern "C" int LLVMFuzzerTestOneInput(const uint8_t *data, size_t size) {
    if (size > 0 && data[0] == 'H')
        if (size > 1 && data[1] == 'I')
            if (size > 2 && data[2] == '!')
                __builtin_trap();
    return 0;
}
EOF
# Build test_fuzzer.cc with asan and link against libFuzzer.
clang++ -fsanitize=address,uzzer test_fuzzer.cc
# Run the fuzzer with no corpus.
./a.out
```

You should get an error pretty quickly:

```
INFO: Seed: 1523017872
INFO: Loaded 1 modules (16 guards): [0x744e60, 0x744ea0),
INFO: -max_len is not provided, using 64

```

More examples

Examples of real-life fuzz targets and the bugs they find can be found at <http://tutorial.libfuzzer.info>. Among other things you can learn how to detect [Heartbleed](#) in one second.

3.9.7 Advanced features

- *Dictionaries*
- *Tracing CMP instructions*
- *Value Profile*
- *Fuzzer-friendly build mode*
- *AFL compatibility*
- *How good is my fuzzer?*
- *User-supplied mutators*
- *Startup initialization*
- *Leaks*

Dictionaries

LibFuzzer supports user-supplied dictionaries with input language keywords or other interesting byte sequences (e.g. multi-byte magic values). Use `-dict=DICTIONARY_FILE`. For some input languages using a dictionary may significantly improve the search speed. The dictionary syntax is similar to that used by [AFL](#) for its `-x` option:

```
# Lines starting with '#' and empty lines are ignored.

# Adds "blah" (w/o quotes) to the dictionary.
kw1="blah"
# Use \\ for backslash and \" for quotes.
kw2=\"\\ac\\dc\"
# Use \xAB for hex values
kw3=\"\xF7\xF8\"
# the name of the keyword followed by '=' may be omitted:
"foo\x0Abar"
```

Tracing CMP instructions

With an additional compiler flag `-fsanitize-coverage=trace-cmp` (on by default as part of `-fsanitize=fuzzer`, see [SanitizerCoverageTraceDataFlow](#)) libFuzzer will intercept CMP instructions and guide mutations based on the arguments of intercepted CMP instructions. This may slow down the fuzzing but is very likely to improve the results.

Value Profile

With `-fsanitize-coverage=trace-cmp` (default with `-fsanitize=fuzzer`) and extra run-time flag `-use_value_profile=1` the fuzzer will collect value profiles for the parameters of compare instructions and treat some new values as new coverage.

The current implementation does roughly the following:

- The compiler instruments all CMP instructions with a callback that receives both CMP arguments.
- The callback computes $(caller_pc \& 4095) \mid (popcnt(Arg1 \wedge Arg2) \ll 12)$ and uses this value to set a bit in a bitset.
- Every new observed bit in the bitset is treated as new coverage.

This feature has a potential to discover many interesting inputs, but there are two downsides. First, the extra instrumentation may bring up to 2x additional slowdown. Second, the corpus may grow by several times.

Fuzzer-friendly build mode

Sometimes the code under test is not fuzzing-friendly. Examples:

- The target code uses a PRNG seeded e.g. by system time and thus two consequent invocations may potentially execute different code paths even if the end result will be the same. This will cause a fuzzer to treat two similar inputs as significantly different and it will blow up the test corpus. E.g. libxml uses `rand()` inside its hash table.
- The target code uses checksums to protect from invalid inputs. E.g. png checks CRC for every chunk.

In many cases it makes sense to build a special fuzzing-friendly build with certain fuzzing-unfriendly features disabled. We propose to use a common build macro for all such cases for consistency: `FUZZING_BUILD_MODE_UNSAFE_FOR_PRODUCTION`.

```
void MyInitPRNG() {
#ifdef FUZZING_BUILD_MODE_UNSAFE_FOR_PRODUCTION
    // In fuzzing mode the behavior of the code should be deterministic.
    srand(0);
#else
    srand(time(0));
#endif
}
```

AFL compatibility

LibFuzzer can be used together with [AFL](#) on the same test corpus. Both fuzzers expect the test corpus to reside in a directory, one file per input. You can run both fuzzers on the same corpus, one after another:

```
./afl-fuzz -i testcase_dir -o findings_dir /path/to/program @@
./llvm-fuzz testcase_dir findings_dir # Will write new tests to testcase_dir
```

Periodically restart both fuzzers so that they can use each other's findings. Currently, there is no simple way to run both fuzzing engines in parallel while sharing the same corpus dir.

You may also use AFL on your target function `LLVMFuzzerTestOneInput`: see an example [here](#).

How good is my fuzzer?

Once you implement your target function `LLVMFuzzerTestOneInput` and fuzz it to death, you will want to know whether the function or the corpus can be improved further. One easy to use metric is, of course, code coverage.

We recommend to use [Clang Coverage](#), to visualize and study your code coverage ([example](#)).

User-supplied mutators

LibFuzzer allows to use custom (user-supplied) mutators, see [Structure-Aware Fuzzing](#) for more details.

Startup initialization

If the library being tested needs to be initialized, there are several options.

The simplest way is to have a statically initialized global object inside `LLVMFuzzerTestOneInput` (or in global scope if that works for you):

```
extern "C" int LLVMFuzzerTestOneInput(const uint8_t *Data, size_t Size) {
    static bool Initialized = DoInitialization();
    ...
}
```

Alternatively, you may define an optional init function and it will receive the program arguments that you can read and modify. Do this **only** if you really need to access `argv/argc`.

```
extern "C" int LLVMFuzzerInitialize(int *argc, char ***argv) {
    ReadAndMaybeModify(argc, argv);
    return 0;
}
```

Leaks

Binaries built with [AddressSanitizer](#) or [LeakSanitizer](#) will try to detect memory leaks at the process shutdown. For in-process fuzzing this is inconvenient since the fuzzer needs to report a leak with a reproducer as soon as the leaky mutation is found. However, running full leak detection after every mutation is expensive.

By default (`-detect_leaks=1`) libFuzzer will count the number of `malloc` and `free` calls when executing every mutation. If the numbers don't match (which by itself doesn't mean there is a leak) libFuzzer will invoke the more expensive [LeakSanitizer](#) pass and if the actual leak is found, it will be reported with the reproducer and the process will exit.

If your target has massive leaks and the leak detection is disabled you will eventually run out of RAM (see the `-rss_limit_mb` flag).

3.9.8 Developing libFuzzer

LibFuzzer is built as a part of LLVM project by default on macOS and Linux. Users of other operating systems can explicitly request compilation using `-DLIBFUZZER_ENABLE=YES` flag. Tests are run using `check-fuzzer` target from the build directory which was configured with `-DLIBFUZZER_ENABLE_TESTS=ON` flag.

```
ninja check-fuzzer
```

3.9.9 FAQ

Q. Why doesn't libFuzzer use any of the LLVM support?

There are two reasons.

First, we want this library to be used outside of the LLVM without users having to build the rest of LLVM. This may sound unconvincing for many LLVM folks, but in practice the need for building the whole LLVM frightens many potential users -- and we want more users to use this code.

Second, there is a subtle technical reason not to rely on the rest of LLVM, or any other large body of code (maybe not even STL). When coverage instrumentation is enabled, it will also instrument the LLVM support code which will blow up the coverage set of the process (since the fuzzer is in-process). In other words, by using more external dependencies we will slow down the fuzzer while the main reason for it to exist is extreme speed.

Q. Does libFuzzer Support Windows?

Yes, libFuzzer now supports Windows. Initial support was added in r341082. Any build of Clang 9 supports it. You can download a build of Clang for Windows that has libFuzzer from [LLVM Snapshot Builds](#).

Using libFuzzer on Windows without ASAN is unsupported. Building fuzzers with the `/MD` (dynamic runtime library) compile option is unsupported. Support for these may be added in the future. Linking fuzzers with the `/INCREMENTAL` link option (or the `/DEBUG` option which implies it) is also unsupported.

Send any questions or comments to the mailing list: [libfuzzer\(#\)googlegroups.com](mailto:libfuzzer@googlegroups.com)

Q. When libFuzzer is not a good solution for a problem?

- If the test inputs are validated by the target library and the validator asserts/crashes on invalid inputs, in-process fuzzing is not applicable.
- Bugs in the target library may accumulate without being detected. E.g. a memory corruption that goes undetected at first and then leads to a crash while testing another input. This is why it is highly recommended to run this in-process fuzzer with all sanitizers to detect most bugs on the spot.
- It is harder to protect the in-process fuzzer from excessive memory consumption and infinite loops in the target library (still possible).
- The target library should not have significant global state that is not reset between the runs.
- Many interesting target libraries are not designed in a way that supports the in-process fuzzer interface (e.g. require a file path instead of a byte array).
- If a single test run takes a considerable fraction of a second (or more) the speed benefit from the in-process fuzzer is negligible.
- If the target library runs persistent threads (that outlive execution of one test) the fuzzing results will be unreliable.

Q. So, what exactly this Fuzzer is good for?

This Fuzzer might be a good choice for testing libraries that have relatively small inputs, each input takes < 10ms to run, and the library code is not expected to crash on invalid inputs. Examples: regular expression matchers, text or binary format parsers, compression, network, crypto.

Q. LibFuzzer crashes on my complicated fuzz target (but works fine for me on smaller targets).

Check if your fuzz target uses `dlclose`. Currently, libFuzzer doesn't support targets that call `dlclose`, this may be fixed in future.

- *Utilities for Writing Fuzzers*

3.10.1 Introduction

The LLVM tree includes a number of fuzzers for various components. These are built on top of *LibFuzzer*. In order to build and run these fuzzers, see *Configuring LLVM to Build Fuzzers*.

3.10.2 Available Fuzzers

clang-fuzzer

A *generic fuzzer* that tries to compile textual input as C++ code. Some of the bugs this fuzzer has reported are on [bugzilla](#) and on [OSS Fuzz's tracker](#).

clang-proto-fuzzer

A *libprotobuf-mutator* based fuzzer that compiles valid C++ programs generated from a protobuf class that describes a subset of the C++ language.

This fuzzer accepts clang command line options after *ignore_remaining_args=1*. For example, the following command will fuzz clang with a higher optimization level:

```
% bin/clang-proto-fuzzer <corpus-dir> -ignore_remaining_args=1 -O3
```

clang-format-fuzzer

A *generic fuzzer* that runs `clang-format` on C++ text fragments. Some of the bugs this fuzzer has reported are [on bugzilla](#) and [on OSS Fuzz's tracker](#).

llvm-as-fuzzer

A *generic fuzzer* that tries to parse text as *LLVM assembly*. Some of the bugs this fuzzer has reported are [on bugzilla](#).

llvm-dwarfdump-fuzzer

A *generic fuzzer* that interprets inputs as object files and runs *llvm-dwarfdump* on them. Some of the bugs this fuzzer has reported are [on OSS Fuzz's tracker](#)

llvm-demangle-fuzzer

A *generic fuzzer* for the Itanium demangler used in various LLVM tools. We've fuzzed `__cxx_demangle` to death, why not fuzz LLVM's implementation of the same function!

llvm-isel-fuzzer

A *structured LLVM IR fuzzer* aimed at finding bugs in instruction selection.

This fuzzer accepts flags after *ignore_remaining_args=1*. The flags match those of *llc* and the triple is required. For example, the following command would fuzz AArch64 with *Global Instruction Selection*:

```
% bin/llvm-isel-fuzzer <corpus-dir> -ignore_remaining_args=1 -mtriple aarch64 -global-  
↪ isel -O0
```

Some flags can also be specified in the binary name itself in order to support OSS Fuzz, which has trouble with required arguments. To do this, you can copy or move `llvm-isel-fuzzer` to `llvm-isel-fuzzer--x-y-z`, separating options from the binary name using `--`. The valid options are architecture names (`aarch64`, `x86_64`), optimization levels (`O0`, `O2`), or specific keywords, like `gisel` for enabling global instruction selection. In this mode, the same example could be run like so:

```
% bin/llvm-isel-fuzzer--aarch64-O0-gisel <corpus-dir>
```

llvm-opt-fuzzer

A *structured LLVM IR fuzzer* aimed at finding bugs in optimization passes.

It receives optimization pipeline and runs it for each fuzzer input.

Interface of this fuzzer almost directly mirrors `llvm-isel-fuzzer`. Both `mtriple` and `passes` arguments are required. Passes are specified in a format suitable for the new pass manager. You can find some documentation about this format in the doxygen for `PassBuilder::parsePassPipeline`.

```
% bin/llvm-opt-fuzzer <corpus-dir> -ignore_remaining_args=1 -mtriple x86_64 -passes_  
↳ instcombine
```

Similarly to the `llvm-isel-fuzzer` arguments in some predefined configurations might be embedded directly into the binary file name:

```
% bin/llvm-opt-fuzzer--x86_64-instcombine <corpus-dir>
```

llvm-mc-assemble-fuzzer

A *generic fuzzer* that fuzzes the MC layer's assemblers by treating inputs as target specific assembly.

Note that this fuzzer has an unusual command line interface which is not fully compatible with all of libFuzzer's features. Fuzzer arguments must be passed after `--fuzzer-args`, and any `llc` flags must use two dashes. For example, to fuzz the AArch64 assembler you might use the following command:

```
llvm-mc-fuzzer --triple=aarch64-linux-gnu --fuzzer-args -max_len=4
```

This scheme will likely change in the future.

llvm-mc-disassemble-fuzzer

A *generic fuzzer* that fuzzes the MC layer's disassemblers by treating inputs as assembled binary data.

Note that this fuzzer has an unusual command line interface which is not fully compatible with all of libFuzzer's features. See the notes above about `llvm-mc-assemble-fuzzer` for details.

3.10.3 Mutators and Input Generators

The inputs for a fuzz target are generated via random mutations of a *corpus*. There are a few options for the kinds of mutations that a fuzzer in LLVM might want.

Generic Random Fuzzing

The most basic form of input mutation is to use the built in mutators of LibFuzzer. These simply treat the input corpus as a bag of bits and make random mutations. This type of fuzzer is good for stressing the surface layers of a program, and is good at testing things like lexers, parsers, or binary protocols.

Some of the in-tree fuzzers that use this type of mutator are *clang-fuzzer*, *clang-format-fuzzer*, *llvm-as-fuzzer*, *llvm-dwarfdump-fuzzer*, *llvm-mc-assemble-fuzzer*, and *llvm-mc-disassemble-fuzzer*.

Structured Fuzzing using `libprotobuf-mutator`

We can use `libprotobuf-mutator` in order to perform structured fuzzing and stress deeper layers of programs. This works by defining a protobuf class that translates arbitrary data into structurally interesting input. Specifically, we use this to work with a subset of the C++ language and perform mutations that produce valid C++ programs in order to exercise parts of clang that are more interesting than parser error handling.

To build this kind of fuzzer you need `protobuf` and its dependencies installed, and you need to specify some extra flags when configuring the build with `CMake`. For example, `clang-proto-fuzzer` can be enabled by adding `-DCLANG_ENABLE_PROTO_FUZZER=ON` to the flags described in *Configuring LLVM to Build Fuzzers*.

The only in-tree fuzzer that uses `libprotobuf-mutator` today is `clang-proto-fuzzer`.

Structured Fuzzing of LLVM IR

We also use a more direct form of structured fuzzing for fuzzers that take *LLVM IR* as input. This is achieved through the `FuzzMutate` library, which was discussed at EuroLLVM 2017.

The `FuzzMutate` library is used to structurally fuzz backends in `llvm-isel-fuzzer`.

3.10.4 Building and Running

Configuring LLVM to Build Fuzzers

Fuzzers will be built and linked to `libFuzzer` by default as long as you build LLVM with sanitizer coverage enabled. You would typically also enable at least one sanitizer to find bugs faster. The most common way to build the fuzzers is by adding the following two flags to your CMake invocation: `-DLLVM_USE_SANITIZER=Address` `-DLLVM_USE_SANITIZE_COVERAGE=On`.

Note: If you have `compiler-rt` checked out in an LLVM tree when building with sanitizers, you'll want to specify `-DLLVM_BUILD_RUNTIME=Off` to avoid building the sanitizers themselves with sanitizers enabled.

Note: You may run into issues if you build with BFD ld, which is the default linker on many unix systems. These issues are being tracked in <https://llvm.org/PR34636>.

Continuously Running and Finding Bugs

There used to be a public buildbot running LLVM fuzzers continuously, and while this did find issues, it didn't have a very good way to report problems in an actionable way. Because of this, we're moving towards using *OSS Fuzz* more instead.

You can browse the *LLVM project issue list* for the bugs found by LLVM on *OSS Fuzz*. These are also mailed to the *llvm-bugs mailing list*.

3.10.5 Utilities for Writing Fuzzers

There are some utilities available for writing fuzzers in LLVM.

Some helpers for handling the command line interface are available in `include/llvm/FuzzMutate/FuzzerCLI.h`, including functions to parse command line options in a consistent way and to implement standalone main functions so your fuzzer can be built and tested when not built against libFuzzer.

There is also some handling of the CMake config for fuzzers, where you should use the `add_llvm_fuzzer` to set up fuzzer targets. This function works similarly to functions such as `add_llvm_tool`, but they take care of linking to LibFuzzer when appropriate and can be passed the `DUMMY_MAIN` argument to enable standalone testing.

3.11 Scudo Hardened Allocator

- *Introduction*
- *Design*
- *Usage*
- *Error Types*

3.11.1 Introduction

The Scudo Hardened Allocator is a user-mode allocator based on LLVM Sanitizer's CombinedAllocator, which aims at providing additional mitigations against heap based vulnerabilities, while maintaining good performance.

Currently, the allocator supports (was tested on) the following architectures:

- i386 (& i686) (32-bit);
- x86_64 (64-bit);
- armhf (32-bit);
- AArch64 (64-bit);
- MIPS (32-bit & 64-bit).

The name "Scudo" has been retained from the initial implementation (Escudo meaning Shield in Spanish and Portuguese).

3.11.2 Design

Allocator

Scudo can be considered a Frontend to the Sanitizers' common allocator (later referenced as the Backend). It is split between a Primary allocator, fast and efficient, that services smaller allocation sizes, and a Secondary allocator that services larger allocation sizes and is backed by the operating system memory mapping primitives.

Scudo was designed with security in mind, but aims at striking a good balance between security and performance. It is highly tunable and configurable.

Chunk Header

Every chunk of heap memory will be preceded by a chunk header. This has two purposes, the first one being to store various information about the chunk, the second one being to detect potential heap overflows. In order to achieve this, the header will be checksummed, involving the pointer to the chunk itself and a global secret. Any corruption of the header will be detected when said header is accessed, and the process terminated.

The following information is stored in the header:

- the 16-bit checksum;
- the class ID for that chunk, which is the "bucket" where the chunk resides for Primary backed allocations, or 0 for Secondary backed allocations;
- the size (Primary) or unused bytes amount (Secondary) for that chunk, which is necessary for computing the size of the chunk;
- the state of the chunk (available, allocated or quarantined);
- the allocation type (malloc, new, new[] or memalign), to detect potential mismatches in the allocation APIs used;
- the offset of the chunk, which is the distance in bytes from the beginning of the returned chunk to the beginning of the Backend allocation;

This header fits within 8 bytes, on all platforms supported.

The checksum is computed as a CRC32 (made faster with hardware support) of the global secret, the chunk pointer itself, and the 8 bytes of header with the checksum field zeroed out. It is not intended to be cryptographically strong.

The header is atomically loaded and stored to prevent races. This is important as two consecutive chunks could belong to different threads. We also want to avoid any type of double fetches of information located in the header, and use local copies of the header for this purpose.

Delayed Freelist

A delayed freelist allows us to not return a chunk directly to the Backend, but to keep it aside for a while. Once a criterion is met, the delayed freelist is emptied, and the quarantined chunks are returned to the Backend. This helps mitigate use-after-free vulnerabilities by reducing the determinism of the allocation and deallocation patterns.

This feature is using the Sanitizer's Quarantine as its base, and the amount of memory that it can hold is configurable by the user (see the Options section below).

Randomness

It is important for the allocator to not make use of fixed addresses. We use the dynamic base option for the SizeClassAllocator, allowing us to benefit from the randomness of the system memory mapping functions.

3.11.3 Usage

Library

The allocator static library can be built from the LLVM build tree thanks to the `scudo` CMake rule. The associated tests can be exercised thanks to the `check-scudo` CMake rule.

Linking the static library to your project can require the use of the `whole-archive` linker flag (or equivalent), depending on your linker. Additional flags might also be necessary.

Your linked binary should now make use of the Scudo allocation and deallocation functions.

You may also build Scudo like this:

```
cd $LLVM/projects/compiler-rt/lib
clang++ -fPIC -std=c++11 -msse4.2 -O2 -I. scudo/*.cpp \
  $(\ls sanitizer_common/*.{cc,S} | grep -v "sanitizer_termination\|sanitizer_common_
  ↪nolibc\|sancov\|sanitizer_unwind\|sanitizer_symbol") \
  -shared -o libscudo.so -pthread
```

and then use it with existing binaries as follows:

```
LD_PRELOAD=`pwd`/libscudo.so ./a.out
```

Clang

With a recent version of Clang (post rL317337), the allocator can be linked with a binary at compilation using the `-fsanitize=scudo` command-line argument, if the target platform is supported. Currently, the only other Sanitizer Scudo is compatible with is UBSan (eg: `-fsanitize=scudo,undefined`). Compiling with Scudo will also enforce PIE for the output binary.

Options

Several aspects of the allocator can be configured on a per process basis through the following ways:

- at compile time, by defining `SCUDO_DEFAULT_OPTIONS` to the options string you want set by default;
- by defining a `__scudo_default_options` function in one's program that returns the options string to be parsed. Said function must have the following prototype: `extern "C" const char* __scudo_default_options(void)`, with a default visibility. This will override the compile time define;
- through the environment variable `SCUDO_OPTIONS`, containing the options string to be parsed. Options defined this way will override any definition made through `__scudo_default_options`.

The options string follows a syntax similar to ASan, where distinct options can be assigned in the same string, separated by colons.

For example, using the environment variable:

```
SCUDO_OPTIONS="DeleteSizeMismatch=1:QuarantineSizeKb=64" ./a.out
```

Or using the function:

```
extern "C" const char *__scudo_default_options() {
    return "DeleteSizeMismatch=1:QuarantineSizeKb=64";
}
```

The following options are available:

Option	64-bit default	32-bit default	Description
Quarantine-SizeKb	256	64	The size (in Kb) of quarantine used to delay the actual deallocation of chunks. Lower value may reduce memory usage but decrease the effectiveness of the mitigation; a negative value will fallback to the defaults. Setting <i>both</i> this and ThreadLocalQuarantine-SizeKb to zero will disable the quarantine entirely.
QuarantineChunksUp-ToSize	2048	512	Size (in bytes) up to which chunks can be quarantined.
Thread-LocalQuarantine-SizeKb	1024	256	The size (in Kb) of per-thread cache use to offload the global quarantine. Lower value may reduce memory usage but might increase contention on the global quarantine. Setting <i>both</i> this and QuarantineSizeKb to zero will disable the quarantine entirely.
Deallocation-TypeMismatch	true	true	Whether or not we report errors on malloc/delete, new/free, new/delete[], etc.
Delete-SizeMismatch	true	true	Whether or not we report errors on mismatch between sizes of new and delete.
Zero-Contents	false	false	Whether or not we zero chunk contents on allocation and deallocation.

Allocator related common Sanitizer options can also be passed through Scudo options, such as `allocator_may_return_null` or `abort_on_error`. A detailed list including those can be found here: <https://github.com/google/sanitizers/wiki/SanitizerCommonFlags>.

3.11.4 Error Types

The allocator will output an error message, and potentially terminate the process, when an unexpected behavior is detected. The output usually starts with "Scudo ERROR: " followed by a short summary of the problem that occurred as well as the pointer(s) involved. Once again, Scudo is meant to be a mitigation, and might not be the most useful of tools to help you root-cause the issue, please consider [ASan](#) for this purpose.

Here is a list of the current error messages and their potential cause:

- "corrupted chunk header": the checksum verification of the chunk header has failed. This is likely due to one of two things: the header was overwritten (partially or totally), or the pointer passed to the function is not a chunk at all;
- "race on chunk header": two different threads are attempting to manipulate the same header at the same time. This is usually symptomatic of a race-condition or general lack of locking when performing operations on that chunk;
- "invalid chunk state": the chunk is not in the expected state for a given operation, eg: it is not allocated when trying to free it, or it's not quarantined when trying to recycle it, etc. A double-free is the typical reason this error would occur;
- "misaligned pointer": we strongly enforce basic alignment requirements, 8 bytes on 32-bit platforms, 16 bytes on 64-bit platforms. If a pointer passed to our functions does not fit those, something is definitely

wrong.

- `"allocation type mismatch"`: when the optional deallocation type mismatch check is enabled, a deallocation function called on a chunk has to match the type of function that was called to allocate it. Security implications of such a mismatch are not necessarily obvious but situational at best;
- `"invalid sized delete"`: when the C++14 sized delete operator is used, and the optional check enabled, this indicates that the size passed when deallocating a chunk is not congruent with the one requested when allocating it. This is likely to be a [compiler issue](#), as was the case with Intel C++ Compiler, or some type confusion on the object being deallocated;
- `"RSS limit exhausted"`: the maximum RSS optionally specified has been exceeded;

Several other error messages relate to parameter checking on the libc allocation APIs and are fairly straightforward to understand.

3.12 Using `-opt-bisect-limit` to debug optimization errors

- *Introduction*
- *Getting Started*
- *Bisection Index Values*
- *Example Usage*
- *Pass Skipping Implementation*
- *Adding Finer Granularity*

3.12.1 Introduction

The `-opt-bisect-limit` option provides a way to disable all optimization passes above a specified limit without modifying the way in which the Pass Managers are populated. The intention of this option is to assist in tracking down problems where incorrect transformations during optimization result in incorrect run-time behavior.

This feature is implemented on an opt-in basis. Passes which can be safely skipped while still allowing correct code generation call a function to check the opt-bisect limit before performing optimizations. Passes which either must be run or do not modify the IR do not perform this check and are therefore never skipped. Generally, this means analysis passes, passes that are run at `CodeGenOpt::None` and passes which are required for register allocation.

The `-opt-bisect-limit` option can be used with any tool, including front ends such as clang, that uses the core LLVM library for optimization and code generation. The exact syntax for invoking the option is discussed below.

This feature is not intended to replace other debugging tools such as bugpoint. Rather it provides an alternate course of action when reproducing the problem requires a complex build infrastructure that would make using bugpoint impractical or when reproducing the failure requires a sequence of transformations that is difficult to replicate with tools like `opt` and `llc`.

3.12.2 Getting Started

The `-opt-bisect-limit` command line option can be passed directly to tools such as `opt`, `llc` and `lli`. The syntax is as follows:

```
<tool name> [other options] -opt-bisect-limit=<limit>
```

If a value of `-1` is used the tool will perform all optimizations but a message will be printed to `stderr` for each optimization that could be skipped indicating the index value that is associated with that optimization. To skip optimizations, pass the value of the last optimization to be performed as the `opt-bisect-limit`. All optimizations with a higher index value will be skipped.

In order to use the `-opt-bisect-limit` option with a driver that provides a wrapper around the LLVM core library, an additional prefix option may be required, as defined by the driver. For example, to use this option with `clang`, the `"-mllvm"` prefix must be used. A typical `clang` invocation would look like this:

```
clang -O2 -mllvm -opt-bisect-limit=256 my_file.c
```

The `-opt-bisect-limit` option may also be applied to link-time optimizations by using a prefix to indicate that this is a plug-in option for the linker. The following syntax will set a bisect limit for LTO transformations:

```
# When using lld, or ld64 (macOS)
clang -flto -Wl,-mllvm,-opt-bisect-limit=256 my_file.o my_other_file.o
# When using Gold
clang -flto -Wl,-plugin-opt,-opt-bisect-limit=256 my_file.o my_other_file.o
```

LTO passes are run by a library instance invoked by the linker. Therefore any passes run in the primary driver compilation phase are not affected by options passed via `'-Wl,-plugin-opt'` and LTO passes are not affected by options passed to the driver-invoked LLVM invocation via `'-mllvm'`.

3.12.3 Bisection Index Values

The granularity of the optimizations associated with a single index value is variable. Depending on how the optimization pass has been instrumented the value may be associated with as much as all transformations that would have been performed by an optimization pass on an IR unit for which it is invoked (for instance, during a single call of `runOnFunction` for a `FunctionPass`) or as little as a single transformation. The index values may also be nested so that if an invocation of the pass is not skipped individual transformations within that invocation may still be skipped.

The order of the values assigned is guaranteed to remain stable and consistent from one run to the next up to and including the value specified as the limit. Above the limit value skipping of optimizations can cause a change in the numbering, but because all optimizations above the limit are skipped this is not a problem.

When an `opt-bisect` index value refers to an entire invocation of the run function for a pass, the pass will query whether or not it should be skipped each time it is invoked and each invocation will be assigned a unique value. For example, if a `FunctionPass` is used with a module containing three functions a different index value will be assigned to the pass for each of the functions as the pass is run. The pass may be run on two functions but skipped for the third.

If the pass internally performs operations on a smaller IR unit the pass must be specifically instrumented to enable bisection at this finer level of granularity (see below for details).

3.12.4 Example Usage

```
$ opt -O2 -o test-opt.bc -opt-bisect-limit=16 test.ll

BISECT: running pass (1) Simplify the CFG on function (g)
BISECT: running pass (2) SROA on function (g)
BISECT: running pass (3) Early CSE on function (g)
BISECT: running pass (4) Infer set function attributes on module (test.ll)
BISECT: running pass (5) Interprocedural Sparse Conditional Constant Propagation on
↳module (test.ll)
BISECT: running pass (6) Global Variable Optimizer on module (test.ll)
BISECT: running pass (7) Promote Memory to Register on function (g)
BISECT: running pass (8) Dead Argument Elimination on module (test.ll)
BISECT: running pass (9) Combine redundant instructions on function (g)
BISECT: running pass (10) Simplify the CFG on function (g)
BISECT: running pass (11) Remove unused exception handling info on SCC (<<null
↳function>>)
BISECT: running pass (12) Function Integration/Inlining on SCC (<<null function>>)
BISECT: running pass (13) Deduce function attributes on SCC (<<null function>>)
BISECT: running pass (14) Remove unused exception handling info on SCC (f)
BISECT: running pass (15) Function Integration/Inlining on SCC (f)
BISECT: running pass (16) Deduce function attributes on SCC (f)
BISECT: NOT running pass (17) Remove unused exception handling info on SCC (g)
BISECT: NOT running pass (18) Function Integration/Inlining on SCC (g)
BISECT: NOT running pass (19) Deduce function attributes on SCC (g)
BISECT: NOT running pass (20) SROA on function (g)
BISECT: NOT running pass (21) Early CSE on function (g)
BISECT: NOT running pass (22) Speculatively execute instructions if target has
↳divergent branches on function (g)
... etc. ...
```

3.12.5 Pass Skipping Implementation

The `-opt-bisect-limit` implementation depends on individual passes opting in to the `opt-bisect` process. The `OptBisect` object that manages the process is entirely passive and has no knowledge of how any pass is implemented. When a pass is run if the pass may be skipped, it should call the `OptBisect` object to see if it should be skipped.

The `OptBisect` object is intended to be accessed through `LLVMContext` and each `Pass` base class contains a helper function that abstracts the details in order to make this check uniform across all passes. These helper functions are:

```
bool ModulePass::skipModule(Module &M);
bool CallGraphSCCPass::skipSCC(CallGraphSCC &SCC);
bool FunctionPass::skipFunction(const Function &F);
bool BasicBlockPass::skipBasicBlock(const BasicBlock &BB);
bool LoopPass::skipLoop(const Loop *L);
```

A `MachineFunctionPass` should use `FunctionPass::skipFunction()` as such:

```
bool MyMachineFunctionPass::runOnMachineFunction(Function &MF) {
    if (skipFunction(*MF.getFunction()))
        return false;
    // Otherwise, run the pass normally.
}
```

In addition to checking with the `OptBisect` class to see if the pass should be skipped, the `skipFunction()`, `skipLoop()` and `skipBasicBlock()` helper functions also look for the presence of the "optnone" function attribute. The calling

pass will be unable to determine whether it is being skipped because the "optnone" attribute is present or because the opt-bisect-limit has been reached. This is desirable because the behavior should be the same in either case.

The majority of LLVM passes which can be skipped have already been instrumented in the manner described above. If you are adding a new pass or believe you have found a pass which is not being included in the opt-bisect process but should be, you can add it as described above.

3.12.6 Adding Finer Granularity

Once the pass in which an incorrect transformation is performed has been determined, it may be useful to perform further analysis in order to determine which specific transformation is causing the problem. Debug counters can be used for this purpose.

4.1.1 Introduction

Alias Analysis (aka Pointer Analysis) is a class of techniques which attempt to determine whether or not two pointers ever can point to the same object in memory. There are many different algorithms for alias analysis and many different ways of classifying them: flow-sensitive vs. flow-insensitive, context-sensitive vs. context-insensitive, field-sensitive vs. field-insensitive, unification-based vs. subset-based, etc. Traditionally, alias analyses respond to a query with a *Must, May, or No* alias response, indicating that two pointers always point to the same object, might point to the same object, or are known to never point to the same object.

The LLVM `AliasAnalysis` class is the primary interface used by clients and implementations of alias analyses in the LLVM system. This class is the common interface between clients of alias analysis information and the implementations providing it, and is designed to support a wide range of implementations and clients (but currently all clients are assumed to be flow-insensitive). In addition to simple alias analysis information, this class exposes Mod/Ref information from those implementations which can provide it, allowing for powerful analyses and transformations to work well together.

This document contains information necessary to successfully implement this interface, use it, and to test both sides. It also explains some of the finer points about what exactly results mean.

4.1.2 AliasAnalysis Class Overview

The `AliasAnalysis` class defines the interface that the various alias analysis implementations should support. This class exports two important enums: `AliasResult` and `ModRefResult` which represent the result of an alias query or a mod/ref query, respectively.

The `AliasAnalysis` interface exposes information about memory, represented in several different ways. In particular, memory objects are represented as a starting address and size, and function calls are represented as the actual `call` or `invoke` instructions that performs the call. The `AliasAnalysis` interface also exposes some helper methods which allow you to get mod/ref information for arbitrary instructions.

All `AliasAnalysis` interfaces require that in queries involving multiple values, values which are not *constants* are all defined within the same function.

Representation of Pointers

Most importantly, the `AliasAnalysis` class provides several methods which are used to query whether or not two memory objects alias, whether function calls can modify or read a memory object, etc. For all of these queries, memory objects are represented as a pair of their starting address (a symbolic LLVM `Value*`) and a static size.

Representing memory objects as a starting address and a size is critically important for correct Alias Analyses. For example, consider this (silly, but possible) C code:

```
int i;
char C[2];
char A[10];
/* ... */
for (i = 0; i != 10; ++i) {
    C[0] = A[i];           /* One byte store */
    C[1] = A[9-i];        /* One byte store */
}
```

In this case, the `basicaa` pass will disambiguate the stores to `C[0]` and `C[1]` because they are accesses to two distinct locations one byte apart, and the accesses are each one byte. In this case, the Loop Invariant Code Motion (LICM) pass can use store motion to remove the stores from the loop. In contrast, the following code:

```
int i;
char C[2];
char A[10];
/* ... */
for (i = 0; i != 10; ++i) {
    ((short*)C)[0] = A[i]; /* Two byte store! */
    C[1] = A[9-i];        /* One byte store */
}
```

In this case, the two stores to `C` do alias each other, because the access to the `&C[0]` element is a two byte access. If size information wasn't available in the query, even the first case would have to conservatively assume that the accesses alias.

The `alias` method

The `alias` method is the primary interface used to determine whether or not two memory objects alias each other. It takes two memory objects as input and returns `MustAlias`, `PartialAlias`, `MayAlias`, or `NoAlias` as appropriate.

Like all `AliasAnalysis` interfaces, the `alias` method requires that either the two pointer values be defined within the same function, or at least one of the values is a *constant*.

Must, May, and No Alias Responses

The `NoAlias` response may be used when there is never an immediate dependence between any memory reference *based* on one pointer and any memory reference *based* the other. The most obvious example is when the two pointers point to non-overlapping memory ranges. Another is when the two pointers are only ever used for reading memory. Another is when the memory is freed and reallocated between accesses through one pointer and accesses through the other --- in this case, there is a dependence, but it's mediated by the free and reallocation.

As an exception to this is with the *noalias* keyword; the "irrelevant" dependencies are ignored.

The `MayAlias` response is used whenever the two pointers might refer to the same object.

The `PartialAlias` response is used when the two memory objects are known to be overlapping in some way, regardless whether they start at the same address or not.

The `MustAlias` response may only be returned if the two memory objects are guaranteed to always start at exactly the same location. A `MustAlias` response does not imply that the pointers compare equal.

The `getModRefInfo` methods

The `getModRefInfo` methods return information about whether the execution of an instruction can read or modify a memory location. Mod/Ref information is always conservative: if an instruction **might** read or write a location, `ModRef` is returned.

The `AliasAnalysis` class also provides a `getModRefInfo` method for testing dependencies between function calls. This method takes two call sites (`CS1` & `CS2`), returns `NoModRef` if neither call writes to memory read or written by the other, `Ref` if `CS1` reads memory written by `CS2`, `Mod` if `CS1` writes to memory read or written by `CS2`, or `ModRef` if `CS1` might read or write memory written to by `CS2`. Note that this relation is not commutative.

Other useful `AliasAnalysis` methods

Several other tidbits of information are often collected by various alias analysis implementations and can be put to good use by various clients.

The `pointsToConstantMemory` method

The `pointsToConstantMemory` method returns true if and only if the analysis can prove that the pointer only points to unchanging memory locations (functions, constant global variables, and the null pointer). This information can be used to refine mod/ref information: it is impossible for an unchanging memory location to be modified.

The `doesNotAccessMemory` and `onlyReadsMemory` methods

These methods are used to provide very simple mod/ref information for function calls. The `doesNotAccessMemory` method returns true for a function if the analysis can prove that the function never reads or writes to memory, or if the function only reads from constant memory. Functions with this property are side-effect free and only depend on their input arguments, allowing them to be eliminated if they form common subexpressions or be hoisted out of loops. Many common functions behave this way (e.g., `sin` and `cos`) but many others do not (e.g., `acos`, which modifies the `errno` variable).

The `onlyReadsMemory` method returns true for a function if analysis can prove that (at most) the function only reads from non-volatile memory. Functions with this property are side-effect free, only depending on their input arguments and the state of memory when they are called. This property allows calls to these functions to be eliminated and moved around, as long as there is no store instruction that changes the contents of memory. Note that all functions that satisfy the `doesNotAccessMemory` method also satisfy `onlyReadsMemory`.

4.1.3 Writing a new `AliasAnalysis` Implementation

Writing a new alias analysis implementation for LLVM is quite straight-forward. There are already several implementations that you can use for examples, and the following information should help fill in any details. For a examples, take a look at the *various alias analysis implementations* included with LLVM.

Different Pass styles

The first step to determining what type of *LLVM pass* you need to use for your Alias Analysis. As is the case with most other analyses and transformations, the answer should be fairly obvious from what type of problem you are trying to solve:

1. If you require interprocedural analysis, it should be a `Pass`.
2. If you are a function-local analysis, subclass `FunctionPass`.
3. If you don't need to look at the program at all, subclass `ImmutablePass`.

In addition to the pass that you subclass, you should also inherit from the `AliasAnalysis` interface, of course, and use the `RegisterAnalysisGroup` template to register as an implementation of `AliasAnalysis`.

Required initialization calls

Your subclass of `AliasAnalysis` is required to invoke two methods on the `AliasAnalysis` base class: `getAnalysisUsage` and `InitializeAliasAnalysis`. In particular, your implementation of `getAnalysisUsage` should explicitly call into the `AliasAnalysis::getAnalysisUsage` method in addition to doing any declaring any pass dependencies your pass has. Thus you should have something like this:

```
void getAnalysisUsage(AnalysisUsage &AU) const {
    AliasAnalysis::getAnalysisUsage(AU);
    // declare your dependencies here.
}
```

Additionally, you must invoke the `InitializeAliasAnalysis` method from your analysis run method (`run` for a `Pass`, `runOnFunction` for a `FunctionPass`, or `InitializePass` for an `ImmutablePass`). For example (as part of a `Pass`):

```
bool run(Module &M) {
    InitializeAliasAnalysis(this);
    // Perform analysis here...
    return false;
}
```

Required methods to override

You must override the `getAdjustedAnalysisPointer` method on all subclasses of `AliasAnalysis`. An example implementation of this method would look like:

```
void *getAdjustedAnalysisPointer(const void* ID) override {
    if (ID == &AliasAnalysis::ID)
        return (AliasAnalysis*)this;
    return this;
}
```

Interfaces which may be specified

All of the `AliasAnalysis` virtual methods default to providing *chaining* to another alias analysis implementation, which ends up returning conservatively correct information (returning "May" Alias and "Mod/Ref" for alias and mod/ref queries respectively). Depending on the capabilities of the analysis you are implementing, you just override the interfaces you can improve.

AliasAnalysis chaining behavior

With only one special exception (the `-no-aa` pass) every alias analysis pass chains to another alias analysis implementation (for example, the user can specify `"-basicaa -ds-aa -licm"` to get the maximum benefit from both alias analyses). The alias analysis class automatically takes care of most of this for methods that you don't override. For methods that you do override, in code paths that return a conservative MayAlias or Mod/Ref result, simply return whatever the superclass computes. For example:

```
AliasResult alias(const Value *V1, unsigned V1Size,
                  const Value *V2, unsigned V2Size) {
    if (...)
        return NoAlias;
    ...

    // Couldn't determine a must or no-alias result.
    return AliasAnalysis::alias(V1, V1Size, V2, V2Size);
}
```

In addition to analysis queries, you must make sure to unconditionally pass LLVM *update notification* methods to the superclass as well if you override them, which allows all alias analyses in a change to be updated.

Updating analysis results for transformations

Alias analysis information is initially computed for a static snapshot of the program, but clients will use this information to make transformations to the code. All but the most trivial forms of alias analysis will need to have their analysis results updated to reflect the changes made by these transformations.

The `AliasAnalysis` interface exposes four methods which are used to communicate program changes from the clients to the analysis implementations. Various alias analysis implementations should use these methods to ensure that their internal data structures are kept up-to-date as the program changes (for example, when an instruction is deleted), and clients of alias analysis must be sure to call these interfaces appropriately.

The `deleteValue` method

The `deleteValue` method is called by transformations when they remove an instruction or any other value from the program (including values that do not use pointers). Typically alias analyses keep data structures that have entries for each value in the program. When this method is called, they should remove any entries for the specified value, if they exist.

The `copyValue` method

The `copyValue` method is used when a new value is introduced into the program. There is no way to introduce a value into the program that did not exist before (this doesn't make sense for a safe compiler transformation), so this is the only way to introduce a new value. This method indicates that the new value has exactly the same properties as the value being copied.

The `replaceWithNewValue` method

This method is a simple helper method that is provided to make clients easier to use. It is implemented by copying the old analysis information to the new value, then deleting the old value. This method cannot be overridden by alias analysis implementations.

The `addEscapingUse` method

The `addEscapingUse` method is used when the uses of a pointer value have changed in ways that may invalidate precomputed analysis information. Implementations may either use this callback to provide conservative responses for points whose uses have change since analysis time, or may recompute some or all of their internal state to continue providing accurate responses.

In general, any new use of a pointer value is considered an escaping use, and must be reported through this callback, *except* for the uses below:

- A `bitcast` or `getelementptr` of the pointer
- A `store` through the pointer (but not a `store of` the pointer)
- A `load` through the pointer

Efficiency Issues

From the LLVM perspective, the only thing you need to do to provide an efficient alias analysis is to make sure that alias analysis **queries** are serviced quickly. The actual calculation of the alias analysis results (the "run" method) is only performed once, but many (perhaps duplicate) queries may be performed. Because of this, try to move as much computation to the run method as possible (within reason).

Limitations

The AliasAnalysis infrastructure has several limitations which make writing a new AliasAnalysis implementation difficult.

There is no way to override the default alias analysis. It would be very useful to be able to do something like "opt -my-aa -O2" and have it use -my-aa for all passes which need AliasAnalysis, but there is currently no support for that, short of changing the source code and recompiling. Similarly, there is also no way of setting a chain of analyses as the default.

There is no way for transform passes to declare that they preserve AliasAnalysis implementations. The AliasAnalysis interface includes deleteValue and copyValue methods which are intended to allow a pass to keep an AliasAnalysis consistent, however there's no way for a pass to declare in its getAnalysisUsage that it does so. Some passes attempt to use AU.addPreserved<AliasAnalysis>, however this doesn't actually have any effect.

Similarly, the opt -p option introduces ModulePass passes between each pass, which prevents the use of FunctionPass alias analysis passes.

The AliasAnalysis API does have functions for notifying implementations when values are deleted or copied, however these aren't sufficient. There are many other ways that LLVM IR can be modified which could be relevant to AliasAnalysis implementations which can not be expressed.

The AliasAnalysisDebugger utility seems to suggest that AliasAnalysis implementations can expect that they will be informed of any relevant Value before it appears in an alias query. However, popular clients such as GVN don't support this, and are known to trigger errors when run with the AliasAnalysisDebugger.

The AliasSetTracker class (which is used by LICM) makes a non-deterministic number of alias queries. This can cause debugging techniques involving pausing execution after a predetermined number of queries to be unreliable.

Many alias queries can be reformulated in terms of other alias queries. When multiple AliasAnalysis queries are chained together, it would make sense to start those queries from the beginning of the chain, with care taken to avoid infinite looping, however currently an implementation which wants to do this can only start such queries from itself.

4.1.4 Using alias analysis results

There are several different ways to use alias analysis results. In order of preference, these are:

Using the MemoryDependenceAnalysis Pass

The memdep pass uses alias analysis to provide high-level dependence information about memory-using instructions. This will tell you which store feeds into a load, for example. It uses caching and other techniques to be efficient, and is used by Dead Store Elimination, GVN, and memcpy optimizations.

Using the `AliasSetTracker` class

Many transformations need information about alias **sets** that are active in some scope, rather than information about pairwise aliasing. The `AliasSetTracker` class is used to efficiently build these Alias Sets from the pairwise alias analysis information provided by the `AliasAnalysis` interface.

First you initialize the `AliasSetTracker` by using the "add" methods to add information about various potentially aliasing instructions in the scope you are interested in. Once all of the alias sets are completed, your pass should simply iterate through the constructed alias sets, using the `AliasSetTracker begin()/end()` methods.

The `AliasSets` formed by the `AliasSetTracker` are guaranteed to be disjoint, calculate mod/ref information and volatility for the set, and keep track of whether or not all of the pointers in the set are **Must** aliases. The `AliasSetTracker` also makes sure that sets are properly folded due to call instructions, and can provide a list of pointers in each set.

As an example user of this, the `Loop Invariant Code Motion` pass uses `AliasSetTrackers` to calculate alias sets for each loop nest. If an `AliasSet` in a loop is not modified, then all load instructions from that set may be hoisted out of the loop. If any alias sets are stored to **and** are **must** alias sets, then the stores may be sunk to outside of the loop, promoting the memory location to a register for the duration of the loop nest. Both of these transformations only apply if the pointer argument is loop-invariant.

The `AliasSetTracker` implementation

The `AliasSetTracker` class is implemented to be as efficient as possible. It uses the union-find algorithm to efficiently merge `AliasSets` when a pointer is inserted into the `AliasSetTracker` that aliases multiple sets. The primary data structure is a hash table mapping pointers to the `AliasSet` they are in.

The `AliasSetTracker` class must maintain a list of all of the LLVM `Value*s` that are in each `AliasSet`. Since the hash table already has entries for each LLVM `Value*` of interest, the `AliasesSets` thread the linked list through these hash-table nodes to avoid having to allocate memory unnecessarily, and to make merging alias sets extremely efficient (the linked list merge is constant time).

You shouldn't need to understand these details if you are just a client of the `AliasSetTracker`, but if you look at the code, hopefully this brief description will help make sense of why things are designed the way they are.

Using the `AliasAnalysis` interface directly

If neither of these utility class are what your pass needs, you should use the interfaces exposed by the `AliasAnalysis` class directly. Try to use the higher-level methods when possible (e.g., use mod/ref information instead of the `alias` method directly if possible) to get the best precision and efficiency.

4.1.5 Existing alias analysis implementations and clients

If you're going to be working with the LLVM alias analysis infrastructure, you should know what clients and implementations of alias analysis are available. In particular, if you are implementing an alias analysis, you should be aware of the *the clients* that are useful for monitoring and evaluating different implementations.

Available `AliasAnalysis` implementations

This section lists the various implementations of the `AliasAnalysis` interface. With the exception of the `-no-aa` implementation, all of these *chain* to other alias analysis implementations.

The `-no-aa` pass

The `-no-aa` pass is just like what it sounds: an alias analysis that never returns any useful information. This pass can be useful if you think that alias analysis is doing something wrong and are trying to narrow down a problem.

The `-basicaa` pass

The `-basicaa` pass is an aggressive local analysis that *knows* many important facts:

- Distinct globals, stack allocations, and heap allocations can never alias.
- Globals, stack allocations, and heap allocations never alias the null pointer.
- Different fields of a structure do not alias.
- Indexes into arrays with statically differing subscripts cannot alias.
- Many common standard C library functions *never access memory or only read memory*.
- Pointers that obviously point to constant globals "pointToConstantMemory".
- Function calls can not modify or references stack allocations if they never escape from the function that allocates them (a common case for automatic arrays).

The `-globalsmodref-aa` pass

This pass implements a simple context-sensitive mod/ref and alias analysis for internal global variables that don't "have their address taken". If a global does not have its address taken, the pass knows that no pointers alias the global. This pass also keeps track of functions that it knows never access memory or never read memory. This allows certain optimizations (e.g. GVN) to eliminate call instructions entirely.

The real power of this pass is that it provides context-sensitive mod/ref information for call instructions. This allows the optimizer to know that calls to a function do not clobber or read the value of the global, allowing loads and stores to be eliminated.

Note: This pass is somewhat limited in its scope (only support non-address taken globals), but is very quick analysis.

The `-steens-aa` pass

The `-steens-aa` pass implements a variation on the well-known "Steensgaard's algorithm" for interprocedural alias analysis. Steensgaard's algorithm is a unification-based, flow-insensitive, context-insensitive, and field-insensitive alias analysis that is also very scalable (effectively linear time).

The LLVM `-steens-aa` pass implements a "speculatively field-**sensitive**" version of Steensgaard's algorithm using the Data Structure Analysis framework. This gives it substantially more precision than the standard algorithm while maintaining excellent analysis scalability.

Note: `-steens-aa` is available in the optional "poolalloc" module. It is not part of the LLVM core.

The `-ds-aa` pass

The `-ds-aa` pass implements the full Data Structure Analysis algorithm. Data Structure Analysis is a modular unification-based, flow-insensitive, context-**sensitive**, and speculatively field-**sensitive** alias analysis that is also quite scalable, usually at $O(n * \log(n))$.

This algorithm is capable of responding to a full variety of alias analysis queries, and can provide context-sensitive mod/ref information as well. The only major facility not implemented so far is support for must-alias information.

Note: `-ds-aa` is available in the optional "poolalloc" module. It is not part of the LLVM core.

The `-scev-aa` pass

The `-scev-aa` pass implements AliasAnalysis queries by translating them into ScalarEvolution queries. This gives it a more complete understanding of `getelementptr` instructions and loop induction variables than other alias analyses have.

Alias analysis driven transformations

LLVM includes several alias-analysis driven transformations which can be used with any of the implementations above.

The `-adce` pass

The `-adce` pass, which implements Aggressive Dead Code Elimination uses the `AliasAnalysis` interface to delete calls to functions that do not have side-effects and are not used.

The `-licm` pass

The `-licm` pass implements various Loop Invariant Code Motion related transformations. It uses the `AliasAnalysis` interface for several different transformations:

- It uses mod/ref information to hoist or sink load instructions out of loops if there are no instructions in the loop that modifies the memory loaded.
- It uses mod/ref information to hoist function calls out of loops that do not write to memory and are loop-invariant.
- It uses alias information to promote memory objects that are loaded and stored to in loops to live in a register instead. It can do this if there are no may aliases to the loaded/stored memory location.

The `-argpromotion` pass

The `-argpromotion` pass promotes by-reference arguments to be passed in by-value instead. In particular, if pointer arguments are only loaded from it passes in the value loaded instead of the address to the function. This pass uses alias information to make sure that the value loaded from the argument pointer is not modified between the entry of the function and any load of the pointer.

The `-gvn`, `-memcpropt`, and `-dse` passes

These passes use AliasAnalysis information to reason about loads and stores.

Clients for debugging and evaluation of implementations

These passes are useful for evaluating the various alias analysis implementations. You can use them with commands like:

```
% opt -ds-aa -aa-eval foo.bc -disable-output -stats
```

The `-print-alias-sets` pass

The `-print-alias-sets` pass is exposed as part of the `opt` tool to print out the Alias Sets formed by the *AliasSetTracker* class. This is useful if you're using the *AliasSetTracker* class. To use it, use something like:

```
% opt -ds-aa -print-alias-sets -disable-output
```

The `-aa-eval` pass

The `-aa-eval` pass simply iterates through all pairs of pointers in a function and asks an alias analysis whether or not the pointers alias. This gives an indication of the precision of the alias analysis. Statistics are printed indicating the percent of no/may/must aliases found (a more precise algorithm will have a lower number of may aliases).

4.1.6 Memory Dependence Analysis

Note: We are currently in the process of migrating things from *MemoryDependenceAnalysis* to *MemorySSA*. Please try to use that instead.

If you're just looking to be a client of alias analysis information, consider using the Memory Dependence Analysis interface instead. MemDep is a lazy, caching layer on top of alias analysis that is able to answer the question of what preceding memory operations a given instruction depends on, either at an intra- or inter-block level. Because of its laziness and caching policy, using MemDep can be a significant performance win over accessing alias analysis directly.

4.2 MemorySSA

- *Introduction*
- *MemorySSA Structure*

 - * *Use Optimization*

4.2.1 Introduction

MemorySSA is an analysis that allows us to cheaply reason about the interactions between various memory operations. Its goal is to replace MemoryDependenceAnalysis for most (if not all) use-cases. This is because, unless you're very careful, use of MemoryDependenceAnalysis can easily result in quadratic-time algorithms in LLVM. Additionally, MemorySSA doesn't have as many arbitrary limits as MemoryDependenceAnalysis, so you should get better results, too.

At a high level, one of the goals of MemorySSA is to provide an SSA based form for memory, complete with def-use and use-def chains, which enables users to quickly find may-def and may-uses of memory operations. It can also be thought of as a way to cheaply give versions to the complete state of heap memory, and associate memory operations with those versions.

This document goes over how MemorySSA is structured, and some basic intuition on how MemorySSA works.

A paper on MemorySSA (with notes about how it's implemented in GCC) [can be found here](#). Though, it's relatively out-of-date; the paper references multiple heap partitions, but GCC eventually swapped to just using one, like we now have in LLVM. Like GCC's, LLVM's MemorySSA is intraprocedural.

4.2.2 MemorySSA Structure

MemorySSA is a virtual IR. After it's built, MemorySSA will contain a structure that maps Instructions to MemoryAccesses, which are MemorySSA's parallel to LLVM Instructions.

Each MemoryAccess can be one of three types:

- MemoryPhi
- MemoryUse
- MemoryDef

MemoryPhis are PhiNodes, but for memory operations. If at any point we have two (or more) MemoryDefs that could flow into a BasicBlock, the block's top MemoryAccess will be a MemoryPhi. As in LLVM IR, MemoryPhis don't correspond to any concrete operation. As such, BasicBlocks are mapped to MemoryPhis inside MemorySSA, whereas Instructions are mapped to MemoryUses and MemoryDefs.

Note also that in SSA, Phi nodes merge must-reach definitions (that is, definitions that *must* be new versions of variables). In MemorySSA, PHI nodes merge may-reach definitions (that is, until disambiguated, the versions that reach a phi node may or may not clobber a given variable).

MemoryUses are operations which use but don't modify memory. An example of a MemoryUse is a load, or a readonly function call.

MemoryDefs are operations which may either modify memory, or which introduce some kind of ordering constraints. Examples of MemoryDefs include stores, function calls, loads with acquire (or higher) ordering, volatile operations, memory fences, etc.

Every function that exists has a special MemoryDef called liveOnEntry. It dominates every MemoryAccess in the function that MemorySSA is being run on, and implies that we've hit the top of the function. It's the only MemoryDef that maps to no Instruction in LLVM IR. Use of liveOnEntry implies that the memory being used is either undefined or defined before the function begins.

An example of all of this overlaid on LLVM IR (obtained by running `opt -passes='print<memoryssa>' -disable-output` on an `.ll` file) is below. When viewing this example, it may be helpful to view it in terms of clobbers. The operands of a given MemoryAccess are all (potential) clobbers of said MemoryAccess, and the value produced by a MemoryAccess can act as a clobber for other MemoryAccesses. Another useful way of looking at it is in terms of heap versions. In that view, operands of a given MemoryAccess are the version of the heap before the operation, and if the access produces a value, the value is the new version of the heap after the operation.

```
define void @foo() {
entry:
    %p1 = alloca i8
    %p2 = alloca i8
    %p3 = alloca i8
    ; 1 = MemoryDef(liveOnEntry)
    store i8 0, i8* %p3
    br label %while.cond

while.cond:
    ; 6 = MemoryPhi({%0,1},{if.end,4})
    br i1 undef, label %if.then, label %if.else

if.then:
    ; 2 = MemoryDef(6)
    store i8 0, i8* %p1
    br label %if.end

if.else:
    ; 3 = MemoryDef(6)
    store i8 1, i8* %p2
    br label %if.end

if.end:
    ; 5 = MemoryPhi({if.then,2},{if.else,3})
    ; MemoryUse(5)
    %1 = load i8, i8* %p1
    ; 4 = MemoryDef(5)
    store i8 2, i8* %p2
    ; MemoryUse(1)
```

(continues on next page)

(continued from previous page)

```

%2 = load i8, i8* %p3
br label %while.cond
}

```

The MemorySSA IR is shown in comments that precede the instructions they map to (if such an instruction exists). For example, `1 = MemoryDef(liveOnEntry)` is a `MemoryAccess` (specifically, a `MemoryDef`), and it describes the LLVM instruction `store i8 0, i8* %p3`. Other places in MemorySSA refer to this particular `MemoryDef` as `1` (much like how one can refer to `load i8, i8* %p1` in LLVM with `%1`). Again, `MemoryPhi`s don't correspond to any LLVM Instruction, so the line directly below a `MemoryPhi` isn't special.

Going from the top down:

- `6 = MemoryPhi({entry, 1}, {if.end, 4})` notes that, when entering `while.cond`, the reaching definition for it is either `1` or `4`. This `MemoryPhi` is referred to in the textual IR by the number `6`.
- `2 = MemoryDef(6)` notes that `store i8 0, i8* %p1` is a definition, and its reaching definition before it is `6`, or the `MemoryPhi` after `while.cond`. (See the [Build-time use optimization](#) and [Precision](#) sections below for why this `MemoryDef` isn't linked to a separate, disambiguated `MemoryPhi`.)
- `3 = MemoryDef(6)` notes that `store i8 0, i8* %p2` is a definition; its reaching definition is also `6`.
- `5 = MemoryPhi({if.then, 2}, {if.else, 3})` notes that the clobber before this block could either be `2` or `3`.
- `MemoryUse(5)` notes that `load i8, i8* %p1` is a use of memory, and that it's clobbered by `5`.
- `4 = MemoryDef(5)` notes that `store i8 2, i8* %p2` is a definition; its reaching definition is `5`.
- `MemoryUse(1)` notes that `load i8, i8* %p3` is just a user of memory, and the last thing that could clobber this use is above `while.cond` (e.g. the store to `%p3`). In heap versioning parlance, it really only depends on the heap version `1`, and is unaffected by the new heap versions generated since then.

As an aside, `MemoryAccess` is a `Value` mostly for convenience; it's not meant to interact with LLVM IR.

4.2.3 Design of MemorySSA

MemorySSA is an analysis that can be built for any arbitrary function. When it's built, it does a pass over the function's IR in order to build up its mapping of `MemoryAccesses`. You can then query MemorySSA for things like the dominance relation between `MemoryAccesses`, and get the `MemoryAccess` for any given `Instruction`.

When MemorySSA is done building, it also hands you a `MemorySSAWalker` that you can use (see below).

The walker

A structure that helps MemorySSA do its job is the `MemorySSAWalker`, or the *walker*, for short. The goal of the walker is to provide answers to clobber queries beyond what's represented directly by `MemoryAccesses`. For example, given:

```

define void @foo() {
  %a = alloca i8
  %b = alloca i8

  ; 1 = MemoryDef(liveOnEntry)
  store i8 0, i8* %a
  ; 2 = MemoryDef(1)
  store i8 0, i8* %b
}

```

The store to %a is clearly not a clobber for the store to %b. It would be the walker's goal to figure this out, and return `liveOnEntry` when queried for the clobber of `MemoryAccess 2`.

By default, `MemorySSA` provides a walker that can optimize `MemoryDefs` and `MemoryUses` by consulting whatever alias analysis stack you happen to be using. Walkers were built to be flexible, though, so it's entirely reasonable (and expected) to create more specialized walkers (e.g. one that specifically queries `GlobalsAA`, one that always stops at `MemoryPhi` nodes, etc).

Locating clobbers yourself

If you choose to make your own walker, you can find the clobber for a `MemoryAccess` by walking every `MemoryDef` that dominates said `MemoryAccess`. The structure of `MemoryDefs` makes this relatively simple; they ultimately form a linked list of every clobber that dominates the `MemoryAccess` that you're trying to optimize. In other words, the `definingAccess` of a `MemoryDef` is always the nearest dominating `MemoryDef` or `MemoryPhi` of said `MemoryDef`.

Build-time use optimization

`MemorySSA` will optimize some `MemoryAccesses` at build-time. Specifically, we optimize the operand of every `MemoryUse` to point to the actual clobber of said `MemoryUse`. This can be seen in the above example; the second `MemoryUse` in `if.end` has an operand of 1, which is a `MemoryDef` from the entry block. This is done to make walking, value numbering, etc, faster and easier.

It is not possible to optimize `MemoryDef` in the same way, as we restrict `MemorySSA` to one heap variable and, thus, one `Phi` node per block.

Invalidation and updating

Because `MemorySSA` keeps track of LLVM IR, it needs to be updated whenever the IR is updated. "Update", in this case, includes the addition, deletion, and motion of `Instructions`. The update API is being made on an as-needed basis. If you'd like examples, `GVNHoist` is a user of `MemorySSAs` update API.

Phi placement

`MemorySSA` only places `MemoryPhis` where they're actually needed. That is, it is a pruned SSA form, like LLVM's SSA form. For example, consider:

```
define void @foo() {
entry:
    %p1 = alloca i8
    %p2 = alloca i8
    %p3 = alloca i8
    ; 1 = MemoryDef(liveOnEntry)
    store i8 0, i8* %p3
    br label %while.cond

while.cond:
    ; 3 = MemoryPhi({%0,1},{if.end,2})
    br i1 undef, label %if.then, label %if.else

if.then:
    br label %if.end
```

(continues on next page)

(continued from previous page)

```

if.else:
    br label %if.end

if.end:
    ; MemoryUse(1)
    %1 = load i8, i8* %p1
    ; 2 = MemoryDef(3)
    store i8 2, i8* %p2
    ; MemoryUse(1)
    %2 = load i8, i8* %p3
    br label %while.cond
}

```

Because we removed the stores from `if.then` and `if.else`, a `MemoryPhi` for `if.end` would be pointless, so we don't place one. So, if you need to place a `MemoryDef` in `if.then` or `if.else`, you'll need to also create a `MemoryPhi` for `if.end`.

If it turns out that this is a large burden, we can just place `MemoryPhis` everywhere. Because we have Walkers that are capable of optimizing above said phis, doing so shouldn't prohibit optimizations.

Non-Goals

`MemorySSA` is meant to reason about the relation between memory operations, and enable quicker querying. It isn't meant to be the single source of truth for all potential memory-related optimizations. Specifically, care must be taken when trying to use `MemorySSA` to reason about atomic or volatile operations, as in:

```

define i8 @foo(i8* %a) {
entry:
    br i1 undef, label %if.then, label %if.end

if.then:
    ; 1 = MemoryDef(liveOnEntry)
    %0 = load volatile i8, i8* %a
    br label %if.end

if.end:
    %av = phi i8 [0, %entry], [%0, %if.then]
    ret i8 %av
}

```

Going solely by `MemorySSA`'s analysis, hoisting the `load` to `entry` may seem legal. Because it's a volatile load, though, it's not.

Design tradeoffs

Precision

`MemorySSA` in LLVM deliberately trades off precision for speed. Let us think about memory variables as if they were disjoint partitions of the heap (that is, if you have one variable, as above, it represents the entire heap, and if you have multiple variables, each one represents some disjoint portion of the heap)

First, because alias analysis results conflict with each other, and each result may be what an analysis wants (IE TBAA may say no-alias, and something else may say must-alias), it is not possible to partition the heap the way every

optimization wants. Second, some alias analysis results are not transitive (IE A noalias B, and B noalias C, does not mean A noalias C), so it is not possible to come up with a precise partitioning in all cases without variables to represent every pair of possible aliases. Thus, partitioning precisely may require introducing at least N^2 new virtual variables, phi nodes, etc.

Each of these variables may be clobbered at multiple def sites.

To give an example, if you were to split up struct fields into individual variables, all aliasing operations that may-def multiple struct fields, will may-def more than one of them. This is pretty common (calls, copies, field stores, etc).

Experience with SSA forms for memory in other compilers has shown that it is simply not possible to do this precisely, and in fact, doing it precisely is not worth it, because now all the optimizations have to walk tons and tons of virtual variables and phi nodes.

So we partition. At the point at which you partition, again, experience has shown us there is no point in partitioning to more than one variable. It simply generates more IR, and optimizations still have to query something to disambiguate further anyway.

As a result, LLVM partitions to one variable.

Use Optimization

Unlike other partitioned forms, LLVM's `MemorySSA` does make one useful guarantee - all loads are optimized to point at the thing that actually clobbers them. This gives some nice properties. For example, for a given store, you can find all loads actually clobbered by that store by walking the immediate uses of the store.

4.3.1 Abstract

This document describes the LLVM bitstream file format and the encoding of the LLVM IR into it.

4.3.2 Overview

What is commonly known as the LLVM bitcode file format (also, sometimes anachronistically known as bytecode) is actually two things: a *bitstream container format* and an *encoding of LLVM IR* into the container format.

The bitstream format is an abstract encoding of structured data, very similar to XML in some ways. Like XML, bitstream files contain tags, and nested structures, and you can parse the file without having to understand the tags. Unlike XML, the bitstream format is a binary encoding, and unlike XML it provides a mechanism for the file to self-describe "abbreviations", which are effectively size optimizations for the content.

LLVM IR files may be optionally embedded into a *wrapper* structure, or in a *native object file*. Both of these mechanisms make it easy to embed extra data along with LLVM IR files.

This document first describes the LLVM bitstream format, describes the wrapper format, then describes the record structure used by LLVM IR files.

4.3.3 Bitstream Format

The bitstream format is literally a stream of bits, with a very simple structure. This structure consists of the following concepts:

- A "*magic number*" that identifies the contents of the stream.
- Encoding *primitives* like variable bit-rate integers.
- *Blocks*, which define nested content.
- *Data Records*, which describe entities within the file.
- Abbreviations, which specify compression optimizations for the file.

Note that the *llvm-bcanalyzer* tool can be used to dump and inspect arbitrary bitstreams, which is very useful for understanding the encoding.

Magic Numbers

The first four bytes of a bitstream are used as an application-specific magic number. Generic bitcode tools may look at the first four bytes to determine whether the stream is a known stream type. However, these tools should *not* determine whether a bitstream is valid based on its magic number alone. New application-specific bitstream formats are being developed all the time; tools should not reject them just because they have a hitherto unseen magic number.

Primitives

A bitstream literally consists of a stream of bits, which are read in order starting with the least significant bit of each byte. The stream is made up of a number of primitive values that encode a stream of unsigned integer values. These integers are encoded in two ways: either as *Fixed Width Integers* or as *Variable Width Integers*.

Fixed Width Integers

Fixed-width integer values have their low bits emitted directly to the file. For example, a 3-bit integer value encodes 1 as 001. Fixed width integers are used when there are a well-known number of options for a field. For example, boolean values are usually encoded with a 1-bit wide integer.

Variable Width Integers

Variable-width integer (VBR) values encode values of arbitrary size, optimizing for the case where the values are small. Given a 4-bit VBR field, any 3-bit value (0 through 7) is encoded directly, with the high bit set to zero. Values larger than N-1 bits emit their bits in a series of N-1 bit chunks, where all but the last set the high bit.

For example, the value 27 (0x1B) is encoded as 1011 0011 when emitted as a vbr4 value. The first set of four bits indicates the value 3 (011) with a continuation piece (indicated by a high bit of 1). The next word indicates a value of 24 (011 << 3) with no continuation. The sum (3+24) yields the value 27.

6-bit characters

6-bit characters encode common characters into a fixed 6-bit field. They represent the following characters with the following 6-bit values:

'a'	..	'z'	---	0	..	25
'A'	..	'Z'	---	26	..	51
'0'	..	'9'	---	52	..	61
		'.'	---	62		
		'_'	---	63		

This encoding is only suitable for encoding characters and strings that consist only of the above characters. It is completely incapable of encoding characters not in the set.

Word Alignment

Occasionally, it is useful to emit zero bits until the bitstream is a multiple of 32 bits. This ensures that the bit position in the stream can be represented as a multiple of 32-bit words.

Abbreviation IDs

A bitstream is a sequential series of *Blocks* and *Data Records*. Both of these start with an abbreviation ID encoded as a fixed-bitwidth field. The width is specified by the current block, as described below. The value of the abbreviation ID specifies either a builtin ID (which have special meanings, defined below) or one of the abbreviation IDs defined for the current block by the stream itself.

The set of builtin abbrev IDs is:

- 0 - *END_BLOCK* --- This abbrev ID marks the end of the current block.
- 1 - *ENTER_SUBBLOCK* --- This abbrev ID marks the beginning of a new block.
- 2 - *DEFINE_ABBREV* --- This defines a new abbreviation.
- 3 - *UNABBREV_RECORD* --- This ID specifies the definition of an unabbreviated record.

Abbreviation IDs 4 and above are defined by the stream itself, and specify an *abbreviated record encoding*.

Blocks

Blocks in a bitstream denote nested regions of the stream, and are identified by a content-specific id number (for example, LLVM IR uses an ID of 12 to represent function bodies). Block IDs 0-7 are reserved for *standard blocks* whose meaning is defined by Bitcode; block IDs 8 and greater are application specific. Nested blocks capture the hierarchical structure of the data encoded in it, and various properties are associated with blocks as the file is parsed. Block definitions allow the reader to efficiently skip blocks in constant time if the reader wants a summary of blocks, or if it wants to efficiently skip data it does not understand. The LLVM IR reader uses this mechanism to skip function bodies, lazily reading them on demand.

When reading and encoding the stream, several properties are maintained for the block. In particular, each block maintains:

1. A current abbrev id width. This value starts at 2 at the beginning of the stream, and is set every time a block record is entered. The block entry specifies the abbrev id width for the body of the block.
2. A set of abbreviations. Abbreviations may be defined within a block, in which case they are only defined in that block (neither subblocks nor enclosing blocks see the abbreviation). Abbreviations can also be defined inside a

BLOCKINFO block, in which case they are defined in all blocks that match the ID that the *BLOCKINFO* block is describing.

As sub blocks are entered, these properties are saved and the new sub-block has its own set of abbreviations, and its own abbrev id width. When a sub-block is popped, the saved values are restored.

ENTER_SUBBLOCK Encoding

[ENTER_SUBBLOCK, blockid_{vbr8}, newabbrevlen_{vbr4}, <align32bits>, blocklen_32]

The ENTER_SUBBLOCK abbreviation ID specifies the start of a new block record. The blockid value is encoded as an 8-bit VBR identifier, and indicates the type of block being entered, which can be a *standard block* or an application-specific block. The newabbrevlen value is a 4-bit VBR, which specifies the abbrev id width for the sub-block. The blocklen value is a 32-bit aligned value that specifies the size of the subblock in 32-bit words. This value allows the reader to skip over the entire block in one jump.

END_BLOCK Encoding

[END_BLOCK, <align32bits>]

The END_BLOCK abbreviation ID specifies the end of the current block record. Its end is aligned to 32-bits to ensure that the size of the block is an even multiple of 32-bits.

Data Records

Data records consist of a record code and a number of (up to) 64-bit integer values. The interpretation of the code and values is application specific and may vary between different block types. Records can be encoded either using an unabbrev record, or with an abbreviation. In the LLVM IR format, for example, there is a record which encodes the target triple of a module. The code is MODULE_CODE_TRIPLE, and the values of the record are the ASCII codes for the characters in the string.

UNABBREV_RECORD Encoding

[UNABBREV_RECORD, code_{vbr6}, numops_{vbr6}, op0_{vbr6}, op1_{vbr6}, ...]

An UNABBREV_RECORD provides a default fallback encoding, which is both completely general and extremely inefficient. It can describe an arbitrary record by emitting the code and operands as VBRs.

For example, emitting an LLVM IR target triple as an unabbreviated record requires emitting the UNABBREV_RECORD abbrevid, a vbr6 for the MODULE_CODE_TRIPLE code, a vbr6 for the length of the string, which is equal to the number of operands, and a vbr6 for each character. Because there are no letters with values less than 32, each letter would need to be emitted as at least a two-part VBR, which means that each letter would require at least 12 bits. This is not an efficient encoding, but it is fully general.

Abbreviated Record Encoding

[<abbrevid>, fields...]

An abbreviated record is a abbreviation id followed by a set of fields that are encoded according to the *abbreviation definition*. This allows records to be encoded significantly more densely than records encoded with the *UNAB-BREV_RECORD* type, and allows the abbreviation types to be specified in the stream itself, which allows the files to be completely self describing. The actual encoding of abbreviations is defined below.

The record code, which is the first field of an abbreviated record, may be encoded in the abbreviation definition (as a literal operand) or supplied in the abbreviated record (as a Fixed or VBR operand value).

Abbreviations

Abbreviations are an important form of compression for bitstreams. The idea is to specify a dense encoding for a class of records once, then use that encoding to emit many records. It takes space to emit the encoding into the file, but the space is recouped (hopefully plus some) when the records that use it are emitted.

Abbreviations can be determined dynamically per client, per file. Because the abbreviations are stored in the bitstream itself, different streams of the same format can contain different sets of abbreviations according to the needs of the specific stream. As a concrete example, LLVM IR files usually emit an abbreviation for binary operators. If a specific LLVM module contained no or few binary operators, the abbreviation does not need to be emitted.

DEFINE_ABBREV Encoding

[DEFINE_ABBREV, numabbrevops_{vbr5}, abbrevop0, abbrevop1, ...]

A *DEFINE_ABBREV* record adds an abbreviation to the list of currently defined abbreviations in the scope of this block. This definition only exists inside this immediate block --- it is not visible in subblocks or enclosing blocks. Abbreviations are implicitly assigned IDs sequentially starting from 4 (the first application-defined abbreviation ID). Any abbreviations defined in a *BLOCKINFO* record for the particular block type receive IDs first, in order, followed by any abbreviations defined within the block itself. Abbreviated data records reference this ID to indicate what abbreviation they are invoking.

An abbreviation definition consists of the *DEFINE_ABBREV* abbrevid followed by a VBR that specifies the number of abbrev operands, then the abbrev operands themselves. Abbreviation operands come in three forms. They all start with a single bit that indicates whether the abbrev operand is a literal operand (when the bit is 1) or an encoding operand (when the bit is 0).

1. Literal operands --- [1₁, litvalue_{vbr8}] --- Literal operands specify that the value in the result is always a single specific value. This specific value is emitted as a vbr8 after the bit indicating that it is a literal operand.
2. Encoding info without data --- [0₁, encoding₃] --- Operand encodings that do not have extra data are just emitted as their code.
3. Encoding info with data --- [0₁, encoding₃, value_{vbr5}] --- Operand encodings that do have extra data are emitted as their code, followed by the extra data.

The possible operand encodings are:

- Fixed (code 1): The field should be emitted as a *fixed-width value*, whose width is specified by the operand's extra data.
- VBR (code 2): The field should be emitted as a *variable-width value*, whose width is specified by the operand's extra data.
- Array (code 3): This field is an array of values. The array operand has no extra data, but expects another operand to follow it, indicating the element type of the array. When reading an array in an abbreviated record, the first

integer is a vbr6 that indicates the array length, followed by the encoded elements of the array. An array may only occur as the last operand of an abbreviation (except for the one final operand that gives the array's type).

- Char6 (code 4): This field should be emitted as a *char6-encoded value*. This operand type takes no extra data. Char6 encoding is normally used as an array element type.
- Blob (code 5): This field is emitted as a vbr6, followed by padding to a 32-bit boundary (for alignment) and an array of 8-bit objects. The array of bytes is further followed by tail padding to ensure that its total length is a multiple of 4 bytes. This makes it very efficient for the reader to decode the data without having to make a copy of it: it can use a pointer to the data in the mapped in file and poke directly at it. A blob may only occur as the last operand of an abbreviation.

For example, target triples in LLVM modules are encoded as a record of the form [TRIPLE, 'a', 'b', 'c', 'd']. Consider if the bitstream emitted the following abbrev entry:

```
[0, Fixed, 4]
[0, Array]
[0, Char6]
```

When emitting a record with this abbreviation, the above entry would be emitted as:

```
[4abbrevwidth, 24, 4vbr6, 06, 16, 26, 36]
```

These values are:

1. The first value, 4, is the abbreviation ID for this abbreviation.
2. The second value, 2, is the record code for TRIPLE records within LLVM IR file MODULE_BLOCK blocks.
3. The third value, 4, is the length of the array.
4. The rest of the values are the char6 encoded values for "abcd".

With this abbreviation, the triple is emitted with only 37 bits (assuming a abbrev id width of 3). Without the abbreviation, significantly more space would be required to emit the target triple. Also, because the TRIPLE value is not emitted as a literal in the abbreviation, the abbreviation can also be used for any other string value.

Standard Blocks

In addition to the basic block structure and record encodings, the bitstream also defines specific built-in block types. These block types specify how the stream is to be decoded or other metadata. In the future, new standard blocks may be added. Block IDs 0-7 are reserved for standard blocks.

#0 - BLOCKINFO Block

The BLOCKINFO block allows the description of metadata for other blocks. The currently specified records are:

```
[SETBID (#1), blockid]
[DEFINE_ABBREV, ...]
[BLOCKNAME, ...name...]
[SETRECORDNAME, RecordID, ...name...]
```

The SETBID record (code 1) indicates which block ID is being described. SETBID records can occur multiple times throughout the block to change which block ID is being described. There must be a SETBID record prior to any other records.

Standard DEFINE_ABBREV records can occur inside BLOCKINFO blocks, but unlike their occurrence in normal blocks, the abbreviation is defined for blocks matching the block ID we are describing, *not* the BLOCKINFO block itself. The abbreviations defined in BLOCKINFO blocks receive abbreviation IDs as described in [DEFINE_ABBREV](#).

The `BLOCKNAME` record (code 2) can optionally occur in this block. The elements of the record are the bytes of the string name of the block. `llvm-bcanalyzer` can use this to dump out bitcode files symbolically.

The `SETRECORDNAME` record (code 3) can also optionally occur in this block. The first operand value is a record ID number, and the rest of the elements of the record are the bytes for the string name of the record. `llvm-bcanalyzer` can use this to dump out bitcode files symbolically.

Note that although the data in `BLOCKINFO` blocks is described as "metadata," the abbreviations they contain are essential for parsing records from the corresponding blocks. It is not safe to skip them.

4.3.4 Bitcode Wrapper Format

Bitcode files for LLVM IR may optionally be wrapped in a simple wrapper structure. This structure contains a simple header that indicates the offset and size of the embedded BC file. This allows additional information to be stored alongside the BC file. The structure of this file header is:

```
[Magic32, Version32, Offset32, Size32, CPUType32]
```

Each of the fields are 32-bit fields stored in little endian form (as with the rest of the bitcode file fields). The Magic number is always `0x0B17C0DE` and the version is currently always 0. The Offset field is the offset in bytes to the start of the bitcode stream in the file, and the Size field is the size in bytes of the stream. CPUType is a target-specific value that can be used to encode the CPU of the target.

4.3.5 Native Object File Wrapper Format

Bitcode files for LLVM IR may also be wrapped in a native object file (i.e. ELF, COFF, Mach-O). The bitcode must be stored in a section of the object file named `__LLVM`, `__bitcode` for MachO and `.llvmbc` for the other object formats. This wrapper format is useful for accommodating LTO in compilation pipelines where intermediate objects must be native object files which contain metadata in other sections.

Not all tools support this format.

4.3.6 LLVM IR Encoding

LLVM IR is encoded into a bitstream by defining blocks and records. It uses blocks for things like constant pools, functions, symbol tables, etc. It uses records for things like instructions, global variable descriptors, type descriptions, etc. This document does not describe the set of abbreviations that the writer uses, as these are fully self-described in the file, and the reader is not allowed to build in any knowledge of this.

Basics

LLVM IR Magic Number

The magic number for LLVM IR files is:

```
['B', 'C', 0x04, 0xC4, 0xE4, 0xD4]
```

Signed VBRs

Variable Width Integer encoding is an efficient way to encode arbitrary sized unsigned values, but is an extremely inefficient for encoding signed values, as signed values are otherwise treated as maximally large unsigned values.

As such, signed VBR values of a specific width are emitted as follows:

- Positive values are emitted as VBRs of the specified width, but with their value shifted left by one.
- Negative values are emitted as VBRs of the specified width, but the negated value is shifted left by one, and the low bit is set.

With this encoding, small positive and small negative values can both be emitted efficiently. Signed VBR encoding is used in `CST_CODE_INTEGER` and `CST_CODE_WIDE_INTEGER` records within `CONSTANTS_BLOCK` blocks. It is also used for phi instruction operands in *MODULE_CODE_VERSION* 1.

LLVM IR Blocks

LLVM IR is defined with the following blocks:

- 8 --- *MODULE_BLOCK* --- This is the top-level block that contains the entire module, and describes a variety of per-module information.
- 9 --- *PARAMATTR_BLOCK* --- This enumerates the parameter attributes.
- 10 --- *PARAMATTR_GROUP_BLOCK* --- This describes the attribute group table.
- 11 --- *CONSTANTS_BLOCK* --- This describes constants for a module or function.
- 12 --- *FUNCTION_BLOCK* --- This describes a function body.
- 14 --- *VALUE_SYMTAB_BLOCK* --- This describes a value symbol table.
- 15 --- *METADATA_BLOCK* --- This describes metadata items.
- 16 --- *METADATA_ATTACHMENT* --- This contains records associating metadata with function instruction values.
- 17 --- *TYPE_BLOCK* --- This describes all of the types in the module.
- 23 --- *STRTAB_BLOCK* --- The bitcode file's string table.

MODULE_BLOCK Contents

The `MODULE_BLOCK` block (id 8) is the top-level block for LLVM bitcode files, and each bitcode file must contain exactly one. In addition to records (described below) containing information about the module, a `MODULE_BLOCK` block may contain the following sub-blocks:

- *BLOCKINFO*
- *PARAMATTR_BLOCK*
- *PARAMATTR_GROUP_BLOCK*
- *TYPE_BLOCK*
- *VALUE_SYMTAB_BLOCK*
- *CONSTANTS_BLOCK*
- *FUNCTION_BLOCK*
- *METADATA_BLOCK*

MODULE_CODE_VERSION Record

```
[VERSION, version#]
```

The `VERSION` record (code 1) contains a single value indicating the format version. Versions 0, 1 and 2 are supported at this time. The difference between version 0 and 1 is in the encoding of instruction operands in each *FUNCTION_BLOCK*.

In version 0, each value defined by an instruction is assigned an ID unique to the function. Function-level value IDs are assigned starting from `NumModuleValues` since they share the same namespace as module-level values. The value enumerator resets after each function. When a value is an operand of an instruction, the value ID is used to represent the operand. For large functions or large modules, these operand values can be large.

The encoding in version 1 attempts to avoid large operand values in common cases. Instead of using the value ID directly, operands are encoded as relative to the current instruction. Thus, if an operand is the value defined by the previous instruction, the operand will be encoded as 1.

For example, instead of

```
#n = load #n-1
#n+1 = icmp eq #n, #const0
br #n+1, label #(bb1), label #(bb2)
```

version 1 will encode the instructions as

```
#n = load #1
#n+1 = icmp eq #1, (#n+1)-#const0
br #1, label #(bb1), label #(bb2)
```

Note in the example that operands which are constants also use the relative encoding, while operands like basic block labels do not use the relative encoding.

Forward references will result in a negative value. This can be inefficient, as operands are normally encoded as unsigned VBRs. However, forward references are rare, except in the case of phi instructions. For phi instructions, operands are encoded as *Signed VBRs* to deal with forward references.

In version 2, the meaning of module records `FUNCTION`, `GLOBALVAR`, `ALIAS`, `IFUNC` and `COMDAT` change such that the first two operands specify an offset and size of a string in a string table (see *STRTAB_BLOCK Contents*), the function name is removed from the `FNENTRY` record in the value symbol table, and the top-level `VALUE_SYMTAB_BLOCK` may only contain `FNENTRY` records.

MODULE_CODE_TRIPLE Record

```
[TRIPLE, ...string...]
```

The `TRIPLE` record (code 2) contains a variable number of values representing the bytes of the target triple specification string.

MODULE_CODE_DATA_LAYOUT Record

[DATA_LAYOUT, ...string...]

The DATA_LAYOUT record (code 3) contains a variable number of values representing the bytes of the target datalayout specification string.

MODULE_CODE_ASM Record

[ASM, ...string...]

The ASM record (code 4) contains a variable number of values representing the bytes of module asm strings, with individual assembly blocks separated by newline (ASCII 10) characters.

MODULE_CODE_SECTIONNAME Record

[SECTIONNAME, ...string...]

The SECTIONNAME record (code 5) contains a variable number of values representing the bytes of a single section name string. There should be one SECTIONNAME record for each section name referenced (e.g., in global variable or function section attributes) within the module. These records can be referenced by the 1-based index in the *section* fields of GLOBALVAR or FUNCTION records.

MODULE_CODE_DEPLIB Record

[DEPLIB, ...string...]

The DEPLIB record (code 6) contains a variable number of values representing the bytes of a single dependent library name string, one of the libraries mentioned in a deplibs declaration. There should be one DEPLIB record for each library name referenced.

MODULE_CODE_GLOBALVAR Record

[GLOBALVAR, strtab offset, strtab size, pointer type, isconst, initid, linkage, alignment, section, visibility, threadlocal, unnamed_addr, externally_initialized, dllstorageclass, comdat, attributes, preemption_specifier]

The GLOBALVAR record (code 7) marks the declaration or definition of a global variable. The operand fields are:

- *strtab offset, strtab size*: Specifies the name of the global variable. See [STRTAB_BLOCK Contents](#).
- *pointer type*: The type index of the pointer type used to point to this global variable
- *isconst*: Non-zero if the variable is treated as constant within the module, or zero if it is not
- *initid*: If non-zero, the value index of the initializer for this variable, plus 1.
- *linkage*: An encoding of the linkage type for this variable:
 - external: code 0
 - weak: code 1
 - appending: code 2
 - internal: code 3

- linkonce: code 4
 - dllimport: code 5
 - dllexport: code 6
 - extern_weak: code 7
 - common: code 8
 - private: code 9
 - weak_odr: code 10
 - linkonce_odr: code 11
 - available_externally: code 12
 - deprecated : code 13
 - deprecated : code 14
- *alignment**: The logarithm base 2 of the variable's requested alignment, plus 1
- *section*: If non-zero, the 1-based section index in the table of *MODULE_CODE_SECTIONNAME* entries.
- *visibility*: If present, an encoding of the visibility of this variable:
 - default: code 0
 - hidden: code 1
 - protected: code 2
- *threadlocal*: If present, an encoding of the thread local storage mode of the variable:
 - not thread local: code 0
 - thread local; default TLS model: code 1
 - localdynamic: code 2
 - initialexec: code 3
 - localexec: code 4
- *unnamed_addr*: If present, an encoding of the *unnamed_addr* attribute of this variable:
 - not unnamed_addr: code 0
 - unnamed_addr: code 1
 - local_unnamed_addr: code 2
- *dllstorageclass*: If present, an encoding of the DLL storage class of this variable:
 - default: code 0
 - dllimport: code 1
 - dllexport: code 2
- *comdat*: An encoding of the COMDAT of this function
- *attributes*: If nonzero, the 1-based index into the table of AttributeLists.
- *preemptionspecifier*: If present, an encoding of the runtime preemption specifier of this variable:
 - dso_preemptable: code 0
 - dso_local: code 1

MODULE_CODE_FUNCTION Record

[FUNCTION, strtab offset, strtab size, type, callingconv, isproto, linkage, paramattr, alignment, section, visibility, gc, prologuedata, dllstorageclass, comdat, prefixdata, personalityfn, preemptionspecifier]

The FUNCTION record (code 8) marks the declaration or definition of a function. The operand fields are:

- *strtab offset, strtab size*: Specifies the name of the function. See [STRTAB_BLOCK Contents](#).
- *type*: The type index of the function type describing this function
- *callingconv*: The calling convention number: * ccc: code 0 * fastcc: code 8 * coldcc: code 9 * webkit_jscc: code 12 * anyregcc: code 13 * preserve_mostcc: code 14 * preserve_allcc: code 15 * swiftcc : code 16 * cxx_fast_tlscc: code 17 * x86_stdcallcc: code 64 * x86_fastcallcc: code 65 * arm_apcsc: code 66 * arm_aapcsc: code 67 * arm_aapcs_vfpcc: code 68
- *isproto**: Non-zero if this entry represents a declaration rather than a definition
- *linkage*: An encoding of the [linkage type](#) for this function
- *paramattr*: If nonzero, the 1-based parameter attribute index into the table of [PARAMATTR_CODE_ENTRY](#) entries.
- *alignment*: The logarithm base 2 of the function's requested alignment, plus 1
- *section*: If non-zero, the 1-based section index in the table of [MODULE_CODE_SECTIONNAME](#) entries.
- *visibility*: An encoding of the [visibility](#) of this function
- *gc*: If present and nonzero, the 1-based garbage collector index in the table of [MODULE_CODE_GCNAME](#) entries.
- *unnamed_addr*: If present, an encoding of the [unnamed_addr](#) attribute of this function
- *prologuedata*: If non-zero, the value index of the prologue data for this function, plus 1.
- *dllstorageclass*: An encoding of the [dllstorageclass](#) of this function
- *comdat*: An encoding of the COMDAT of this function
- *prefixdata*: If non-zero, the value index of the prefix data for this function, plus 1.
- *personalityfn*: If non-zero, the value index of the personality function for this function, plus 1.
- *preemptionspecifier*: If present, an encoding of the [runtime preemption specifier](#) of this function.

MODULE_CODE_ALIAS Record

[ALIAS, strtab offset, strtab size, alias type, aliasee val#, linkage, visibility, dllstorageclass, threadlocal, unnamed_addr, preemptionspecifier]

The ALIAS record (code 9) marks the definition of an alias. The operand fields are

- *strtab offset, strtab size*: Specifies the name of the alias. See [STRTAB_BLOCK Contents](#).
- *alias type*: The type index of the alias
- *aliasee val#*: The value index of the aliased value
- *linkage*: An encoding of the [linkage type](#) for this alias
- *visibility*: If present, an encoding of the [visibility](#) of the alias

- *dllstorageclass*: If present, an encoding of the *dllstorageclass* of the alias
- *threadlocal*: If present, an encoding of the *thread local property* of the alias
- *unnamed_addr*: If present, an encoding of the *unnamed_addr* attribute of this alias
- *preemptionspecifier*: If present, an encoding of the *runtime preemption specifier* of this alias.

MODULE_CODE_GCNAME Record

```
[GCNAME, ...string...]
```

The GCNAME record (code 11) contains a variable number of values representing the bytes of a single garbage collector name string. There should be one GCNAME record for each garbage collector name referenced in function `gc` attributes within the module. These records can be referenced by 1-based index in the `gc` fields of FUNCTION records.

PARAMATTR_BLOCK Contents

The PARAMATTR_BLOCK block (id 9) contains a table of entries describing the attributes of function parameters. These entries are referenced by 1-based index in the *paramattr* field of module block *FUNCTION* records, or within the *attr* field of function block INST_INVOKE and INST_CALL records.

Entries within PARAMATTR_BLOCK are constructed to ensure that each is unique (i.e., no two indices represent equivalent attribute lists).

PARAMATTR_CODE_ENTRY Record

```
[ENTRY, attrgrp0, attrgrp1, ...]
```

The ENTRY record (code 2) contains a variable number of values describing a unique set of function parameter attributes. Each *attrgrp* value is used as a key with which to look up an entry in the attribute group table described in the PARAMATTR_GROUP_BLOCK block.

PARAMATTR_CODE_ENTRY_OLD Record

Note: This is a legacy encoding for attributes, produced by LLVM versions 3.2 and earlier. It is guaranteed to be understood by the current LLVM version, as specified in the *IR Backwards Compatibility* policy.

```
[ENTRY, paramidx0, attr0, paramidx1, attr1...]
```

The ENTRY record (code 1) contains an even number of values describing a unique set of function parameter attributes. Each *paramidx* value indicates which set of attributes is represented, with 0 representing the return value attributes, 0xFFFFFFFF representing function attributes, and other values representing 1-based function parameters. Each *attr* value is a bitmap with the following interpretation:

- bit 0: zeroext
- bit 1: signext
- bit 2: noreturn
- bit 3: inreg
- bit 4: sret

- bit 5: nounwind
- bit 6: noalias
- bit 7: byval
- bit 8: nest
- bit 9: readnone
- bit 10: readonly
- bit 11: noinline
- bit 12: alwaysinline
- bit 13: optsize
- bit 14: ssp
- bit 15: sspreq
- bits 16-31: align *n*
- bit 32: nocapture
- bit 33: noredzone
- bit 34: noimplicitfloat
- bit 35: naked
- bit 36: inlinehint
- bits 37-39: alignstack *n*, represented as the logarithm base 2 of the requested alignment, plus 1

PARAMATTR_GROUP_BLOCK Contents

The `PARAMATTR_GROUP_BLOCK` block (id 10) contains a table of entries describing the attribute groups present in the module. These entries can be referenced within `PARAMATTR_CODE_ENTRY` entries.

PARAMATTR_GRP_CODE_ENTRY Record

```
[ENTRY, grpid, paramidx, attr0, attr1, ...]
```

The `ENTRY` record (code 3) contains *grpid* and *paramidx* values, followed by a variable number of values describing a unique group of attributes. The *grpid* value is a unique key for the attribute group, which can be referenced within `PARAMATTR_CODE_ENTRY` entries. The *paramidx* value indicates which set of attributes is represented, with 0 representing the return value attributes, 0xFFFFFFFF representing function attributes, and other values representing 1-based function parameters.

Each *attr* is itself represented as a variable number of values:

```
kind, key [, ...], [value [, ...]]
```

Each attribute is either a well-known LLVM attribute (possibly with an integer value associated with it), or an arbitrary string (possibly with an arbitrary string value associated with it). The *kind* value is an integer code distinguishing between these possibilities:

- code 0: well-known attribute
- code 1: well-known attribute with an integer value
- code 3: string attribute

- code 4: string attribute with a string value

For well-known attributes (code 0 or 1), the *key* value is an integer code identifying the attribute. For attributes with an integer argument (code 1), the *value* value indicates the argument.

For string attributes (code 3 or 4), the *key* value is actually a variable number of values representing the bytes of a null-terminated string. For attributes with a string argument (code 4), the *value* value is similarly a variable number of values representing the bytes of a null-terminated string.

The integer codes are mapped to well-known attributes as follows.

- code 1: `align(<n>)`
- code 2: `alwaysinline`
- code 3: `byval`
- code 4: `inlinehint`
- code 5: `inreg`
- code 6: `minsize`
- code 7: `naked`
- code 8: `nest`
- code 9: `noalias`
- code 10: `nobuiltin`
- code 11: `nocapture`
- code 12: `noduplicates`
- code 13: `noimplicitfloat`
- code 14: `noinline`
- code 15: `nonlazybind`
- code 16: `noredzone`
- code 17: `noreturn`
- code 18: `nounwind`
- code 19: `optsize`
- code 20: `readnone`
- code 21: `readonly`
- code 22: `returned`
- code 23: `returns_twice`
- code 24: `signext`
- code 25: `alignstack(<n>)`
- code 26: `ssp`
- code 27: `sspreq`
- code 28: `sspstrong`
- code 29: `sret`
- code 30: `sanitize_address`

- code 31: `sanitize_thread`
- code 32: `sanitize_memory`
- code 33: `uwttable`
- code 34: `zeroext`
- code 35: `builtin`
- code 36: `cold`
- code 37: `optnone`
- code 38: `inalloca`
- code 39: `nonnull`
- code 40: `jumptable`
- code 41: `dereferenceable(<n>)`
- code 42: `dereferenceable_or_null(<n>)`
- code 43: `convergent`
- code 44: `safestack`
- code 45: `argmemonly`
- code 46: `swiftself`
- code 47: `swifterror`
- code 48: `norecurse`
- code 49: `inaccessiblememonly`
- code 50: `inaccessiblememonly_or_argmemonly`
- code 51: `allocsize(<EltSizeParam>[, <NumEltsParam>])`
- code 52: `writeonly`
- code 53: `speculatable`
- code 54: `strictfp`
- code 55: `sanitize_hwaddress`
- code 56: `nocf_check`
- code 57: `optforfuzzing`
- code 58: `shadowcallstack`
- code 64: `sanitize_memtag`

Note: The `allocsize` attribute has a special encoding for its arguments. Its two arguments, which are 32-bit integers, are packed into one 64-bit integer value (i.e. `(EltSizeParam << 32) | NumEltsParam`), with `NumEltsParam` taking on the sentinel value -1 if it is not specified.

TYPE_BLOCK Contents

The `TYPE_BLOCK` block (id 17) contains records which constitute a table of type operator entries used to represent types referenced within an LLVM module. Each record (with the exception of *NUMENTRY*) generates a single type table entry, which may be referenced by 0-based index from instructions, constants, metadata, type symbol table entries, or other type operator records.

Entries within `TYPE_BLOCK` are constructed to ensure that each entry is unique (i.e., no two indices represent structurally equivalent types).

TYPE_CODE_NUMENTRY Record

```
[NUMENTRY, numentries]
```

The `NUMENTRY` record (code 1) contains a single value which indicates the total number of type code entries in the type table of the module. If present, `NUMENTRY` should be the first record in the block.

TYPE_CODE_VOID Record

```
[VOID]
```

The `VOID` record (code 2) adds a `void` type to the type table.

TYPE_CODE_HALF Record

```
[HALF]
```

The `HALF` record (code 10) adds a `half` (16-bit floating point) type to the type table.

TYPE_CODE_FLOAT Record

```
[FLOAT]
```

The `FLOAT` record (code 3) adds a `float` (32-bit floating point) type to the type table.

TYPE_CODE_DOUBLE Record

```
[DOUBLE]
```

The `DOUBLE` record (code 4) adds a `double` (64-bit floating point) type to the type table.

TYPE_CODE_LABEL Record

```
[LABEL]
```

The `LABEL` record (code 5) adds a `label` type to the type table.

TYPE_CODE_OPAQUE Record

[OPAQUE]

The OPAQUE record (code 6) adds an opaque type to the type table, with a name defined by a previously encountered STRUCT_NAME record. Note that distinct opaque types are not unified.

TYPE_CODE_INTEGER Record

[INTEGER, width]

The INTEGER record (code 7) adds an integer type to the type table. The single *width* field indicates the width of the integer type.

TYPE_CODE_POINTER Record

[POINTER, pointee type, address space]

The POINTER record (code 8) adds a pointer type to the type table. The operand fields are

- *pointee type*: The type index of the pointed-to type
- *address space*: If supplied, the target-specific numbered address space where the pointed-to object resides. Otherwise, the default address space is zero.

TYPE_CODE_FUNCTION_OLD Record

Note: This is a legacy encoding for functions, produced by LLVM versions 3.0 and earlier. It is guaranteed to be understood by the current LLVM version, as specified in the *IR Backwards Compatibility* policy.

[FUNCTION_OLD, vararg, ignored, retty, ...paramty...]

The FUNCTION_OLD record (code 9) adds a function type to the type table. The operand fields are

- *vararg*: Non-zero if the type represents a varargs function
- *ignored*: This value field is present for backward compatibility only, and is ignored
- *retty*: The type index of the function's return type
- *paramty*: Zero or more type indices representing the parameter types of the function

TYPE_CODE_ARRAY Record

[ARRAY, numelts, eltty]

The ARRAY record (code 11) adds an array type to the type table. The operand fields are

- *numelts*: The number of elements in arrays of this type
- *eltty*: The type index of the array element type

TYPE_CODE_VECTOR Record

[VECTOR, numelts, eltty]

The VECTOR record (code 12) adds a vector type to the type table. The operand fields are

- *numelts*: The number of elements in vectors of this type
- *eltty*: The type index of the vector element type

TYPE_CODE_X86_FP80 Record

[X86_FP80]

The X86_FP80 record (code 13) adds an x86_fp80 (80-bit floating point) type to the type table.

TYPE_CODE_FP128 Record

[FP128]

The FP128 record (code 14) adds an fp128 (128-bit floating point) type to the type table.

TYPE_CODE_PPC_FP128 Record

[PPC_FP128]

The PPC_FP128 record (code 15) adds a ppc_fp128 (128-bit floating point) type to the type table.

TYPE_CODE_METADATA Record

[METADATA]

The METADATA record (code 16) adds a metadata type to the type table.

TYPE_CODE_X86_MMX Record

[X86_MMX]

The X86_MMX record (code 17) adds an x86_mmx type to the type table.

TYPE_CODE_STRUCT_ANON Record

[STRUCT_ANON, ispacked, ...eltty...]

The STRUCT_ANON record (code 18) adds a literal struct type to the type table. The operand fields are

- *ispacked*: Non-zero if the type represents a packed structure
- *eltty*: Zero or more type indices representing the element types of the structure

TYPE_CODE_STRUCT_NAME Record

[STRUCT_NAME, ...string...]

The STRUCT_NAME record (code 19) contains a variable number of values representing the bytes of a struct name. The next OPAQUE or STRUCT_NAMED record will use this name.

TYPE_CODE_STRUCT_NAMED Record

[STRUCT_NAMED, ispacked, ...elty...]

The STRUCT_NAMED record (code 20) adds an identified struct type to the type table, with a name defined by a previously encountered STRUCT_NAME record. The operand fields are

- *ispacked*: Non-zero if the type represents a packed structure
- *elty*: Zero or more type indices representing the element types of the structure

TYPE_CODE_FUNCTION Record

[FUNCTION, vararg, retty, ...paramty...]

The FUNCTION record (code 21) adds a function type to the type table. The operand fields are

- *vararg*: Non-zero if the type represents a varargs function
- *retty*: The type index of the function's return type
- *paramty*: Zero or more type indices representing the parameter types of the function

CONSTANTS_BLOCK Contents

The CONSTANTS_BLOCK block (id 11) ...

FUNCTION_BLOCK Contents

The FUNCTION_BLOCK block (id 12) ...

In addition to the record types described below, a FUNCTION_BLOCK block may contain the following sub-blocks:

- *CONSTANTS_BLOCK*
- *VALUE_SYMTAB_BLOCK*
- *METADATA_ATTACHMENT*

VALUE_SYMTAB_BLOCK Contents

The VALUE_SYMTAB_BLOCK block (id 14) ...

METADATA_BLOCK Contents

The METADATA_BLOCK block (id 15) ...

METADATA_ATTACHMENT Contents

The METADATA_ATTACHMENT block (id 16) ...

STRTAB_BLOCK Contents

The STRTAB block (id 23) contains a single record (STRTAB_BLOB, id 1) with a single blob operand containing the bitcode file's string table.

Strings in the string table are not null terminated. A record's *strtab offset* and *strtab size* operands specify the byte offset and size of a string within the string table.

The string table is used by all preceding blocks in the bitcode file that are not succeeded by another intervening STRTAB block. Normally a bitcode file will have a single string table, but it may have more than one if it was created by binary concatenation of multiple bitcode files.

4.4 LLVM Block Frequency Terminology

- *Introduction*
- *Branch Probability*
- *Branch Weight*
- *Block Frequency*
- *Implementation: a series of DAGs*
- *Block Mass*
- *Loop Scale*
- *Implementation: Getting from mass and scale to frequency*
- *Block Bias*

4.4.1 Introduction

Block Frequency is a metric for estimating the relative frequency of different basic blocks. This document describes the terminology that the `BlockFrequencyInfo` and `MachineBlockFrequencyInfo` analysis passes use.

4.4.2 Branch Probability

Blocks with multiple successors have probabilities associated with each outgoing edge. These are called branch probabilities. For a given block, the sum of its outgoing branch probabilities should be 1.0.

4.4.3 Branch Weight

Rather than storing fractions on each edge, we store an integer weight. Weights are relative to the other edges of a given predecessor block. The branch probability associated with a given edge is its own weight divided by the sum of the weights on the predecessor's outgoing edges.

For example, consider this IR:

```
define void @foo() {
    ; ...
    A:
        br i1 %cond, label %B, label %C, !prof !0
    ; ...
}
!0 = metadata !{metadata !"branch_weights", i32 7, i32 8}
```

and this simple graph representation:

```
A -> B (edge-weight: 7)
A -> C (edge-weight: 8)
```

The probability of branching from block A to block B is 7/15, and the probability of branching from block A to block C is 8/15.

See *LLVM Branch Weight Metadata* for details about the branch weight IR representation.

4.4.4 Block Frequency

Block frequency is a relative metric that represents the number of times a block executes. The ratio of a block frequency to the entry block frequency is the expected number of times the block will execute per entry to the function.

Block frequency is the main output of the `BlockFrequencyInfo` and `MachineBlockFrequencyInfo` analysis passes.

4.4.5 Implementation: a series of DAGs

The implementation of the block frequency calculation analyses each loop, bottom-up, ignoring backedges; i.e., as a DAG. After each loop is processed, it's packaged up to act as a pseudo-node in its parent loop's (or the function's) DAG analysis.

4.4.6 Block Mass

For each DAG, the entry node is assigned a mass of `UINT64_MAX` and mass is distributed to successors according to branch weights. Block Mass uses a fixed-point representation where `UINT64_MAX` represents 1.0 and 0 represents a number just above 0.0.

After mass is fully distributed, in any cut of the DAG that separates the exit nodes from the entry node, the sum of the block masses of the nodes succeeded by a cut edge should equal `UINT64_MAX`. In other words, mass is conserved as it "falls" through the DAG.

If a function's basic block graph is a DAG, then block masses are valid block frequencies. This works poorly in practise though, since downstream users rely on adding block frequencies together without hitting the maximum.

4.4.7 Loop Scale

Loop scale is a metric that indicates how many times a loop iterates per entry. As mass is distributed through the loop's DAG, the (otherwise ignored) backedge mass is collected. This backedge mass is used to compute the exit frequency, and thus the loop scale.

4.4.8 Implementation: Getting from mass and scale to frequency

After analysing the complete series of DAGs, each block has a mass (local to its containing loop, if any), and each loop pseudo-node has a loop scale and its own mass (from its parent's DAG).

We can get an initial frequency assignment (with entry frequency of 1.0) by multiplying these masses and loop scales together. A given block's frequency is the product of its mass, the mass of containing loops' pseudo nodes, and the containing loops' loop scales.

Since downstream users need integers (not floating point), this initial frequency assignment is shifted as necessary into the range of `uint64_t`.

4.4.9 Block Bias

Block bias is a proposed *absolute* metric to indicate a bias toward or away from a given block during a function's execution. The idea is that bias can be used in isolation to indicate whether a block is relatively hot or cold, or to compare two blocks to indicate whether one is hotter or colder than the other.

The proposed calculation involves calculating a *reference* block frequency, where:

- every branch weight is assumed to be 1 (i.e., every branch probability distribution is even) and
- loop scales are ignored.

This reference frequency represents what the block frequency would be in an unbiased graph.

The bias is the ratio of the block frequency to this reference block frequency.

4.5 LLVM Branch Weight Metadata

- *Introduction*
- *Supported Instructions*
 - *BranchInst*
 - *SwitchInst*
 - *IndirectBrInst*
 - *CallInst*
 - *Other*
- *Built-in expect Instructions*
 - *if statement*
 - *switch statement*
- *CFG Modifications*
- *Function Entry Counts*

4.5.1 Introduction

Branch Weight Metadata represents branch weights as its likeliness to be taken (see *LLVM Block Frequency Terminology*). Metadata is assigned to an Instruction that is a terminator as a MDNode of the MD_prof kind. The first operator is always a MDString node with the string "branch_weights". Number of operators depends on the terminator type.

Branch weights might be fetch from the profiling file, or generated based on `__builtin_expect` instruction.

All weights are represented as an unsigned 32-bit values, where higher value indicates greater chance to be taken.

4.5.2 Supported Instructions

BranchInst

Metadata is only assigned to the conditional branches. There are two extra operands for the true and the false branch.

```
!0 = metadata !{
  metadata !"branch_weights",
  i32 <TRUE_BRANCH_WEIGHT>,
  i32 <FALSE_BRANCH_WEIGHT>
}
```

SwitchInst

Branch weights are assigned to every case (including the `default` case which is always case #0).

```
!0 = metadata !{
  metadata !"branch_weights",
  i32 <DEFAULT_BRANCH_WEIGHT>
  [ , i32 <CASE_BRANCH_WEIGHT> ... ]
}
```

IndirectBrInst

Branch weights are assigned to every destination.

```
!0 = metadata !{
  metadata !"branch_weights",
  i32 <LABEL_BRANCH_WEIGHT>
  [ , i32 <LABEL_BRANCH_WEIGHT> ... ]
}
```

CallInst

Calls may have branch weight metadata, containing the execution count of the call. It is currently used in SamplePGO mode only, to augment the block and entry counts which may not be accurate with sampling.

```
!0 = metadata !{
  metadata !"branch_weights",
  i32 <CALL_BRANCH_WEIGHT>
}
```

Other

Other terminator instructions are not allowed to contain Branch Weight Metadata.

4.5.3 Built-in expect Instructions

`__builtin_expect(long exp, long c)` instruction provides branch prediction information. The return value is the value of `exp`.

It is especially useful in conditional statements. Currently Clang supports two conditional statements:

if statement

The `exp` parameter is the condition. The `c` parameter is the expected comparison value. If it is equal to 1 (true), the condition is likely to be true, in other case condition is likely to be false. For example:

```
if (__builtin_expect(x > 0, 1)) {
  // This block is likely to be taken.
}
```

switch statement

The `exp` parameter is the value. The `c` parameter is the expected value. If the expected value doesn't show on the cases list, the `default` case is assumed to be likely taken.

```
switch (__builtin_expect(x, 5)) {
default: break;
case 0: // ...
case 3: // ...
case 5: // This case is likely to be taken.
}
```

4.5.4 CFG Modifications

Branch Weight Metadata is not proof against CFG changes. If terminator operands' are changed some action should be taken. In other case some misoptimizations may occur due to incorrect branch prediction information.

4.5.5 Function Entry Counts

To allow comparing different functions during inter-procedural analysis and optimization, `MD_prof` nodes can also be assigned to a function definition. The first operand is a string indicating the name of the associated counter.

Currently, one counter is supported: "function_entry_count". The second operand is a 64-bit counter that indicates the number of times that this function was invoked (in the case of instrumentation-based profiles). In the case of sampling-based profiles, this operand is an approximation of how many times the function was invoked.

For example, in the code below, the instrumentation for function `foo()` indicates that it was called 2,590 times at runtime.

```
define i32 @foo() !prof !1 {
  ret i32 0
}
!1 = !{"function_entry_count", i64 2590}
```

If "function_entry_count" has more than 2 operands, the later operands are the GUID of the functions that needs to be imported by ThinLTO. This is only set by sampling based profile. It is needed because the sampling based profile was collected on a binary that had already imported and inlined these functions, and we need to ensure the IR matches in the ThinLTO backends for profile annotation. The reason why we cannot annotate this on the callsite is that it can only go down 1 level in the call chain. For the cases where `foo_in_a_cc()->bar_in_b_cc()->baz_in_c_cc()`, we will need to go down 2 levels in the call chain to import both `bar_in_b_cc` and `baz_in_c_cc`.

4.6 LLVM bugpoint tool: design and usage

- *Description*
- *Design Philosophy*
 - *Automatic Debugger Selection*
 - *Crash debugger*
 - *Code generator debugger*

- *Miscompilation debugger*
- *Advice for using bugpoint*
- *What to do when bugpoint isn't enough*

4.6.1 Description

`bugpoint` narrows down the source of problems in LLVM tools and passes. It can be used to debug three types of failures: optimizer crashes, miscompilations by optimizers, or bad native code generation (including problems in the static and JIT compilers). It aims to reduce large test cases to small, useful ones. For example, if `opt` crashes while optimizing a file, it will identify the optimization (or combination of optimizations) that causes the crash, and reduce the file down to a small example which triggers the crash.

For detailed case scenarios, such as debugging `opt`, or one of the LLVM code generators, see [How to submit an LLVM bug report](#).

4.6.2 Design Philosophy

`bugpoint` is designed to be a useful tool without requiring any hooks into the LLVM infrastructure at all. It works with any and all LLVM passes and code generators, and does not need to "know" how they work. Because of this, it may appear to do stupid things or miss obvious simplifications. `bugpoint` is also designed to trade off programmer time for computer time in the compiler-debugging process; consequently, it may take a long period of (unattended) time to reduce a test case, but we feel it is still worth it. Note that `bugpoint` is generally very quick unless debugging a miscompilation where each test of the program (which requires executing it) takes a long time.

Automatic Debugger Selection

`bugpoint` reads each `.bc` or `.ll` file specified on the command line and links them together into a single module, called the test program. If any LLVM passes are specified on the command line, it runs these passes on the test program. If any of the passes crash, or if they produce malformed output (which causes the verifier to abort), `bugpoint` starts the [crash debugger](#).

Otherwise, if the `-output` option was not specified, `bugpoint` runs the test program with the "safe" backend (which is assumed to generate good code) to generate a reference output. Once `bugpoint` has a reference output for the test program, it tries executing it with the selected code generator. If the selected code generator crashes, `bugpoint` starts the [crash debugger](#) on the code generator. Otherwise, if the resulting output differs from the reference output, it assumes the difference resulted from a code generator failure, and starts the [code generator debugger](#).

Finally, if the output of the selected code generator matches the reference output, `bugpoint` runs the test program after all of the LLVM passes have been applied to it. If its output differs from the reference output, it assumes the difference resulted from a failure in one of the LLVM passes, and enters the [miscompilation debugger](#). Otherwise, there is no problem `bugpoint` can debug.

Crash debugger

If an optimizer or code generator crashes, `bugpoint` will try as hard as it can to reduce the list of passes (for optimizer crashes) and the size of the test program. First, `bugpoint` figures out which combination of optimizer passes triggers the bug. This is useful when debugging a problem exposed by `opt`, for example, because it runs over 38 passes.

Next, `bugpoint` tries removing functions from the test program, to reduce its size. Usually it is able to reduce a test program to a single function, when debugging intraprocedural optimizations. Once the number of functions has been reduced, it attempts to delete various edges in the control flow graph, to reduce the size of the function as much as possible. Finally, `bugpoint` deletes any individual LLVM instructions whose absence does not eliminate the failure. At the end, `bugpoint` should tell you what passes crash, give you a bitcode file, and give you instructions on how to reproduce the failure with `opt` or `llc`.

Code generator debugger

The code generator debugger attempts to narrow down the amount of code that is being miscompiled by the selected code generator. To do this, it takes the test program and partitions it into two pieces: one piece which it compiles with the "safe" backend (into a shared object), and one piece which it runs with either the JIT or the static LLC compiler. It uses several techniques to reduce the amount of code pushed through the LLVM code generator, to reduce the potential scope of the problem. After it is finished, it emits two bitcode files (called "test" [to be compiled with the code generator] and "safe" [to be compiled with the "safe" backend], respectively), and instructions for reproducing the problem. The code generator debugger assumes that the "safe" backend produces good code.

Miscompilation debugger

The miscompilation debugger works similarly to the code generator debugger. It works by splitting the test program into two pieces, running the optimizations specified on one piece, linking the two pieces back together, and then executing the result. It attempts to narrow down the list of passes to the one (or few) which are causing the miscompilation, then reduce the portion of the test program which is being miscompiled. The miscompilation debugger assumes that the selected code generator is working properly.

4.6.3 Advice for using bugpoint

`bugpoint` can be a remarkably useful tool, but it sometimes works in non-obvious ways. Here are some hints and tips:

- In the code generator and miscompilation debuggers, `bugpoint` only works with programs that have deterministic output. Thus, if the program outputs `argv[0]`, the date, time, or any other "random" data, `bugpoint` may misinterpret differences in these data, when output, as the result of a miscompilation. Programs should be temporarily modified to disable outputs that are likely to vary from run to run.
- In the code generator and miscompilation debuggers, debugging will go faster if you manually modify the program or its inputs to reduce the runtime, but still exhibit the problem.
- `bugpoint` is extremely useful when working on a new optimization: it helps track down regressions quickly. To avoid having to relink `bugpoint` every time you change your optimization however, have `bugpoint` dynamically load your optimization with the `-load` option.
- `bugpoint` can generate a lot of output and run for a long period of time. It is often useful to capture the output of the program to file. For example, in the C shell, you can run:

```
$ bugpoint ... |& tee bugpoint.log
```

to get a copy of `bugpoint`'s output in the file `bugpoint.log`, as well as on your terminal.

- `bugpoint` cannot debug problems with the LLVM linker. If `bugpoint` crashes before you see its "All input ok" message, you might try `llvm-link -v` on the same set of input files. If that also crashes, you may be experiencing a linker bug.
- `bugpoint` is useful for proactively finding bugs in LLVM. Invoking `bugpoint` with the `-find-bugs` option will cause the list of specified optimizations to be randomized and applied to the program. This process will repeat until a bug is found or the user kills `bugpoint`.
- `bugpoint` can produce IR which contains long names. Run `opt -metarenamer` over the IR to rename everything using easy-to-read, metasyntactic names. Alternatively, run `opt -strip -instnamer` to rename everything with very short (often purely numeric) names.

4.6.4 What to do when bugpoint isn't enough

Sometimes, `bugpoint` is not enough. In particular, `InstCombine` and `TargetLowering` both have visitor structured code with lots of potential transformations. If the process of using `bugpoint` has left you with still too much code to figure out and the problem seems to be in `instcombine`, the following steps may help. These same techniques are useful with `TargetLowering` as well.

Turn on `-debug-only=instcombine` and see which transformations within `instcombine` are firing by selecting out lines with "IC" in them.

At this point, you have a decision to make. Is the number of transformations small enough to step through them using a debugger? If so, then try that.

If there are too many transformations, then a source modification approach may be helpful. In this approach, you can modify the source code of `instcombine` to disable just those transformations that are being performed on your test input and perform a binary search over the set of transformations. One set of places to modify are the "visit*" methods of `InstCombiner` (e.g. `visitICmpInst`) by adding a `"return false"` as the first line of the method.

If that still doesn't remove enough, then change the caller of `InstCombiner::DoOneIteration`, `InstCombiner::runOnFunction` to limit the number of iterations.

You may also find it useful to use `"-stats"` now to see what parts of `instcombine` are firing. This can guide where to put additional reporting code.

At this point, if the amount of transformations is still too large, then inserting code to limit whether or not to execute the body of the code in the visit function can be helpful. Add a static counter which is incremented on every invocation of the function. Then add code which simply returns false on desired ranges. For example:

```
static int calledCount = 0;
calledCount++;
LLVM_DEBUG(if (calledCount < 212) return false);
LLVM_DEBUG(if (calledCount > 217) return false);
LLVM_DEBUG(if (calledCount == 213) return false);
LLVM_DEBUG(if (calledCount == 214) return false);
LLVM_DEBUG(if (calledCount == 215) return false);
LLVM_DEBUG(if (calledCount == 216) return false);
LLVM_DEBUG(dbgs() << "visitXOR calledCount: " << calledCount << "\n");
LLVM_DEBUG(dbgs() << "I: "; I->dump());
```

could be added to `visitXOR` to limit `visitXor` to being applied only to calls 212 and 217. This is from an actual test case and raises an important point---a simple binary search may not be sufficient, as transformations that interact may require isolating more than one call. In `TargetLowering`, use `return SDNode();` instead of `return false;`.

Now that the number of transformations is down to a manageable number, try examining the output to see if you can figure out which transformations are being done. If that can be figured out, then do the usual debugging. If which code

corresponds to the transformation being performed isn't obvious, set a breakpoint after the call count based disabling and step through the code. Alternatively, you can use "printf" style debugging to report waypoints.

4.7.1 Introduction

The LLVM target-independent code generator is a framework that provides a suite of reusable components for translating the LLVM internal representation to the machine code for a specified target---either in assembly form (suitable for a static compiler) or in binary machine code format (usable for a JIT compiler). The LLVM target-independent code generator consists of six main components:

1. *Abstract target description* interfaces which capture important properties about various aspects of the machine, independently of how they will be used. These interfaces are defined in `include/llvm/Target/`.
2. Classes used to represent the *code being generated* for a target. These classes are intended to be abstract enough to represent the machine code for *any* target machine. These classes are defined in `include/llvm/CodeGen/`. At this level, concepts like "constant pool entries" and "jump tables" are explicitly exposed.
3. Classes and algorithms used to represent code at the object file level, the *MC Layer*. These classes represent assembly level constructs like labels, sections, and instructions. At this level, concepts like "constant pool entries" and "jump tables" don't exist.
4. *Target-independent algorithms* used to implement various phases of native code generation (register allocation, scheduling, stack frame representation, etc). This code lives in `lib/CodeGen/`.
5. *Implementations of the abstract target description interfaces* for particular targets. These machine descriptions make use of the components provided by LLVM, and can optionally provide custom target-specific passes, to build complete code generators for a specific target. Target descriptions live in `lib/Target/`.
6. The target-independent JIT components. The LLVM JIT is completely target independent (it uses the `TargetJITInfo` structure to interface for target-specific issues. The code for the target-independent JIT lives in `lib/ExecutionEngine/JIT`.

Depending on which part of the code generator you are interested in working on, different pieces of this will be useful to you. In any case, you should be familiar with the *target description* and *machine code representation* classes. If you want to add a backend for a new target, you will need to *implement the target description* classes for your new target and understand the *LLVM code representation*. If you are interested in implementing a new *code generation algorithm*, it should only depend on the target-description and machine code representation classes, ensuring that it is portable.

Required components in the code generator

The two pieces of the LLVM code generator are the high-level interface to the code generator and the set of reusable components that can be used to build target-specific backends. The two most important interfaces (*TargetMachine* and *DataLayout*) are the only ones that are required to be defined for a backend to fit into the LLVM system, but the others must be defined if the reusable code generator components are going to be used.

This design has two important implications. The first is that LLVM can support completely non-traditional code generation targets. For example, the C backend does not require register allocation, instruction selection, or any of the other standard components provided by the system. As such, it only implements these two interfaces, and does its own thing. Note that C backend was removed from the trunk since LLVM 3.1 release. Another example of a code generator like this is a (purely hypothetical) backend that converts LLVM to the GCC RTL form and uses GCC to emit machine code for a target.

This design also implies that it is possible to design and implement radically different code generators in the LLVM system that do not make use of any of the built-in components. Doing so is not recommended at all, but could be required for radically different targets that do not fit into the LLVM machine description model: FPGAs for example.

The high-level design of the code generator

The LLVM target-independent code generator is designed to support efficient and quality code generation for standard register-based microprocessors. Code generation in this model is divided into the following stages:

1. *Instruction Selection* --- This phase determines an efficient way to express the input LLVM code in the target instruction set. This stage produces the initial code for the program in the target instruction set, then makes use of virtual registers in SSA form and physical registers that represent any required register assignments due to target constraints or calling conventions. This step turns the LLVM code into a DAG of target instructions.
2. *Scheduling and Formation* --- This phase takes the DAG of target instructions produced by the instruction selection phase, determines an ordering of the instructions, then emits the instructions as *MachineInstrs* with that ordering. Note that we describe this in the *instruction selection section* because it operates on a *SelectionDAG*.
3. *SSA-based Machine Code Optimizations* --- This optional stage consists of a series of machine-code optimizations that operate on the SSA-form produced by the instruction selector. Optimizations like modulo-scheduling or peephole optimization work here.
4. *Register Allocation* --- The target code is transformed from an infinite virtual register file in SSA form to the concrete register file used by the target. This phase introduces spill code and eliminates all virtual register references from the program.
5. *Prolog/Epilog Code Insertion* --- Once the machine code has been generated for the function and the amount of stack space required is known (used for LLVM alloca's and spill slots), the prolog and epilog code for the function can be inserted and "abstract stack location references" can be eliminated. This stage is responsible for implementing optimizations like frame-pointer elimination and stack packing.
6. *Late Machine Code Optimizations* --- Optimizations that operate on "final" machine code can go here, such as spill code scheduling and peephole optimizations.
7. *Code Emission* --- The final stage actually puts out the code for the current function, either in the target assembler format or in machine code.

The code generator is based on the assumption that the instruction selector will use an optimal pattern matching selector to create high-quality sequences of native instructions. Alternative code generator designs based on pattern expansion and aggressive iterative peephole optimization are much slower. This design permits efficient compilation (important for JIT environments) and aggressive optimization (used when generating code offline) by allowing components of varying levels of sophistication to be used for any step of compilation.

In addition to these stages, target implementations can insert arbitrary target-specific passes into the flow. For example, the X86 target uses a special pass to handle the 80x87 floating point stack architecture. Other targets with unusual requirements can be supported with custom passes as needed.

Using TableGen for target description

The target description classes require a detailed description of the target architecture. These target descriptions often have a large amount of common information (e.g., an `add` instruction is almost identical to a `sub` instruction). In order to allow the maximum amount of commonality to be factored out, the LLVM code generator uses the *TableGen* tool to describe big chunks of the target machine, which allows the use of domain-specific and target-specific abstractions to reduce the amount of repetition.

As LLVM continues to be developed and refined, we plan to move more and more of the target description to the `.td` form. Doing so gives us a number of advantages. The most important is that it makes it easier to port LLVM because it reduces the amount of C++ code that has to be written, and the surface area of the code generator that needs to be understood before someone can get something working. Second, it makes it easier to change things. In particular, if tables and other things are all emitted by `tblgen`, we only need a change in one place (`tblgen`) to update all of the targets to a new interface.

4.7.2 Target description classes

The LLVM target description classes (located in the `include/llvm/Target` directory) provide an abstract description of the target machine independent of any particular client. These classes are designed to capture the *abstract* properties of the target (such as the instructions and registers it has), and do not incorporate any particular pieces of code generation algorithms.

All of the target description classes (except the *DataLayout* class) are designed to be subclassed by the concrete target implementation, and have virtual methods implemented. To get to these implementations, the *TargetMachine* class provides accessors that should be implemented by the target.

The *TargetMachine* class

The *TargetMachine* class provides virtual methods that are used to access the target-specific implementations of the various target description classes via the `get*Info` methods (`getInstrInfo`, `getRegisterInfo`, `getFrameInfo`, etc.). This class is designed to be specialized by a concrete target implementation (e.g., *X86TargetMachine*) which implements the various virtual methods. The only required target description class is the *DataLayout* class, but if the code generator components are to be used, the other interfaces should be implemented as well.

The *DataLayout* class

The *DataLayout* class is the only required target description class, and it is the only class that is not extensible (you cannot derive a new class from it). *DataLayout* specifies information about how the target lays out memory for structures, the alignment requirements for various data types, the size of pointers in the target, and whether the target is little-endian or big-endian.

The *TargetLowering* class

The *TargetLowering* class is used by SelectionDAG based instruction selectors primarily to describe how LLVM code should be lowered to SelectionDAG operations. Among other things, this class indicates:

- an initial register class to use for various *ValueTypes*,
- which operations are natively supported by the target machine,
- the return type of `setcc` operations,
- the type to use for shift amounts, and
- various high-level characteristics, like whether it is profitable to turn division by a constant into a multiplication sequence.

The *TargetRegisterInfo* class

The *TargetRegisterInfo* class is used to describe the register file of the target and any interactions between the registers.

Registers are represented in the code generator by unsigned integers. Physical registers (those that actually exist in the target description) are unique small numbers, and virtual registers are generally large. Note that register #0 is reserved as a flag value.

Each register in the processor description has an associated *TargetRegisterDesc* entry, which provides a textual name for the register (used for assembly output and debugging dumps) and a set of aliases (used to indicate whether one register overlaps with another).

In addition to the per-register description, the `TargetRegisterInfo` class exposes a set of processor specific register classes (instances of the `TargetRegisterClass` class). Each register class contains sets of registers that have the same properties (for example, they are all 32-bit integer registers). Each SSA virtual register created by the instruction selector has an associated register class. When the register allocator runs, it replaces virtual registers with a physical register in the set.

The target-specific implementations of these classes is auto-generated from a *TableGen* description of the register file.

The `TargetInstrInfo` class

The `TargetInstrInfo` class is used to describe the machine instructions supported by the target. Descriptions define things like the mnemonic for the opcode, the number of operands, the list of implicit register uses and defs, whether the instruction has certain target-independent properties (accesses memory, is commutable, etc), and holds any target-specific flags.

The `TargetFrameLowering` class

The `TargetFrameLowering` class is used to provide information about the stack frame layout of the target. It holds the direction of stack growth, the known stack alignment on entry to each function, and the offset to the local area. The offset to the local area is the offset from the stack pointer on function entry to the first location where function data (local variables, spill locations) can be stored.

The `TargetSubtarget` class

The `TargetSubtarget` class is used to provide information about the specific chip set being targeted. A sub-target informs code generation of which instructions are supported, instruction latencies and instruction execution itinerary; i.e., which processing units are used, in what order, and for how long.

The `TargetJITInfo` class

The `TargetJITInfo` class exposes an abstract interface used by the Just-In-Time code generator to perform target-specific activities, such as emitting stubs. If a `TargetMachine` supports JIT code generation, it should provide one of these objects through the `getJITInfo` method.

4.7.3 Machine code description classes

At the high-level, LLVM code is translated to a machine specific representation formed out of *MachineFunction* , *MachineBasicBlock* , and *MachineInstr* instances (defined in `include/llvm/CodeGen`). This representation is completely target agnostic, representing instructions in their most abstract form: an opcode and a series of operands. This representation is designed to support both an SSA representation for machine code, as well as a register allocated, non-SSA form.

The MachineInstr class

Target machine instructions are represented as instances of the `MachineInstr` class. This class is an extremely abstract way of representing machine instructions. In particular, it only keeps track of an opcode number and a set of operands.

The opcode number is a simple unsigned integer that only has meaning to a specific backend. All of the instructions for a target should be defined in the `*InstrInfo.td` file for the target. The opcode enum values are auto-generated from this description. The `MachineInstr` class does not have any information about how to interpret the instruction (i.e., what the semantics of the instruction are); for that you must refer to the [TargetInstrInfo](#) class.

The operands of a machine instruction can be of several different types: a register reference, a constant integer, a basic block reference, etc. In addition, a machine operand should be marked as a def or a use of the value (though only registers are allowed to be defs).

By convention, the LLVM code generator orders instruction operands so that all register definitions come before the register uses, even on architectures that are normally printed in other orders. For example, the SPARC add instruction: "add %i1, %i2, %i3" adds the "%i1", and "%i2" registers and stores the result into the "%i3" register. In the LLVM code generator, the operands should be stored as "%i3, %i1, %i2": with the destination first.

Keeping destination (definition) operands at the beginning of the operand list has several advantages. In particular, the debugging printer will print the instruction like this:

```
%r3 = add %i1, %i2
```

Also if the first operand is a def, it is easier to *create instructions* whose only def is the first operand.

Using the MachineInstrBuilder.h functions

Machine instructions are created by using the `BuildMI` functions, located in the `include/llvm/CodeGen/MachineInstrBuilder.h` file. The `BuildMI` functions make it easy to build arbitrary machine instructions. Usage of the `BuildMI` functions look like this:

```
// Create a 'DestReg = mov 42' (rendered in X86 assembly as 'mov DestReg, 42')
// instruction and insert it at the end of the given MachineBasicBlock.
const TargetInstrInfo &TII = ...
MachineBasicBlock &MBB = ...
DebugLoc DL;
MachineInstr *MI = BuildMI(MBB, DL, TII.get(X86::MOV32ri), DestReg).addImm(42);

// Create the same instr, but insert it before a specified iterator point.
MachineBasicBlock::iterator MBBI = ...
BuildMI(MBB, MBBI, DL, TII.get(X86::MOV32ri), DestReg).addImm(42);

// Create a 'cmp Reg, 0' instruction, no destination reg.
MI = BuildMI(MBB, DL, TII.get(X86::CMP32ri8)).addReg(Reg).addImm(42);

// Create an 'sahf' instruction which takes no operands and stores nothing.
MI = BuildMI(MBB, DL, TII.get(X86::SAHF));

// Create a self looping branch instruction.
BuildMI(MBB, DL, TII.get(X86::JNE)).addMBB(&MBB);
```

If you need to add a definition operand (other than the optional destination register), you must explicitly mark it as such:

```
MI.addReg(Reg, RegState::Define);
```

Fixed (preassigned) registers

One important issue that the code generator needs to be aware of is the presence of fixed registers. In particular, there are often places in the instruction stream where the register allocator *must* arrange for a particular value to be in a particular register. This can occur due to limitations of the instruction set (e.g., the X86 can only do a 32-bit divide with the EAX/EDX registers), or external factors like calling conventions. In any case, the instruction selector should emit code that copies a virtual register into or out of a physical register when needed.

For example, consider this simple LLVM example:

```
define i32 @test(i32 %X, i32 %Y) {
    %Z = sdiv i32 %X, %Y
    ret i32 %Z
}
```

The X86 instruction selector might produce this machine code for the `div` and `ret`:

```
;; Start of div
%EAX = mov %reg1024          ;; Copy X (in reg1024) into EAX
%reg1027 = sar %reg1024, 31
%EDX = mov %reg1027          ;; Sign extend X into EDX
idiv %reg1025                ;; Divide by Y (in reg1025)
%reg1026 = mov %EAX          ;; Read the result (Z) out of EAX

;; Start of ret
%EAX = mov %reg1026          ;; 32-bit return value goes in EAX
ret
```

By the end of code generation, the register allocator would coalesce the registers and delete the resultant identity moves producing the following code:

```
;; X is in EAX, Y is in ECX
mov %EAX, %EDX
sar %EDX, 31
idiv %ECX
ret
```

This approach is extremely general (if it can handle the X86 architecture, it can handle anything!) and allows all of the target specific knowledge about the instruction stream to be isolated in the instruction selector. Note that physical registers should have a short lifetime for good code generation, and all physical registers are assumed dead on entry to and exit from basic blocks (before register allocation). Thus, if you need a value to be live across basic block boundaries, it *must* live in a virtual register.

(continued from previous page)

MI bundle support does not change the physical representations of MachineBasicBlock and MachineInstr. All the MIs (including top level and nested ones) are stored as sequential list of MIs. The "bundled" MIs are marked with the 'InsideBundle' flag. A top level MI with the special BUNDLE opcode is used to represent the start of a bundle. It's legal to mix BUNDLE MIs with individual MIs that are not inside bundles nor represent bundles.

MachineInstr passes should operate on a MI bundle as a single unit. Member methods have been taught to correctly handle bundles and MIs inside bundles. The MachineBasicBlock iterator has been modified to skip over bundled MIs to enforce the bundle-as-a-single-unit concept. An alternative iterator `instr_iterator` has been added to MachineBasicBlock to allow passes to iterate over all of the MIs in a MachineBasicBlock, including those which are nested inside bundles. The top level BUNDLE instruction must have the correct set of register MachineOperand's that represent the cumulative inputs and outputs of the bundled MIs.

Packing / bundling of MachineInstr's should be done as part of the register allocation super-pass. More specifically, the pass which determines what MIs should be bundled together must be done after code generator exits SSA form (i.e. after two-address pass, PHI elimination, and copy coalescing). Bundles should only be finalized (i.e. adding BUNDLE MIs and input and output register MachineOperands) after virtual registers have been rewritten into physical registers. This requirement eliminates the need to add virtual register operands to BUNDLE instructions which would effectively double the virtual register def and use lists.

4.7.4 The "MC" Layer

The MC Layer is used to represent and process code at the raw machine code level, devoid of "high level" information like "constant pools", "jump tables", "global variables" or anything like that. At this level, LLVM handles things like label names, machine instructions, and sections in the object file. The code in this layer is used for a number of important purposes: the tail end of the code generator uses it to write a .s or .o file, and it is also used by the llvm-mc tool to implement standalone machine code assemblers and disassemblers.

This section describes some of the important classes. There are also a number of important subsystems that interact at this layer, they are described later in this manual.

The MCStreamer API

MCStreamer is best thought of as an assembler API. It is an abstract API which is *implemented* in different ways (e.g. to output a .s file, output an ELF .o file, etc) but whose API correspond directly to what you see in a .s file. MCStreamer has one method per directive, such as `EmitLabel`, `EmitSymbolAttribute`, `SwitchSection`, `EmitValue` (for .byte, .word), etc, which directly correspond to assembly level directives. It also has an `EmitInstruction` method, which is used to output an `MCInst` to the streamer.

This API is most important for two clients: the `llvm-mc` stand-alone assembler is effectively a parser that parses a line, then invokes a method on MCStreamer. In the code generator, the *Code Emission* phase of the code generator lowers higher level LLVM IR and Machine* constructs down to the MC layer, emitting directives through MCStreamer.

On the implementation side of MCStreamer, there are two major implementations: one for writing out a .s file (`MCAsmStreamer`), and one for writing out a .o file (`MCOjectStreamer`). `MCAsmStreamer` is a straightforward implementation that prints out a directive for each method (e.g. `EmitValue -> .byte`), but `MCOjectStreamer` implements a full assembler.

For target specific directives, the MCStreamer has a `MCTargetStreamer` instance. Each target that needs it defines a class that inherits from it and is a lot like MCStreamer itself: It has one method per directive and two classes that inherit from it, a target object streamer and a target asm streamer. The target asm streamer just prints it (`emitFnStart -> .fnstart`), and the object streamer implement the assembler logic for it.

To make `llvm` use these classes, the target initialization must call `TargetRegistry::RegisterAsmStreamer` and `TargetRegistry::RegisterMCOjectStreamer` passing callbacks that allocate the corresponding target streamer and pass it to `createAsmStreamer` or to the appropriate object streamer constructor.

The MCContext class

The `MCContext` class is the owner of a variety of unique data structures at the MC layer, including symbols, sections, etc. As such, this is the class that you interact with to create symbols and sections. This class can not be subclassed.

The MCSymbol class

The `MCSymbol` class represents a symbol (aka label) in the assembly file. There are two interesting kinds of symbols: assembler temporary symbols, and normal symbols. Assembler temporary symbols are used and processed by the assembler but are discarded when the object file is produced. The distinction is usually represented by adding a prefix to the label, for example "L" labels are assembler temporary labels in MachO.

MCSymbols are created by `MCContext` and unique there. This means that MCSymbols can be compared for pointer equivalence to find out if they are the same symbol. Note that pointer inequality does not guarantee the labels will end up at different addresses though. It's perfectly legal to output something like this to the .s file:

```
foo:
bar:
    .byte 4
```

In this case, both the `foo` and `bar` symbols will have the same address.

The MCSection class

The `MCSection` class represents an object-file specific section. It is subclassed by object file specific implementations (e.g. `MCSectionMachO`, `MCSectionCOFF`, `MCSectionELF`) and these are created and uniqued by `MCContext`. The `MCStreamer` has a notion of the current section, which can be changed with the `SwitchToSection` method (which corresponds to a `".section"` directive in a `.s` file).

The MCInst class

The `MCInst` class is a target-independent representation of an instruction. It is a simple class (much more so than *MachineInstr*) that holds a target-specific opcode and a vector of `MCOperands`. `MCOperand`, in turn, is a simple discriminated union of three cases: 1) a simple immediate, 2) a target register ID, 3) a symbolic expression (e.g. `"Lfoo-Lbar+42"`) as an `MCEExpr`.

`MCInst` is the common currency used to represent machine instructions at the MC layer. It is the type used by the instruction encoder, the instruction printer, and the type generated by the assembly parser and disassembler.

4.7.5 Target-independent code generation algorithms

This section documents the phases described in the *high-level design of the code generator*. It explains how they work and some of the rationale behind their design.

Instruction Selection

Instruction Selection is the process of translating LLVM code presented to the code generator into target-specific machine instructions. There are several well-known ways to do this in the literature. LLVM uses a SelectionDAG based instruction selector.

Portions of the DAG instruction selector are generated from the target description (`*.td`) files. Our goal is for the entire instruction selector to be generated from these `.td` files, though currently there are still things that require custom C++ code.

Introduction to SelectionDAGs

The SelectionDAG provides an abstraction for code representation in a way that is amenable to instruction selection using automatic techniques (e.g. dynamic-programming based optimal pattern matching selectors). It is also well-suited to other phases of code generation; in particular, instruction scheduling (SelectionDAG's are very close to scheduling DAGs post-selection). Additionally, the SelectionDAG provides a host representation where a large variety of very-low-level (but target-independent) *optimizations* may be performed; ones which require extensive information about the instructions efficiently supported by the target.

The SelectionDAG is a Directed-Acyclic-Graph whose nodes are instances of the `SDNode` class. The primary payload of the `SDNode` is its operation code (Opcode) that indicates what operation the node performs and the operands to the operation. The various operation node types are described at the top of the `include/llvm/CodeGen/ISDOpcodes.h` file.

Although most operations define a single value, each node in the graph may define multiple values. For example, a combined div/rem operation will define both the dividend and the remainder. Many other situations require multiple values as well. Each node also has some number of operands, which are edges to the node defining the used value. Because nodes may define multiple values, edges are represented by instances of the `SDValue` class, which is a `<SDNode, unsigned>` pair, indicating the node and result value being used, respectively. Each value produced by an `SDNode` has an associated `MVT` (Machine Value Type) indicating what the type of the value is.

SelectionDAGs contain two different kinds of values: those that represent data flow and those that represent control flow dependencies. Data values are simple edges with an integer or floating point value type. Control edges are represented as "chain" edges which are of type `MVT::Other`. These edges provide an ordering between nodes that have side effects (such as loads, stores, calls, returns, etc). All nodes that have side effects should take a token chain as input and produce a new one as output. By convention, token chain inputs are always operand #0, and chain results are always the last value produced by an operation. However, after instruction selection, the machine nodes have their chain after the instruction's operands, and may be followed by glue nodes.

A SelectionDAG has designated "Entry" and "Root" nodes. The Entry node is always a marker node with an Opcode of `ISD::EntryToken`. The Root node is the final side-effecting node in the token chain. For example, in a single basic block function it would be the return node.

One important concept for SelectionDAGs is the notion of a "legal" vs. "illegal" DAG. A legal DAG for a target is one that only uses supported operations and supported types. On a 32-bit PowerPC, for example, a DAG with a value of type `i1`, `i8`, `i16`, or `i64` would be illegal, as would a DAG that uses a `SREM` or `UREM` operation. The *legalize types* and *legalize operations* phases are responsible for turning an illegal DAG into a legal DAG.

SelectionDAG Instruction Selection Process

SelectionDAG-based instruction selection consists of the following steps:

1. *Build initial DAG* --- This stage performs a simple translation from the input LLVM code to an illegal SelectionDAG.
2. *Optimize SelectionDAG* --- This stage performs simple optimizations on the SelectionDAG to simplify it, and recognize meta instructions (like rotates and `div/rem` pairs) for targets that support these meta operations. This makes the resultant code more efficient and the *select instructions from DAG* phase (below) simpler.
3. *Legalize SelectionDAG Types* --- This stage transforms SelectionDAG nodes to eliminate any types that are unsupported on the target.
4. *Optimize SelectionDAG* --- The SelectionDAG optimizer is run to clean up redundancies exposed by type legalization.
5. *Legalize SelectionDAG Ops* --- This stage transforms SelectionDAG nodes to eliminate any operations that are unsupported on the target.
6. *Optimize SelectionDAG* --- The SelectionDAG optimizer is run to eliminate inefficiencies introduced by operation legalization.
7. *Select instructions from DAG* --- Finally, the target instruction selector matches the DAG operations to target instructions. This process translates the target-independent input DAG into another DAG of target instructions.
8. *SelectionDAG Scheduling and Formation* --- The last phase assigns a linear order to the instructions in the target-instruction DAG and emits them into the MachineFunction being compiled. This step uses traditional prepass scheduling techniques.

After all of these steps are complete, the SelectionDAG is destroyed and the rest of the code generation passes are run.

One great way to visualize what is going on here is to take advantage of a few LLC command line options. The following options pop up a window displaying the SelectionDAG at specific times (if you only get errors printed to the console while using this, you probably [need to configure your system](#) to add support for it).

- `-view-dag-combine1-dags` displays the DAG after being built, before the first optimization pass.
- `-view-legalize-dags` displays the DAG before Legalization.
- `-view-dag-combine2-dags` displays the DAG before the second optimization pass.
- `-view-isel-dags` displays the DAG before the Select phase.

- `-view-sched-dags` displays the DAG before Scheduling.

The `-view-sunit-dags` displays the Scheduler's dependency graph. This graph is based on the final SelectionDAG, with nodes that must be scheduled together bundled into a single scheduling-unit node, and with immediate operands and other nodes that aren't relevant for scheduling omitted.

The option `-filter-view-dags` allows to select the name of the basic block that you are interested to visualize and filters all the previous `view-*-dags` options.

Initial SelectionDAG Construction

The initial SelectionDAG is naively peephole expanded from the LLVM input by the `SelectionDAGBuilder` class. The intent of this pass is to expose as much low-level, target-specific details to the SelectionDAG as possible. This pass is mostly hard-coded (e.g. an LLVM `add` turns into an `SDNode add` while a `getelementptr` is expanded into the obvious arithmetic). This pass requires target-specific hooks to lower calls, returns, varargs, etc. For these features, the *TargetLowering* interface is used.

SelectionDAG LegalizeTypes Phase

The Legalize phase is in charge of converting a DAG to only use the types that are natively supported by the target.

There are two main ways of converting values of unsupported scalar types to values of supported types: converting small types to larger types ("promoting"), and breaking up large integer types into smaller ones ("expanding"). For example, a target might require that all f32 values are promoted to f64 and that all i1/i8/i16 values are promoted to i32. The same target might require that all i64 values be expanded into pairs of i32 values. These changes can insert sign and zero extensions as needed to make sure that the final code has the same behavior as the input.

There are two main ways of converting values of unsupported vector types to value of supported types: splitting vector types, multiple times if necessary, until a legal type is found, and extending vector types by adding elements to the end to round them out to legal types ("widening"). If a vector gets split all the way down to single-element parts with no supported vector type being found, the elements are converted to scalars ("scalarizing").

A target implementation tells the legalizer which types are supported (and which register class to use for them) by calling the `addRegisterClass` method in its `TargetLowering` constructor.

SelectionDAG Legalize Phase

The Legalize phase is in charge of converting a DAG to only use the operations that are natively supported by the target.

Targets often have weird constraints, such as not supporting every operation on every supported datatype (e.g. X86 does not support byte conditional moves and PowerPC does not support sign-extending loads from a 16-bit memory location). Legalize takes care of this by open-coding another sequence of operations to emulate the operation ("expansion"), by promoting one type to a larger type that supports the operation ("promotion"), or by using a target-specific hook to implement the legalization ("custom").

A target implementation tells the legalizer which operations are not supported (and which of the above three actions to take) by calling the `setOperationAction` method in its `TargetLowering` constructor.

If a target has legal vector types, it is expected to produce efficient machine code for common forms of the shufflevector IR instruction using those types. This may require custom legalization for SelectionDAG vector operations that are created from the shufflevector IR. The shufflevector forms that should be handled include:

- Vector select --- Each element of the vector is chosen from either of the corresponding elements of the 2 input vectors. This operation may also be known as a "blend" or "bitwise select" in target assembly. This type of shuffle maps directly to the `shuffle_vector` SelectionDAG node.

- Insert subvector --- A vector is placed into a longer vector type starting at index 0. This type of shuffle maps directly to the `insert_subvector` SelectionDAG node with the `index` operand set to 0.
- Extract subvector --- A vector is pulled from a longer vector type starting at index 0. This type of shuffle maps directly to the `extract_subvector` SelectionDAG node with the `index` operand set to 0.
- Splat --- All elements of the vector have identical scalar elements. This operation may also be known as a "broadcast" or "duplicate" in target assembly. The shufflevector IR instruction may change the vector length, so this operation may map to multiple SelectionDAG nodes including `shuffle_vector`, `concat_vectors`, `insert_subvector`, and `extract_subvector`.

Prior to the existence of the Legalize passes, we required that every target *selector* supported and handled every operator and type even if they are not natively supported. The introduction of the Legalize phases allows all of the canonicalization patterns to be shared across targets, and makes it very easy to optimize the canonicalized code because it is still in the form of a DAG.

SelectionDAG Optimization Phase: the DAG Combiner

The SelectionDAG optimization phase is run multiple times for code generation, immediately after the DAG is built and once after each legalization. The first run of the pass allows the initial code to be cleaned up (e.g. performing optimizations that depend on knowing that the operators have restricted type inputs). Subsequent runs of the pass clean up the messy code generated by the Legalize passes, which allows Legalize to be very simple (it can focus on making code legal instead of focusing on generating *good* and legal code).

One important class of optimizations performed is optimizing inserted sign and zero extension instructions. We currently use ad-hoc techniques, but could move to more rigorous techniques in the future. Here are some good papers on the subject:

"[Widening integer arithmetic](#)" Kevin Redwine and Norman Ramsey International Conference on Compiler Construction (CC) 2004

"[Effective sign extension elimination](#)" Motohiro Kawahito, Hideaki Komatsu, and Toshio Nakatani Proceedings of the ACM SIGPLAN 2002 Conference on Programming Language Design and Implementation.

SelectionDAG Select Phase

The Select phase is the bulk of the target-specific code for instruction selection. This phase takes a legal SelectionDAG as input, pattern matches the instructions supported by the target to this DAG, and produces a new DAG of target code. For example, consider the following LLVM fragment:

```
%t1 = fadd float %W, %X
%t2 = fmul float %t1, %Y
%t3 = fadd float %t2, %Z
```

This LLVM code corresponds to a SelectionDAG that looks basically like this:

```
(fadd:f32 (fmul:f32 (fadd:f32 W, X), Y), Z)
```

If a target supports floating point multiply-and-add (FMA) operations, one of the adds can be merged with the multiply. On the PowerPC, for example, the output of the instruction selector might look like this DAG:

```
(FMADDS (FADDS W, X), Y, Z)
```

The FMADDS instruction is a ternary instruction that multiplies its first two operands and adds the third (as single-precision floating-point numbers). The FADDS instruction is a simple binary single-precision add instruction. To perform this pattern match, the PowerPC backend includes the following instruction definitions:

```
def FMADDS : AForm_1<59, 29,
    (ops F4RC:$FRT, F4RC:$FRA, F4RC:$FRC, F4RC:$FRB),
    "fmadds $FRT, $FRA, $FRC, $FRB",
    [(set F4RC:$FRT, (fadd (fmul F4RC:$FRA, F4RC:$FRC),
                          F4RC:$FRB))]>;
def FADDS : AForm_2<59, 21,
    (ops F4RC:$FRT, F4RC:$FRA, F4RC:$FRB),
    "fadds $FRT, $FRA, $FRB",
    [(set F4RC:$FRT, (fadd F4RC:$FRA, F4RC:$FRB))]>;
```

The highlighted portion of the instruction definitions indicates the pattern used to match the instructions. The DAG operators (like `fmul/fadd`) are defined in the `include/llvm/Target/TargetSelectionDAG.td` file. "F4RC" is the register class of the input and result values.

The TableGen DAG instruction selector generator reads the instruction patterns in the `.td` file and automatically builds parts of the pattern matching code for your target. It has the following strengths:

- At compiler-compile time, it analyzes your instruction patterns and tells you if your patterns make sense or not.
- It can handle arbitrary constraints on operands for the pattern match. In particular, it is straight-forward to say things like "match any immediate that is a 13-bit sign-extended value". For examples, see the `immSExt16` and related `tblgen` classes in the PowerPC backend.
- It knows several important identities for the patterns defined. For example, it knows that addition is commutative, so it allows the FMADDS pattern above to match "`(fadd X, (fmul Y, Z))`" as well as "`(fadd (fmul X, Y), Z)`", without the target author having to specially handle this case.
- It has a full-featured type-inferencing system. In particular, you should rarely have to explicitly tell the system what type parts of your patterns are. In the FMADDS case above, we didn't have to tell `tblgen` that all of the nodes in the pattern are of type 'f32'. It was able to infer and propagate this knowledge from the fact that F4RC has type 'f32'.
- Targets can define their own (and rely on built-in) "pattern fragments". Pattern fragments are chunks of reusable patterns that get inlined into your patterns during compiler-compile time. For example, the integer "`(not x)`" operation is actually defined as a pattern fragment that expands as "`(xor x, -1)`", since the SelectionDAG does not have a native 'not' operation. Targets can define their own short-hand fragments as they see fit. See the definition of 'not' and 'ineg' for examples.
- In addition to instructions, targets can specify arbitrary patterns that map to one or more instructions using the 'Pat' class. For example, the PowerPC has no way to load an arbitrary integer immediate into a register in one instruction. To tell `tblgen` how to do this, it defines:

```
// Arbitrary immediate support. Implement in terms of LIS/ORI.
def : Pat<(i32 imm:$imm),
    (ORI (LIS (HI16 imm:$imm)), (LO16 imm:$imm))>;
```

If none of the single-instruction patterns for loading an immediate into a register match, this will be used. This rule says "match an arbitrary i32 immediate, turning it into an ORI ('or a 16-bit immediate') and an LIS ('load 16-bit immediate, where the immediate is shifted to the left 16 bits') instruction". To make this work, the LO16/HI16 node transformations are used to manipulate the input immediate (in this case, take the high or low 16-bits of the immediate).

- When using the 'Pat' class to map a pattern to an instruction that has one or more complex operands (like e.g. [X86 addressing mode](#)), the pattern may either specify the operand as a whole using a `ComplexPattern`, or else it may specify the components of the complex operand separately. The latter is done e.g. for pre-increment instructions by the PowerPC back end:

```
def STWU : DForm_1<37, (outs ptr_rc:$ea_res), (ins GPRC:$rS, memri:$dst),
    "stwu $rS, $dst", LdStStoreUpd, []>,
    RegConstraint<"$dst.reg = $ea_res">, NoEncode<"$ea_res">;

def : Pat<(pre_store GPRC:$rS, ptr_rc:$ptrreg, iaddroff:$ptroff),
    (STWU GPRC:$rS, iaddroff:$ptroff, ptr_rc:$ptrreg)>;
```

Here, the pair of `ptroff` and `ptrreg` operands is matched onto the complex operand `dst` of class `memri` in the `STWU` instruction.

- While the system does automate a lot, it still allows you to write custom C++ code to match special cases if there is something that is hard to express.

While it has many strengths, the system currently has some limitations, primarily because it is a work in progress and is not yet finished:

- Overall, there is no way to define or match SelectionDAG nodes that define multiple values (e.g. `SMUL_LOHI`, `LOAD`, `CALL`, etc). This is the biggest reason that you currently still *have to* write custom C++ code for your instruction selector.
- There is no great way to support matching complex addressing modes yet. In the future, we will extend pattern fragments to allow them to define multiple values (e.g. the four operands of the *X86 addressing mode*, which are currently matched with custom C++ code). In addition, we'll extend fragments so that a fragment can match multiple different patterns.
- We don't automatically infer flags like `isStore/isLoad` yet.
- We don't automatically generate the set of supported registers and operations for the *Legalizer* yet.
- We don't have a way of tying in custom legalized nodes yet.

Despite these limitations, the instruction selector generator is still quite useful for most of the binary and logical operations in typical instruction sets. If you run into any problems or can't figure out how to do something, please let Chris know!

SelectionDAG Scheduling and Formation Phase

The scheduling phase takes the DAG of target instructions from the selection phase and assigns an order. The scheduler can pick an order depending on various constraints of the machines (i.e. order for minimal register pressure or try to cover instruction latencies). Once an order is established, the DAG is converted to a list of *MachineInstrs* and the SelectionDAG is destroyed.

Note that this phase is logically separate from the instruction selection phase, but is tied to it closely in the code because it operates on SelectionDAGs.

Future directions for the SelectionDAG

1. Optional function-at-a-time selection.
2. Auto-generate entire selector from `.td` file.

SSA-based Machine Code Optimizations

To Be Written

Live Intervals

Live Intervals are the ranges (intervals) where a variable is *live*. They are used by some *register allocator* passes to determine if two or more virtual registers which require the same physical register are live at the same point in the program (i.e., they conflict). When this situation occurs, one virtual register must be *spilled*.

Live Variable Analysis

The first step in determining the live intervals of variables is to calculate the set of registers that are immediately dead after the instruction (i.e., the instruction calculates the value, but it is never used) and the set of registers that are used by the instruction, but are never used after the instruction (i.e., they are killed). Live variable information is computed for each *virtual* register and *register allocatable* physical register in the function. This is done in a very efficient manner because it uses SSA to sparsely compute lifetime information for virtual registers (which are in SSA form) and only has to track physical registers within a block. Before register allocation, LLVM can assume that physical registers are only live within a single basic block. This allows it to do a single, local analysis to resolve physical register lifetimes within each basic block. If a physical register is not register allocatable (e.g., a stack pointer or condition codes), it is not tracked.

Physical registers may be live in to or out of a function. Live in values are typically arguments in registers. Live out values are typically return values in registers. Live in values are marked as such, and are given a dummy "defining" instruction during live intervals analysis. If the last basic block of a function is a `return`, then it's marked as using all live out values in the function.

PHI nodes need to be handled specially, because the calculation of the live variable information from a depth first traversal of the CFG of the function won't guarantee that a virtual register used by the PHI node is defined before it's used. When a PHI node is encountered, only the definition is handled, because the uses will be handled in other basic blocks.

For each PHI node of the current basic block, we simulate an assignment at the end of the current basic block and traverse the successor basic blocks. If a successor basic block has a PHI node and one of the PHI node's operands is coming from the current basic block, then the variable is marked as *alive* within the current basic block and all of its predecessor basic blocks, until the basic block with the defining instruction is encountered.

Live Intervals Analysis

We now have the information available to perform the live intervals analysis and build the live intervals themselves. We start off by numbering the basic blocks and machine instructions. We then handle the "live-in" values. These are in physical registers, so the physical register is assumed to be killed by the end of the basic block. Live intervals for virtual registers are computed for some ordering of the machine instructions $[1, N]$. A live interval is an interval $[i, j)$, where $1 \leq i \leq j \leq N$, for which a variable is live.

Note: More to come...

Register Allocation

The *Register Allocation problem* consists in mapping a program P_v , that can use an unbounded number of virtual registers, to a program P_p that contains a finite (possibly small) number of physical registers. Each target architecture has a different number of physical registers. If the number of physical registers is not enough to accommodate all the virtual registers, some of them will have to be mapped into memory. These virtuals are called *spilled virtuals*.

How registers are represented in LLVM

In LLVM, physical registers are denoted by integer numbers that normally range from 1 to 1023. To see how this numbering is defined for a particular architecture, you can read the `GenRegisterNames.inc` file for that architecture. For instance, by inspecting `lib/Target/X86/X86GenRegisterInfo.inc` we see that the 32-bit register EAX is denoted by 43, and the MMX register MM0 is mapped to 65.

Some architectures contain registers that share the same physical location. A notable example is the X86 platform. For instance, in the X86 architecture, the registers EAX, AX and AL share the first eight bits. These physical registers are marked as *aliased* in LLVM. Given a particular architecture, you can check which registers are aliased by inspecting its `RegisterInfo.td` file. Moreover, the class `MCRRegAliasIterator` enumerates all the physical registers aliased to a register.

Physical registers, in LLVM, are grouped in *Register Classes*. Elements in the same register class are functionally equivalent, and can be interchangeably used. Each virtual register can only be mapped to physical registers of a particular class. For instance, in the X86 architecture, some virtuals can only be allocated to 8 bit registers. A register class is described by `TargetRegisterClass` objects. To discover if a virtual register is compatible with a given physical, this code can be used:

```
bool RegMapping_Fer::compatible_class(MachineFunction &mf,
                                     unsigned v_reg,
                                     unsigned p_reg) {
    assert(TargetRegisterInfo::isPhysicalRegister(p_reg) &&
           "Target register must be physical");
    const TargetRegisterClass *trc = mf.getRegInfo().getRegClass(v_reg);
    return trc->contains(p_reg);
}
```

Sometimes, mostly for debugging purposes, it is useful to change the number of physical registers available in the target architecture. This must be done statically, inside the `TargetRegisterInfo.td` file. Just `grep` for `RegisterClass`, the last parameter of which is a list of registers. Just commenting some out is one simple way to avoid them being used. A more polite way is to explicitly exclude some registers from the *allocation order*. See the definition of the GR8 register class in `lib/Target/X86/X86RegisterInfo.td` for an example of this.

Virtual registers are also denoted by integer numbers. Contrary to physical registers, different virtual registers never share the same number. Whereas physical registers are statically defined in a `TargetRegisterInfo.td` file and cannot be created by the application developer, that is not the case with virtual registers. In order to create new virtual registers, use the method `MachineRegisterInfo::createVirtualRegister()`. This method will return a new virtual register. Use an `IndexedMap<Foo, VirtReg2IndexFunctor>` to hold information per virtual register. If you need to enumerate all virtual registers, use the function `TargetRegisterInfo::index2VirtReg()` to find the virtual register numbers:

```
for (unsigned i = 0, e = MRI->getNumVirtRegs(); i != e; ++i) {
    unsigned VirtReg = TargetRegisterInfo::index2VirtReg(i);
    stuff(VirtReg);
}
```

Before register allocation, the operands of an instruction are mostly virtual registers, although physical registers may also be used. In order to check if a given machine operand is a register, use the

boolean function `MachineOperand::isRegister()`. To obtain the integer code of a register, use `MachineOperand::getReg()`. An instruction may define or use a register. For instance, `ADD reg:1026 := reg:1025 reg:1024` defines the registers 1024, and uses registers 1025 and 1026. Given a register operand, the method `MachineOperand::isUse()` informs if that register is being used by the instruction. The method `MachineOperand::isDef()` informs if that registers is being defined.

We will call physical registers present in the LLVM bitcode before register allocation *pre-colored registers*. Pre-colored registers are used in many different situations, for instance, to pass parameters of functions calls, and to store results of particular instructions. There are two types of pre-colored registers: the ones *implicitly* defined, and those *explicitly* defined. Explicitly defined registers are normal operands, and can be accessed with `MachineInstr::getOperand(int)::getReg()`. In order to check which registers are implicitly defined by an instruction, use the `TargetInstrInfo::get(opcode)::ImplicitDefs`, where `opcode` is the opcode of the target instruction. One important difference between explicit and implicit physical registers is that the latter are defined statically for each instruction, whereas the former may vary depending on the program being compiled. For example, an instruction that represents a function call will always implicitly define or use the same set of physical registers. To read the registers implicitly used by an instruction, use `TargetInstrInfo::get(opcode)::ImplicitUses`. Pre-colored registers impose constraints on any register allocation algorithm. The register allocator must make sure that none of them are overwritten by the values of virtual registers while still alive.

Mapping virtual registers to physical registers

There are two ways to map virtual registers to physical registers (or to memory slots). The first way, that we will call *direct mapping*, is based on the use of methods of the classes `TargetRegisterInfo`, and `MachineOperand`. The second way, that we will call *indirect mapping*, relies on the `VirtRegMap` class in order to insert loads and stores sending and getting values to and from memory.

The direct mapping provides more flexibility to the developer of the register allocator; however, it is more error prone, and demands more implementation work. Basically, the programmer will have to specify where load and store instructions should be inserted in the target function being compiled in order to get and store values in memory. To assign a physical register to a virtual register present in a given operand, use `MachineOperand::setReg(p_reg)`. To insert a store instruction, use `TargetInstrInfo::storeRegToStackSlot(...)`, and to insert a load instruction, use `TargetInstrInfo::loadRegFromStackSlot`.

The indirect mapping shields the application developer from the complexities of inserting load and store instructions. In order to map a virtual register to a physical one, use `VirtRegMap::assignVirt2Phys(vreg, preg)`. In order to map a certain virtual register to memory, use `VirtRegMap::assignVirt2StackSlot(vreg)`. This method will return the stack slot where `vreg`'s value will be located. If it is necessary to map another virtual register to the same stack slot, use `VirtRegMap::assignVirt2StackSlot(vreg, stack_location)`. One important point to consider when using the indirect mapping, is that even if a virtual register is mapped to memory, it still needs to be mapped to a physical register. This physical register is the location where the virtual register is supposed to be found before being stored or after being reloaded.

If the indirect strategy is used, after all the virtual registers have been mapped to physical registers or stack slots, it is necessary to use a spiller object to place load and store instructions in the code. Every virtual that has been mapped to a stack slot will be stored to memory after being defined and will be loaded before being used. The implementation of the spiller tries to recycle load/store instructions, avoiding unnecessary instructions. For an example of how to invoke the spiller, see `RegAllocLinearScan::runOnMachineFunction` in `lib/CodeGen/RegAllocLinearScan.cpp`.

Handling two address instructions

With very rare exceptions (e.g., function calls), the LLVM machine code instructions are three address instructions. That is, each instruction is expected to define at most one register, and to use at most two registers. However, some architectures use two address instructions. In this case, the defined register is also one of the used registers. For instance, an instruction such as `ADD %EAX, %EBX`, in X86 is actually equivalent to `%EAX = %EAX + %EBX`.

In order to produce correct code, LLVM must convert three address instructions that represent two address instructions into true two address instructions. LLVM provides the pass `TwoAddressInstructionPass` for this specific purpose. It must be run before register allocation takes place. After its execution, the resulting code may no longer be in SSA form. This happens, for instance, in situations where an instruction such as `%a = ADD %b %c` is converted to two instructions such as:

```
%a = MOVE %b
%a = ADD %a %c
```

Notice that, internally, the second instruction is represented as `ADD %a[def/use] %c`. I.e., the register operand `%a` is both used and defined by the instruction.

The SSA deconstruction phase

An important transformation that happens during register allocation is called the *SSA Deconstruction Phase*. The SSA form simplifies many analyses that are performed on the control flow graph of programs. However, traditional instruction sets do not implement PHI instructions. Thus, in order to generate executable code, compilers must replace PHI instructions with other instructions that preserve their semantics.

There are many ways in which PHI instructions can safely be removed from the target code. The most traditional PHI deconstruction algorithm replaces PHI instructions with copy instructions. That is the strategy adopted by LLVM. The SSA deconstruction algorithm is implemented in `lib/CodeGen/PHIElimination.cpp`. In order to invoke this pass, the identifier `PHIEliminationID` must be marked as required in the code of the register allocator.

Instruction folding

Instruction folding is an optimization performed during register allocation that removes unnecessary copy instructions. For instance, a sequence of instructions such as:

```
%EBX = LOAD %mem_address
%EAX = COPY %EBX
```

can be safely substituted by the single instruction:

```
%EAX = LOAD %mem_address
```

Instructions can be folded with the `TargetRegisterInfo::foldMemoryOperand(...)` method. Care must be taken when folding instructions; a folded instruction can be quite different from the original instruction. See `LiveIntervals::addIntervalsForSpills` in `lib/CodeGen/LiveIntervalAnalysis.cpp` for an example of its use.

Built in register allocators

The LLVM infrastructure provides the application developer with three different register allocators:

- *Fast* --- This register allocator is the default for debug builds. It allocates registers on a basic block level, attempting to keep values in registers and reusing registers as appropriate.
- *Basic* --- This is an incremental approach to register allocation. Live ranges are assigned to registers one at a time in an order that is driven by heuristics. Since code can be rewritten on-the-fly during allocation, this framework allows interesting allocators to be developed as extensions. It is not itself a production register allocator but is a potentially useful stand-alone mode for triaging bugs and as a performance baseline.
- *Greedy* --- *The default allocator.* This is a highly tuned implementation of the *Basic* allocator that incorporates global live range splitting. This allocator works hard to minimize the cost of spill code.
- *PBQP* --- A Partitioned Boolean Quadratic Programming (PBQP) based register allocator. This allocator works by constructing a PBQP problem representing the register allocation problem under consideration, solving this using a PBQP solver, and mapping the solution back to a register assignment.

The type of register allocator used in `llc` can be chosen with the command line option `-regalloc=...`:

```
$ llc -regalloc=linearscan file.bc -o ln.s
$ llc -regalloc=fast file.bc -o fa.s
$ llc -regalloc=pbqp file.bc -o pbqp.s
```

Prolog/Epilog Code Insertion

Compact Unwind

Throwing an exception requires *unwinding* out of a function. The information on how to unwind a given function is traditionally expressed in DWARF unwind (a.k.a. frame) info. But that format was originally developed for debuggers to backtrace, and each Frame Description Entry (FDE) requires ~20-30 bytes per function. There is also the cost of mapping from an address in a function to the corresponding FDE at runtime. An alternative unwind encoding is called *compact unwind* and requires just 4-bytes per function.

The compact unwind encoding is a 32-bit value, which is encoded in an architecture-specific way. It specifies which registers to restore and from where, and how to unwind out of the function. When the linker creates a final linked image, it will create a `__TEXT,__unwind_info` section. This section is a small and fast way for the runtime to access unwind info for any given function. If we emit compact unwind info for the function, that compact unwind info will be encoded in the `__TEXT,__unwind_info` section. If we emit DWARF unwind info, the `__TEXT,__unwind_info` section will contain the offset of the FDE in the `__TEXT,__eh_frame` section in the final linked image.

For X86, there are three modes for the compact unwind encoding:

Function with a Frame Pointer (``EBP`` or ``RBP``) EBP/RBP-based frame, where EBP/RBP is pushed onto the stack immediately after the return address, then ESP/RSP is moved to EBP/RBP. Thus to unwind, ESP/RSP is restored with the current EBP/RBP value, then EBP/RBP is restored by popping the stack, and the return is done by popping the stack once more into the PC. All non-volatile registers that need to be restored must have been saved in a small range on the stack that starts EBP-4 to EBP-1020 (RBP-8 to RBP-1020). The offset (divided by 4 in 32-bit mode and 8 in 64-bit mode) is encoded in bits 16-23 (mask: 0x00FF0000). The registers saved are encoded in bits 0-14 (mask: 0x00007FFF) as five 3-bit entries from the following table:

Compact Number	i386 Register	x86-64 Register
1	EBX	RBX
2	ECX	R12
3	EDX	R13
4	EDI	R14
5	ESI	R15
6	EBP	RBP

Frameless with a Small Constant Stack Size (`EBP`` or `RBP`` is not used as a frame pointer) To return, a constant (encoded in the compact unwind encoding) is added to the ESP/RSP. Then the return is done by popping the stack into the PC. All non-volatile registers that need to be restored must have been saved on the stack immediately after the return address. The stack size (divided by 4 in 32-bit mode and 8 in 64-bit mode) is encoded in bits 16-23 (mask: 0x00FF0000). There is a maximum stack size of 1024 bytes in 32-bit mode and 2048 in 64-bit mode. The number of registers saved is encoded in bits 9-12 (mask: 0x00001C00). Bits 0-9 (mask: 0x000003FF) contain which registers were saved and their order. (See the `encodeCompactUnwindRegistersWithoutFrame()` function in `lib/Target/X86FrameLowering.cpp` for the encoding algorithm.)

Frameless with a Large Constant Stack Size (`EBP`` or `RBP`` is not used as a frame pointer) This case is like the "Frameless with a Small Constant Stack Size" case, but the stack size is too large to encode in the compact unwind encoding. Instead it requires that the function contains `subl $nnnnnn, %esp` in its prolog. The compact encoding contains the offset to the `$nnnnnn` value in the function in bits 9-12 (mask: 0x00001C00).

Late Machine Code Optimizations

Note: To Be Written

Code Emission

The code emission step of code generation is responsible for lowering from the code generator abstractions (like *MachineFunction*, *MachineInstr*, etc) down to the abstractions used by the MC layer (*MCInst*, *MCStreamer*, etc). This is done with a combination of several different classes: the (misnamed) target-independent *AsmPrinter* class, target-specific subclasses of *AsmPrinter* (such as *SparcAsmPrinter*), and the *TargetLoweringObjectFile* class.

Since the MC layer works at the level of abstraction of object files, it doesn't have a notion of functions, global variables etc. Instead, it thinks about labels, directives, and instructions. A key class used at this time is the *MCStreamer* class. This is an abstract API that is implemented in different ways (e.g. to output a .s file, output an ELF .o file, etc) that is effectively an "assembler API". *MCStreamer* has one method per directive, such as *EmitLabel*, *EmitSymbolAttribute*, *SwitchSection*, etc, which directly correspond to assembly level directives.

If you are interested in implementing a code generator for a target, there are three important things that you have to implement for your target:

1. First, you need a subclass of *AsmPrinter* for your target. This class implements the general lowering process converting *MachineFunction*'s into MC label constructs. The *AsmPrinter* base class provides a number of useful methods and routines, and also allows you to override the lowering process in some important ways. You should get much of the lowering for free if you are implementing an ELF, COFF, or MachO target, because the *TargetLoweringObjectFile* class implements much of the common logic.
2. Second, you need to implement an instruction printer for your target. The instruction printer takes an *MCInst* and renders it to a `raw_ostream` as text. Most of this is automatically generated from the .td file (when you specify

something like "add \$dst, \$src1, \$src2" in the instructions), but you need to implement routines to print operands.

3. Third, you need to implement code that lowers a *MachineInstr* to an *MCIInst*, usually implemented in "<target>MCIInstLower.cpp". This lowering process is often target specific, and is responsible for turning jump table entries, constant pool indices, global variable addresses, etc into *MCLabels* as appropriate. This translation layer is also responsible for expanding pseudo ops used by the code generator into the actual machine instructions they correspond to. The *MCIInsts* that are generated by this are fed into the instruction printer or the encoder.

Finally, at your choosing, you can also implement a subclass of *MCCodeEmitter* which lowers *MCIInst*'s into machine code bytes and relocations. This is important if you want to support direct .o file emission, or would like to implement an assembler for your target.

Emitting function stack size information

A section containing metadata on function stack sizes will be emitted when `TargetLoweringObjectFile::StackSizesSection` is not null, and `TargetOptions::EmitStackSizeSection` is set (-stack-size-section). The section will contain an array of pairs of function symbol values (pointer size) and stack sizes (unsigned LEB128). The stack size values only include the space allocated in the function prologue. Functions with dynamic stack allocations are not included.

VLIW Packetizer

In a Very Long Instruction Word (VLIW) architecture, the compiler is responsible for mapping instructions to functional-units available on the architecture. To that end, the compiler creates groups of instructions called *packets* or *bundles*. The VLIW packetizer in LLVM is a target-independent mechanism to enable the packetization of machine instructions.

Mapping from instructions to functional units

Instructions in a VLIW target can typically be mapped to multiple functional units. During the process of packetizing, the compiler must be able to reason about whether an instruction can be added to a packet. This decision can be complex since the compiler has to examine all possible mappings of instructions to functional units. Therefore to alleviate compilation-time complexity, the VLIW packetizer parses the instruction classes of a target and generates tables at compiler build time. These tables can then be queried by the provided machine-independent API to determine if an instruction can be accommodated in a packet.

How the packetization tables are generated and used

The packetizer reads instruction classes from a target's itineraries and creates a deterministic finite automaton (DFA) to represent the state of a packet. A DFA consists of three major elements: inputs, states, and transitions. The set of inputs for the generated DFA represents the instruction being added to a packet. The states represent the possible consumption of functional units by instructions in a packet. In the DFA, transitions from one state to another occur on the addition of an instruction to an existing packet. If there is a legal mapping of functional units to instructions, then the DFA contains a corresponding transition. The absence of a transition indicates that a legal mapping does not exist and that the instruction cannot be added to the packet.

To generate tables for a VLIW target, add `TargetGenDFAPacketizer.inc` as a target to the Makefile in the target directory. The exported API provides three functions: `DFAPacketizer::clearResources()`, `DFAPacketizer::reserveResources(MachineInstr *MI)`, and `DFAPacketizer::canReserveResources(MachineInstr *MI)`. These functions allow a

target packetizer to add an instruction to an existing packet and to check whether an instruction can be added to a packet. See `llvm/CodeGen/DFAPacketizer.h` for more information.

4.7.6 Implementing a Native Assembler

Though you're probably reading this because you want to write or maintain a compiler backend, LLVM also fully supports building a native assembler. We've tried hard to automate the generation of the assembler from the `.td` files (in particular the instruction syntax and encodings), which means that a large part of the manual and repetitive data entry can be factored and shared with the compiler.

Instruction Parsing

Note: To Be Written

Instruction Alias Processing

Once the instruction is parsed, it enters the `MatchInstructionImpl` function. The `MatchInstructionImpl` function performs alias processing and then does actual matching.

Alias processing is the phase that canonicalizes different lexical forms of the same instructions down to one representation. There are several different kinds of alias that are possible to implement and they are listed below in the order that they are processed (which is in order from simplest/weakest to most complex/powerful). Generally you want to use the first alias mechanism that meets the needs of your instruction, because it will allow a more concise description.

Mnemonic Aliases

The first phase of alias processing is simple instruction mnemonic remapping for classes of instructions which are allowed with two different mnemonics. This phase is a simple and unconditionally remapping from one input mnemonic to one output mnemonic. It isn't possible for this form of alias to look at the operands at all, so the remapping must apply for all forms of a given mnemonic. Mnemonic aliases are defined simply, for example X86 has:

```
def : MnemonicAlias<"cbw",      "cbtw">;
def : MnemonicAlias<"smovq",    "movsq">;
def : MnemonicAlias<"fldcw",    "fldcw">;
def : MnemonicAlias<"fucompi",  "fucomip">;
def : MnemonicAlias<"ud2a",     "ud2">;
```

... and many others. With a `MnemonicAlias` definition, the mnemonic is remapped simply and directly. Though `MnemonicAlias`'s can't look at any aspect of the instruction (such as the operands) they can depend on global modes (the same ones supported by the matcher), through a `Requires` clause:

```
def : MnemonicAlias<"pushf", "pushfq", Requires<[In64BitMode]>;
def : MnemonicAlias<"pushf", "pushfl", Requires<[In32BitMode]>;
```

In this example, the mnemonic gets mapped into a different one depending on the current instruction set.

Instruction Aliases

The most general phase of alias processing occurs while matching is happening: it provides new forms for the matcher to match along with a specific instruction to generate. An instruction alias has two parts: the string to match and the instruction to generate. For example:

```
def : InstAlias<"movsx $src, $dst", (MOVSX16rr8W GR16:$dst, GR8 :$src)>;
def : InstAlias<"movsx $src, $dst", (MOVSX16rm8W GR16:$dst, i8mem:$src)>;
def : InstAlias<"movsx $src, $dst", (MOVSX32rr8 GR32:$dst, GR8 :$src)>;
def : InstAlias<"movsx $src, $dst", (MOVSX32rr16 GR32:$dst, GR16 :$src)>;
def : InstAlias<"movsx $src, $dst", (MOVSX64rr8 GR64:$dst, GR8 :$src)>;
def : InstAlias<"movsx $src, $dst", (MOVSX64rr16 GR64:$dst, GR16 :$src)>;
def : InstAlias<"movsx $src, $dst", (MOVSX64rr32 GR64:$dst, GR32 :$src)>;
```

This shows a powerful example of the instruction aliases, matching the same mnemonic in multiple different ways depending on what operands are present in the assembly. The result of instruction aliases can include operands in a different order than the destination instruction, and can use an input multiple times, for example:

```
def : InstAlias<"clrb $reg", (XOR8rr GR8 :$reg, GR8 :$reg)>;
def : InstAlias<"clrw $reg", (XOR16rr GR16:$reg, GR16:$reg)>;
def : InstAlias<"clrl $reg", (XOR32rr GR32:$reg, GR32:$reg)>;
def : InstAlias<"clrq $reg", (XOR64rr GR64:$reg, GR64:$reg)>;
```

This example also shows that tied operands are only listed once. In the X86 backend, XOR8rr has two input GR8's and one output GR8 (where an input is tied to the output). InstAliases take a flattened operand list without duplicates for tied operands. The result of an instruction alias can also use immediates and fixed physical registers which are added as simple immediate operands in the result, for example:

```
// Fixed Immediate operand.
def : InstAlias<"aad", (AAD8i8 10)>;

// Fixed register operand.
def : InstAlias<"fcomi", (COM_FIr ST1)>;

// Simple alias.
def : InstAlias<"fcomi $reg", (COM_FIr RST:$reg)>;
```

Instruction aliases can also have a Requires clause to make them subtarget specific.

If the back-end supports it, the instruction printer can automatically emit the alias rather than what's being aliased. It typically leads to better, more readable code. If it's better to print out what's being aliased, then pass a '0' as the third parameter to the InstAlias definition.

Instruction Matching

Note: To Be Written

4.7.7 Target-specific Implementation Notes

This section of the document explains features or design decisions that are specific to the code generator for a particular target. First we start with a table that summarizes what features are supported by each target.

Target Feature Matrix

Note that this table does not list features that are not supported fully by any target yet. It considers a feature to be supported if at least one subtarget supports it. A feature being supported means that it is useful and works for most cases, it does not indicate that there are zero known bugs in the implementation. Here is the key:

Here is the table:

Is Generally Reliable

This box indicates whether the target is considered to be production quality. This indicates that the target has been used as a static compiler to compile large amounts of code by a variety of different people and is in continuous use.

Assembly Parser

This box indicates whether the target supports parsing target specific .s files by implementing the MCAsmParser interface. This is required for llvm-mc to be able to act as a native assembler and is required for inline assembly support in the native .o file writer.

Disassembler

This box indicates whether the target supports the MCDisassembler API for disassembling machine opcode bytes into MCInst's.

Inline Asm

This box indicates whether the target supports most popular inline assembly constraints and modifiers.

JIT Support

This box indicates whether the target supports the JIT compiler through the ExecutionEngine interface.

The ARM backend has basic support for integer code in ARM codegen mode, but lacks NEON and full Thumb support.

.o File Writing

This box indicates whether the target supports writing .o files (e.g. MachO, ELF, and/or COFF) files directly from the target. Note that the target also must include an assembly parser and general inline assembly support for full inline assembly support in the .o writer.

Targets that don't support this feature can obviously still write out .o files, they just rely on having an external assembler to translate from a .s file to a .o file (as is the case for many C compilers).

Tail Calls

This box indicates whether the target supports guaranteed tail calls. These are calls marked "tail" and use the fastcc calling convention. Please see the [tail call section](#) for more details.

Segmented Stacks

This box indicates whether the target supports segmented stacks. This replaces the traditional large C stack with many linked segments. It is compatible with the [gcc implementation](#) used by the Go front end.

Basic support exists on the X86 backend. Currently vararg doesn't work and the object files are not marked the way the gold linker expects, but simple Go programs can be built by dragonegg.

Tail call optimization

Tail call optimization, callee reusing the stack of the caller, is currently supported on x86/x86-64, PowerPC, and WebAssembly. It is performed on x86/x86-64 and PowerPC if:

- Caller and callee have the calling convention `fastcc`, `cc 10` (GHC calling convention) or `cc 11` (HiPE calling convention).
- The call is a tail call - in tail position (ret immediately follows call and ret uses value of call or is void).
- Option `-tailcallopt` is enabled.
- Platform-specific constraints are met.

x86/x86-64 constraints:

- No variable argument lists are used.
- On x86-64 when generating GOT/PIC code only module-local calls (visibility = hidden or protected) are supported.

PowerPC constraints:

- No variable argument lists are used.
- No byval parameters are used.
- On ppc32/64 GOT/PIC only module-local calls (visibility = hidden or protected) are supported.

On WebAssembly, tail calls are lowered to `return_call` and `return_call_indirect` instructions whenever the 'tail-call' target attribute is enabled.

Example:

Call as `llc -tailcallopt test.ll`.

```
declare fastcc i32 @tailcallee(i32 inreg %a1, i32 inreg %a2, i32 %a3, i32 %a4)

define fastcc i32 @tailcaller(i32 %in1, i32 %in2) {
    %l1 = add i32 %in1, %in2
    %tmp = tail call fastcc i32 @tailcallee(i32 %in1 inreg, i32 %in2 inreg, i32 %in1,
↪ i32 %l1)
    ret i32 %tmp
}
```

Implications of `-tailcallopt`:

To support tail call optimization in situations where the callee has more arguments than the caller a 'callee pops arguments' convention is used. This currently causes each `fastcc` call that is not tail call optimized (because one or more of above constraints are not met) to be followed by a readjustment of the stack. So performance might be worse in such cases.

Sibling call optimization

Sibling call optimization is a restricted form of tail call optimization. Unlike tail call optimization described in the previous section, it can be performed automatically on any tail calls when `-tailcallopt` option is not specified.

Sibling call optimization is currently performed on x86/x86-64 when the following constraints are met:

- Caller and callee have the same calling convention. It can be either `c` or `fastcc`.
- The call is a tail call - in tail position (ret immediately follows call and ret uses value of call or is void).
- Caller and callee have matching return type or the callee result is not used.
- If any of the callee arguments are being passed in stack, they must be available in caller's own incoming argument stack and the frame offsets must be the same.

Example:

```
declare i32 @bar(i32, i32)

define i32 @foo(i32 %a, i32 %b, i32 %c) {
entry:
    %0 = tail call i32 @bar(i32 %a, i32 %b)
    ret i32 %0
}
```

The X86 backend

The X86 code generator lives in the `lib/Target/X86` directory. This code generator is capable of targeting a variety of x86-32 and x86-64 processors, and includes support for ISA extensions such as MMX and SSE.

X86 Target Triples supported

The following are the known target triples that are supported by the X86 backend. This is not an exhaustive list, and it would be useful to add those that people test.

- **i686-pc-linux-gnu** --- Linux
- **i386-unknown-freebsd5.3** --- FreeBSD 5.3
- **i686-pc-cygwin** --- Cygwin on Win32
- **i686-pc-mingw32** --- MingW on Win32
- **i386-pc-mingw32msvc** --- MingW crosscompiler on Linux
- **i686-apple-darwin*** --- Apple Darwin on X86
- **x86_64-unknown-linux-gnu** --- Linux

X86 Calling Conventions supported

The following target-specific calling conventions are known to backend:

- **x86_StdCall** --- stdcall calling convention seen on Microsoft Windows platform (CC ID = 64).
- **x86_FastCall** --- fastcall calling convention seen on Microsoft Windows platform (CC ID = 65).
- **x86_ThisCall** --- Similar to X86_StdCall. Passes first argument in ECX, others via stack. Callee is responsible for stack cleaning. This convention is used by MSVC by default for methods in its ABI (CC ID = 70).

Representing X86 addressing modes in MachineInstrs

The x86 has a very flexible way of accessing memory. It is capable of forming memory addresses of the following expression directly in integer instructions (which use ModR/M addressing):

```
SegmentReg: Base + [1,2,4,8] * IndexReg + Disp32
```

In order to represent this, LLVM tracks no less than 5 operands for each memory operand of this form. This means that the "load" form of 'mov' has the following MachineOperands in this order:

Index:	0		1	2	3	4	5
Meaning:	DestReg,		BaseReg,	Scale,	IndexReg,	Displacement	Segment
OperandTy:	VirtReg,		VirtReg,	UnsImm,	VirtReg,	SignExtImm	PhysReg

Stores, and all other instructions, treat the four memory operands in the same way and in the same order. If the segment register is unspecified (regno = 0), then no segment override is generated. "Lea" operations do not have a segment register specified, so they only have 4 operands for their memory reference.

X86 address spaces supported

x86 has a feature which provides the ability to perform loads and stores to different address spaces via the x86 segment registers. A segment override prefix byte on an instruction causes the instruction's memory access to go to the specified segment. LLVM address space 0 is the default address space, which includes the stack, and any unqualified memory accesses in a program. Address spaces 1-255 are currently reserved for user-defined code. The GS-segment is represented by address space 256, the FS-segment is represented by address space 257, and the SS-segment is represented by address space 258. Other x86 segments have yet to be allocated address space numbers.

While these address spaces may seem similar to TLS via the `thread_local` keyword, and often use the same underlying hardware, there are some fundamental differences.

The `thread_local` keyword applies to global variables and specifies that they are to be allocated in thread-local memory. There are no type qualifiers involved, and these variables can be pointed to with normal pointers and accessed with normal loads and stores. The `thread_local` keyword is target-independent at the LLVM IR level (though LLVM doesn't yet have implementations of it for some configurations)

Special address spaces, in contrast, apply to static types. Every load and store has a particular address space in its address operand type, and this is what determines which address space is accessed. LLVM ignores these special address space qualifiers on global variables, and does not provide a way to directly allocate storage in them. At the LLVM IR level, the behavior of these special address spaces depends in part on the underlying OS or runtime environment, and they are specific to x86 (and LLVM doesn't yet handle them correctly in some cases).

Some operating systems and runtime environments use (or may in the future use) the FS/GS-segment registers for various low-level purposes, so care should be taken when considering them.

Instruction naming

An instruction name consists of the base name, a default operand size, and a character per operand with an optional special size. For example:

```
ADD8rr      -> add, 8-bit register, 8-bit register
IMUL16rmi   -> imul, 16-bit register, 16-bit memory, 16-bit immediate
IMUL16rmi8  -> imul, 16-bit register, 16-bit memory, 8-bit immediate
MOVSX32rm16 -> movsx, 32-bit register, 16-bit memory
```

The PowerPC backend

The PowerPC code generator lives in the `lib/Target/PowerPC` directory. The code generation is retargetable to several variations or *subtargets* of the PowerPC ISA; including `ppc32`, `ppc64` and `altivec`.

LLVM PowerPC ABI

LLVM follows the AIX PowerPC ABI, with two deviations. LLVM uses a PC relative (PIC) or static addressing for accessing global values, so no TOC (r2) is used. Second, r31 is used as a frame pointer to allow dynamic growth of a stack frame. LLVM takes advantage of having no TOC to provide space to save the frame pointer in the PowerPC linkage area of the caller frame. Other details of PowerPC ABI can be found at [PowerPC ABI](#). Note: This link describes the 32 bit ABI. The 64 bit ABI is similar except space for GPRs are 8 bytes wide (not 4) and r13 is reserved for system use.

Frame Layout

The size of a PowerPC frame is usually fixed for the duration of a function's invocation. Since the frame is fixed size, all references into the frame can be accessed via fixed offsets from the stack pointer. The exception to this is when dynamic alloca or variable sized arrays are present, then a base pointer (r31) is used as a proxy for the stack pointer and stack pointer is free to grow or shrink. A base pointer is also used if llvm-gcc is not passed the -fomit-frame-pointer flag. The stack pointer is always aligned to 16 bytes, so that space allocated for altivec vectors will be properly aligned.

An invocation frame is laid out as follows (low memory at top):

The *linkage* area is used by a callee to save special registers prior to allocating its own frame. Only three entries are relevant to LLVM. The first entry is the previous stack pointer (sp), aka link. This allows probing tools like gdb or exception handlers to quickly scan the frames in the stack. A function epilog can also use the link to pop the frame from the stack. The third entry in the linkage area is used to save the return address from the lr register. Finally, as mentioned above, the last entry is used to save the previous frame pointer (r31.) The entries in the linkage area are the size of a GPR, thus the linkage area is 24 bytes long in 32 bit mode and 48 bytes in 64 bit mode.

32 bit linkage area:

64 bit linkage area:

The *parameter area* is used to store arguments being passed to a callee function. Following the PowerPC ABI, the first few arguments are actually passed in registers, with the space in the parameter area unused. However, if there are not enough registers or the callee is a thunk or vararg function, these register arguments can be spilled into the parameter area. Thus, the parameter area must be large enough to store all the parameters for the largest call sequence made by the caller. The size must also be minimally large enough to spill registers r3-r10. This allows callees blind to the call signature, such as thunks and vararg functions, enough space to cache the argument registers. Therefore, the parameter area is minimally 32 bytes (64 bytes in 64 bit mode.) Also note that since the parameter area is a fixed offset from the top of the frame, that a callee can access its spilt arguments using fixed offsets from the stack pointer (or base pointer.)

Combining the information about the linkage, parameter areas and alignment. A stack frame is minimally 64 bytes in 32 bit mode and 128 bytes in 64 bit mode.

The *dynamic area* starts out as size zero. If a function uses dynamic alloca then space is added to the stack, the linkage and parameter areas are shifted to top of stack, and the new space is available immediately below the linkage and parameter areas. The cost of shifting the linkage and parameter areas is minor since only the link value needs to be copied. The link value can be easily fetched by adding the original frame size to the base pointer. Note that allocations in the dynamic space need to observe 16 byte alignment.

The *locals area* is where the llvm compiler reserves space for local variables.

The *saved registers area* is where the llvm compiler spills callee saved registers on entry to the callee.

Prolog/Epilog

The llvm prolog and epilog are the same as described in the PowerPC ABI, with the following exceptions. Callee saved registers are spilled after the frame is created. This allows the llvm epilog/prolog support to be common with other targets. The base pointer callee saved register r31 is saved in the TOC slot of linkage area. This simplifies allocation of space for the base pointer and makes it convenient to locate programmatically and during debugging.

Dynamic Allocation

Note: TODO - More to come.

The NVPTX backend

The NVPTX code generator under `lib/Target/NVPTX` is an open-source version of the NVIDIA NVPTX code generator for LLVM. It is contributed by NVIDIA and is a port of the code generator used in the CUDA compiler (`nvcc`). It targets the PTX 3.0/3.1 ISA and can target any compute capability greater than or equal to 2.0 (Fermi).

This target is of production quality and should be completely compatible with the official NVIDIA toolchain.

Code Generator Options:

The extended Berkeley Packet Filter (eBPF) backend

Extended BPF (or eBPF) is similar to the original ("classic") BPF (cBPF) used to filter network packets. The `bpf()` system call performs a range of operations related to eBPF. For both cBPF and eBPF programs, the Linux kernel statically analyzes the programs before loading them, in order to ensure that they cannot harm the running system. eBPF is a 64-bit RISC instruction set designed for one to one mapping to 64-bit CPUs. Opcodes are 8-bit encoded, and 87 instructions are defined. There are 10 registers, grouped by function as outlined below.

R0	<code>return</code> value <code>from</code> <code>in</code> -kernel functions; exit value <code>for</code> eBPF program
R1 - R5	function call arguments to <code>in</code> -kernel functions
R6 - R9	callee-saved registers preserved by <code>in</code> -kernel functions
R10	stack frame pointer (read only)

Instruction encoding (arithmetic and jump)

eBPF is reusing most of the opcode encoding from classic to simplify conversion of classic BPF to eBPF. For arithmetic and jump instructions the 8-bit 'code' field is divided into three parts:

+-----+-----+-----+			
4 bits	1 bit	3 bits	
operation code	source	instruction class	
+-----+-----+-----+			
(MSB)			(LSB)

Three LSB bits store instruction class which is one of:

BPF_LD	0x0
BPF_LDX	0x1
BPF_ST	0x2
BPF_STX	0x3
BPF_ALU	0x4
BPF_JMP	0x5
(unused)	0x6
BPF_ALU64	0x7

When `BPF_CLASS(code) == BPF_ALU` or `BPF_ALU64` or `BPF_JMP`, 4th bit encodes source operand

BPF_X	0x1	use src_reg register as source operand
BPF_K	0x0	use 32 bit immediate as source operand

and four MSB bits store operation code

BPF_ADD	0x0	add
BPF_SUB	0x1	subtract
BPF_MUL	0x2	multiply
BPF_DIV	0x3	divide
BPF_OR	0x4	bitwise logical OR
BPF_AND	0x5	bitwise logical AND
BPF_LSH	0x6	left shift
BPF_RSH	0x7	right shift (zero extended)
BPF_NEG	0x8	arithmetic negation
BPF_MOD	0x9	modulo
BPF_XOR	0xa	bitwise logical XOR
BPF_MOV	0xb	move register to register
BPF_ARSH	0xc	right shift (sign extended)
BPF_END	0xd	endianness conversion

If BPF_CLASS(code) == BPF_JMP, BPF_OP(code) is one of

BPF_JA	0x0	unconditional jump
BPF_JEQ	0x1	jump ==
BPF_JGT	0x2	jump >
BPF_JGE	0x3	jump >=
BPF_JSET	0x4	jump if (DST & SRC)
BPF_JNE	0x5	jump !=
BPF_JSGT	0x6	jump signed >
BPF_JSGE	0x7	jump signed >=
BPF_CALL	0x8	function call
BPF_EXIT	0x9	function return

Instruction encoding (load, store)

For load and store instructions the 8-bit 'code' field is divided as:

+-----+-----+-----+-----+			
3 bits	2 bits	3 bits	
mode	size	instruction class	
+-----+-----+-----+-----+			
(MSB)		(LSB)	

Size modifier is one of

BPF_W	0x0	word
BPF_H	0x1	half word
BPF_B	0x2	byte
BPF_DW	0x3	double word

Mode modifier is one of

BPF_IMM	0x0	immediate
BPF_ABS	0x1	used to access packet data
BPF_IND	0x2	used to access packet data

(continues on next page)

(continued from previous page)

BPF_MEM	0x3	memory
(reserved)	0x4	
(reserved)	0x5	
BPF_XADD	0x6	exclusive add

Packet data access (BPF_ABS, BPF_IND)

Two non-generic instructions: (BPF_ABS | <size> | BPF_LD) and (BPF_IND | <size> | BPF_LD) which are used to access packet data. Register R6 is an implicit input that must contain pointer to sk_buff. Register R0 is an implicit output which contains the data fetched from the packet. Registers R1-R5 are scratch registers and must not be used to store the data across BPF_ABS | BPF_LD or BPF_IND | BPF_LD instructions. These instructions have implicit program exit condition as well. When eBPF program is trying to access the data beyond the packet boundary, the interpreter will abort the execution of the program.

BPF_IND | BPF_W | BPF_LD is equivalent to: $R0 = \text{ntohl}(*(\text{u32 } *)(((\text{struct sk_buff } *) R6) \rightarrow \text{data} + \text{src_reg} + \text{imm32}))$

eBPF maps

eBPF maps are provided for sharing data between kernel and user-space. Currently implemented types are hash and array, with potential extension to support bloom filters, radix trees, etc. A map is defined by its type, maximum number of elements, key size and value size in bytes. eBPF syscall supports create, update, find and delete functions on maps.

Function calls

Function call arguments are passed using up to five registers (R1 - R5). The return value is passed in a dedicated register (R0). Four additional registers (R6 - R9) are callee-saved, and the values in these registers are preserved within kernel functions. R0 - R5 are scratch registers within kernel functions, and eBPF programs must therefor store/restore values in these registers if needed across function calls. The stack can be accessed using the read-only frame pointer R10. eBPF registers map 1:1 to hardware registers on x86_64 and other 64-bit architectures. For example, x86_64 in-kernel JIT maps them as

R0	-	rax
R1	-	rdi
R2	-	rsi
R3	-	rdx
R4	-	rcx
R5	-	r8
R6	-	rbx
R7	-	r13
R8	-	r14
R9	-	r15
R10	-	rbp

since x86_64 ABI mandates rdi, rsi, rdx, rcx, r8, r9 for argument passing and rbx, r12 - r15 are callee saved.

Program start

An eBPF program receives a single argument and contains a single eBPF main routine; the program does not contain eBPF functions. Function calls are limited to a predefined set of kernel functions. The size of a program is limited to 4K instructions: this ensures fast termination and a limited number of kernel function calls. Prior to running an eBPF program, a verifier performs static analysis to prevent loops in the code and to ensure valid register usage and operand types.

The AMDGPU backend

The AMDGPU code generator lives in the `lib/Target/AMDGPU` directory. This code generator is capable of targeting a variety of AMD GPU processors. Refer to *User Guide for AMDGPU Backend* for more information.

4.8.1 Introduction

This document is the central repository for all information pertaining to exception handling in LLVM. It describes the format that LLVM exception handling information takes, which is useful for those interested in creating front-ends or dealing directly with the information. Further, this document provides specific examples of what exception handling information is used for in C and C++.

Itanium ABI Zero-cost Exception Handling

Exception handling for most programming languages is designed to recover from conditions that rarely occur during general use of an application. To that end, exception handling should not interfere with the main flow of an application's algorithm by performing checkpointing tasks, such as saving the current pc or register state.

The Itanium ABI Exception Handling Specification defines a methodology for providing outlying data in the form of exception tables without inlining speculative exception handling code in the flow of an application's main algorithm. Thus, the specification is said to add "zero-cost" to the normal execution of an application.

A more complete description of the Itanium ABI exception handling runtime support of can be found at [Itanium C++ ABI: Exception Handling](#). A description of the exception frame format can be found at [Exception Frames](#), with details of the DWARF 4 specification at [DWARF 4 Standard](#). A description for the C++ exception table formats can be found at [Exception Handling Tables](#).

Setjmp/Longjmp Exception Handling

Setjmp/Longjmp (SJLJ) based exception handling uses LLVM intrinsics `llvm.eh.sjlj.setjmp` and `llvm.eh.sjlj.longjmp` to handle control flow for exception handling.

For each function which does exception processing --- be it `try/catch` blocks or cleanups --- that function registers itself on a global frame list. When exceptions are unwinding, the runtime uses this list to identify which functions need processing.

Landing pad selection is encoded in the call site entry of the function context. The runtime returns to the function via `llvm.eh.sjlj.longjmp`, where a switch table transfers control to the appropriate landing pad based on the index stored in the function context.

In contrast to DWARF exception handling, which encodes exception regions and frame information in out-of-line tables, SJLJ exception handling builds and removes the unwind frame context at runtime. This results in faster exception handling at the expense of slower execution when no exceptions are thrown. As exceptions are, by their nature, intended for uncommon code paths, DWARF exception handling is generally preferred to SJLJ.

Windows Runtime Exception Handling

LLVM supports handling exceptions produced by the Windows runtime, but it requires a very different intermediate representation. It is not based on the "*landingpad*" instruction like the other two models, and is described later in this document under *Exception Handling using the Windows Runtime*.

Overview

When an exception is thrown in LLVM code, the runtime does its best to find a handler suited to processing the circumstance.

The runtime first attempts to find an *exception frame* corresponding to the function where the exception was thrown. If the programming language supports exception handling (e.g. C++), the exception frame contains a reference to an exception table describing how to process the exception. If the language does not support exception handling (e.g. C), or if the exception needs to be forwarded to a prior activation, the exception frame contains information about how to unwind the current activation and restore the state of the prior activation. This process is repeated until the exception is handled. If the exception is not handled and no activations remain, then the application is terminated with an appropriate error message.

Because different programming languages have different behaviors when handling exceptions, the exception handling ABI provides a mechanism for supplying *personalities*. An exception handling personality is defined by way of a *personality function* (e.g. `__gxx_personality_v0` in C++), which receives the context of the exception, an *exception structure* containing the exception object type and value, and a reference to the exception table for the current function. The personality function for the current compile unit is specified in a *common exception frame*.

The organization of an exception table is language dependent. For C++, an exception table is organized as a series of code ranges defining what to do if an exception occurs in that range. Typically, the information associated with a range defines which types of exception objects (using C++ *type info*) that are handled in that range, and an associated action that should take place. Actions typically pass control to a *landing pad*.

A landing pad corresponds roughly to the code found in the `catch` portion of a `try/catch` sequence. When execution resumes at a landing pad, it receives an *exception structure* and a *selector value* corresponding to the *type* of exception thrown. The selector is then used to determine which *catch* should actually process the exception.

4.8.2 LLVM Code Generation

From a C++ developer's perspective, exceptions are defined in terms of the `throw` and `try/catch` statements. In this section we will describe the implementation of LLVM exception handling in terms of C++ examples.

Throw

Languages that support exception handling typically provide a `throw` operation to initiate the exception process. Internally, a `throw` operation breaks down into two steps.

1. A request is made to allocate exception space for an exception structure. This structure needs to survive beyond the current activation. This structure will contain the type and value of the object being thrown.
2. A call is made to the runtime to raise the exception, passing the exception structure as an argument.

In C++, the allocation of the exception structure is done by the `__cxa_allocate_exception` runtime function. The exception raising is handled by `__cxa_throw`. The type of the exception is represented using a C++ RTTI structure.

Try/Catch

A call within the scope of a *try* statement can potentially raise an exception. In those circumstances, the LLVM C++ front-end replaces the call with an *invoke* instruction. Unlike a call, the *invoke* has two potential continuation points:

1. where to continue when the call succeeds as per normal, and
2. where to continue if the call raises an exception, either by a throw or the unwinding of a throw

The term used to define the place where an *invoke* continues after an exception is called a *landing pad*. LLVM landing pads are conceptually alternative function entry points where an exception structure reference and a type info index are passed in as arguments. The landing pad saves the exception structure reference and then proceeds to select the catch block that corresponds to the type info of the exception object.

The LLVM '*landingpad*' *Instruction* is used to convey information about the landing pad to the back end. For C++, the *landingpad* instruction returns a pointer and integer pair corresponding to the pointer to the *exception structure* and the *selector value* respectively.

The *landingpad* instruction looks for a reference to the personality function to be used for this *try/catch* sequence in the parent function's attribute list. The instruction contains a list of *cleanup*, *catch*, and *filter* clauses. The exception is tested against the clauses sequentially from first to last. The clauses have the following meanings:

- *catch* <type> @ExcType
 - This clause means that the landingpad block should be entered if the exception being thrown is of type @ExcType or a subtype of @ExcType. For C++, @ExcType is a pointer to the `std::type_info` object (an RTTI object) representing the C++ exception type.
 - If @ExcType is null, any exception matches, so the landingpad should always be entered. This is used for C++ catch-all blocks (`"catch (...)"`).
 - When this clause is matched, the selector value will be equal to the value returned by `"@llvm.eh.typeid.for(i8* @ExcType)"`. This will always be a positive value.
- *filter* <type> [<type> @ExcType1, ..., <type> @ExcTypeN]
 - This clause means that the landingpad should be entered if the exception being thrown does *not* match any of the types in the list (which, for C++, are again specified as `std::type_info` pointers).
 - C++ front-ends use this to implement C++ exception specifications, such as `"void foo() throw (ExcType1, ..., ExcTypeN) { ... }"`.
 - When this clause is matched, the selector value will be negative.
 - The array argument to *filter* may be empty; for example, `"[0 x i8**] undef"`. This means that the landingpad should always be entered. (Note that such a *filter* would not be equivalent to `"catch i8* null"`, because *filter* and *catch* produce negative and positive selector values respectively.)
- *cleanup*
 - This clause means that the landingpad should always be entered.
 - C++ front-ends use this for calling objects' destructors.
 - When this clause is matched, the selector value will be zero.
 - The runtime may treat `"cleanup"` differently from `"catch <type> null"`.

In C++, if an unhandled exception occurs, the language runtime will call `std::terminate()`, but it is implementation-defined whether the runtime unwinds the stack and calls object destructors first. For example, the GNU C++ unwinder does not call object destructors when an unhandled exception occurs. The reason for this is to improve debuggability: it ensures that `std::terminate()` is called from the context of the *throw*, so that this context is not lost by unwinding the stack. A runtime will typically

implement this by searching for a matching `non-cleanup` clause, and aborting if it does not find one, before entering any landingpad blocks.

Once the landing pad has the type info selector, the code branches to the code for the first catch. The catch then checks the value of the type info selector against the index of type info for that catch. Since the type info index is not known until all the type infos have been gathered in the backend, the catch code must call the *llvm.eh.typeid.for* intrinsic to determine the index for a given type info. If the catch fails to match the selector then control is passed on to the next catch.

Finally, the entry and exit of catch code is bracketed with calls to `__cxa_begin_catch` and `__cxa_end_catch`.

- `__cxa_begin_catch` takes an exception structure reference as an argument and returns the value of the exception object.
- `__cxa_end_catch` takes no arguments. This function:
 1. Locates the most recently caught exception and decrements its handler count,
 2. Removes the exception from the *caught* stack if the handler count goes to zero, and
 3. Destroys the exception if the handler count goes to zero and the exception was not re-thrown by throw.

Note: a rethrow from within the catch may replace this call with a `__cxa_rethrow`.

Cleanups

A cleanup is extra code which needs to be run as part of unwinding a scope. C++ destructors are a typical example, but other languages and language extensions provide a variety of different kinds of cleanups. In general, a landing pad may need to run arbitrary amounts of cleanup code before actually entering a catch block. To indicate the presence of cleanups, a *'landingpad' Instruction* should have a *cleanup* clause. Otherwise, the unwinder will not stop at the landing pad if there are no catches or filters that require it to.

Note: Do not allow a new exception to propagate out of the execution of a cleanup. This can corrupt the internal state of the unwinder. Different languages describe different high-level semantics for these situations: for example, C++ requires that the process be terminated, whereas Ada cancels both exceptions and throws a third.

When all cleanups are finished, if the exception is not handled by the current function, resume unwinding by calling the *resume instruction*, passing in the result of the `landingpad` instruction for the original landing pad.

Throw Filters

C++ allows the specification of which exception types may be thrown from a function. To represent this, a top level landing pad may exist to filter out invalid types. To express this in LLVM code the *'landingpad' Instruction* will have a filter clause. The clause consists of an array of type infos. `landingpad` will return a negative value if the exception does not match any of the type infos. If no match is found then a call to `__cxa_call_unexpected` should be made, otherwise `_Unwind_Resume`. Each of these functions requires a reference to the exception structure. Note that the most general form of a `landingpad` instruction can have any number of catch, cleanup, and filter clauses (though having more than one cleanup is pointless). The LLVM C++ front-end can generate such `landingpad` instructions due to inlining creating nested exception handling scopes.

Restrictions

The unwinder delegates the decision of whether to stop in a call frame to that call frame's language-specific personality function. Not all unwinders guarantee that they will stop to perform cleanups. For example, the GNU C++ unwinder doesn't do so unless the exception is actually caught somewhere further up the stack.

In order for inlining to behave correctly, landing pads must be prepared to handle selector results that they did not originally advertise. Suppose that a function catches exceptions of type A, and it's inlined into a function that catches exceptions of type B. The inliner will update the `landingpad` instruction for the inlined landing pad to include the fact that B is also caught. If that landing pad assumes that it will only be entered to catch an A, it's in for a rude awakening. Consequently, landing pads must test for the selector results they understand and then resume exception propagation with the [resume instruction](#) if none of the conditions match.

4.8.3 Exception Handling Intrinsics

In addition to the `landingpad` and `resume` instructions, LLVM uses several intrinsic functions (name prefixed with `llvm.eh`) to provide exception handling information at various points in generated code.

`llvm.eh.typeid.for`

```
i32 @llvm.eh.typeid.for(i8* %type_info)
```

This intrinsic returns the type info index in the exception table of the current function. This value can be used to compare against the result of `landingpad` instruction. The single argument is a reference to a type info.

Uses of this intrinsic are generated by the C++ front-end.

`llvm.eh.begincatch`

```
void @llvm.eh.begincatch(i8* %ehptr, i8* %ehobj)
```

This intrinsic marks the beginning of catch handling code within the blocks following a `landingpad` instruction. The exact behavior of this function depends on the compilation target and the personality function associated with the `landingpad` instruction.

The first argument to this intrinsic is a pointer that was previously extracted from the aggregate return value of the `landingpad` instruction. The second argument to the intrinsic is a pointer to stack space where the exception object should be stored. The runtime handles the details of copying the exception object into the slot. If the second parameter is null, no copy occurs.

Uses of this intrinsic are generated by the C++ front-end. Many targets will use implementation-specific functions (such as `__cxa_begin_catch`) instead of this intrinsic. The intrinsic is provided for targets that require a more abstract interface.

When used in the native Windows C++ exception handling implementation, this intrinsic serves as a placeholder to delimit code before a catch handler is outlined. When the handler is outlined, this intrinsic will be replaced by instructions that retrieve the exception object pointer from the frame allocation block.

`llvm.eh.endcatch`

```
void @llvm.eh.endcatch()
```

This intrinsic marks the end of catch handling code within the current block, which will be a successor of a block which called `llvm.eh.begincatch`'. The exact behavior of this function depends on the compilation target and the personality function associated with the corresponding `landingpad` instruction.

There may be more than one call to `llvm.eh.endcatch` for any given call to `llvm.eh.begincatch` with each `llvm.eh.endcatch` call corresponding to the end of a different control path. All control paths following a call to `llvm.eh.begincatch` must reach a call to `llvm.eh.endcatch`.

Uses of this intrinsic are generated by the C++ front-end. Many targets will use implementation-specific functions (such as `__cxa_begin_catch`) instead of this intrinsic. The intrinsic is provided for targets that require a more abstract interface.

When used in the native Windows C++ exception handling implementation, this intrinsic serves as a placeholder to delimit code before a catch handler is outlined. After the handler is outlined, this intrinsic is simply removed.

`llvm.eh.exceptionpointer`

```
i8 addrspace(N) * @llvm.eh.padparam.pNi8(token %catchpad)
```

This intrinsic retrieves a pointer to the exception caught by the given `catchpad`.

SJLJ Intrinsics

The `llvm.eh.sjlj` intrinsics are used internally within LLVM's backend. Uses of them are generated by the backend's `SjLjEHPrepare` pass.

`llvm.eh.sjlj.setjmp`

```
i32 @llvm.eh.sjlj.setjmp(i8* %setjmp_buf)
```

For SJLJ based exception handling, this intrinsic forces register saving for the current function and stores the address of the following instruction for use as a destination address by [llvm.eh.sjlj.longjmp](#). The buffer format and the overall functioning of this intrinsic is compatible with the GCC `__builtin_setjmp` implementation allowing code built with the clang and GCC to interoperate.

The single parameter is a pointer to a five word buffer in which the calling context is saved. The front end places the frame pointer in the first word, and the target implementation of this intrinsic should place the destination address for a [llvm.eh.sjlj.longjmp](#) in the second word. The following three words are available for use in a target-specific manner.

`llvm.eh.sjlj.longjmp`

```
void @llvm.eh.sjlj.longjmp(i8* %setjmp_buf)
```

For SJLJ based exception handling, the `llvm.eh.sjlj.longjmp` intrinsic is used to implement `__builtin_longjmp()`. The single parameter is a pointer to a buffer populated by `llvm.eh.sjlj.setjmp`. The frame pointer and stack pointer are restored from the buffer, then control is transferred to the destination address.

`llvm.eh.sjlj.lsd`

```
i8* @llvm.eh.sjlj.lsd()
```

For SJLJ based exception handling, the `llvm.eh.sjlj.lsd` intrinsic returns the address of the Language Specific Data Area (LSDA) for the current function. The SJLJ front-end code stores this address in the exception handling function context for use by the runtime.

`llvm.eh.sjlj.callsite`

```
void @llvm.eh.sjlj.callsite(i32 %call_site_num)
```

For SJLJ based exception handling, the `llvm.eh.sjlj.callsite` intrinsic identifies the callsite value associated with the following `invoke` instruction. This is used to ensure that landing pad entries in the LSDA are generated in matching order.

4.8.4 Asm Table Formats

There are two tables that are used by the exception handling runtime to determine which actions should be taken when an exception is thrown.

Exception Handling Frame

An exception handling frame `eh_frame` is very similar to the unwind frame used by DWARF debug info. The frame contains all the information necessary to tear down the current frame and restore the state of the prior frame. There is an exception handling frame for each function in a compile unit, plus a common exception handling frame that defines information common to all functions in the unit.

The format of this call frame information (CFI) is often platform-dependent, however. ARM, for example, defines their own format. Apple has their own compact unwind info format. On Windows, another format is used for all architectures since 32-bit x86. LLVM will emit whatever information is required by the target.

Exception Tables

An exception table contains information about what actions to take when an exception is thrown in a particular part of a function's code. This is typically referred to as the language-specific data area (LSDA). The format of the LSDA table is specific to the personality function, but the majority of personalities out there use a variation of the tables consumed by `__gxx_personality_v0`. There is one exception table per function, except leaf functions and functions that have calls only to non-throwing functions. They do not need an exception table.

4.8.5 Exception Handling using the Windows Runtime

Background on Windows exceptions

Interacting with exceptions on Windows is significantly more complicated than on Itanium C++ ABI platforms. The fundamental difference between the two models is that Itanium EH is designed around the idea of "successive unwinding," while Windows EH is not.

Under Itanium, throwing an exception typically involves allocating thread local memory to hold the exception, and calling into the EH runtime. The runtime identifies frames with appropriate exception handling actions, and successively resets the register context of the current thread to the most recently active frame with actions to run. In LLVM, execution resumes at a `landingpad` instruction, which produces register values provided by the runtime. If a function is only cleaning up allocated resources, the function is responsible for calling `_Unwind_Resume` to transition to the next most recently active frame after it is finished cleaning up. Eventually, the frame responsible for handling the exception calls `__cxa_end_catch` to destroy the exception, release its memory, and resume normal control flow.

The Windows EH model does not use these successive register context resets. Instead, the active exception is typically described by a frame on the stack. In the case of C++ exceptions, the exception object is allocated in stack memory and its address is passed to `__CxxThrowException`. General purpose structured exceptions (SEH) are more analogous to Linux signals, and they are dispatched by userspace DLLs provided with Windows. Each frame on the stack has an assigned EH personality routine, which decides what actions to take to handle the exception. There are a few major personalities for C and C++ code: the C++ personality (`__CxxFrameHandler3`) and the SEH personalities (`_except_handler3`, `_except_handler4`, and `__C_specific_handler`). All of them implement cleanups by calling back into a "funclet" contained in the parent function.

Funclets, in this context, are regions of the parent function that can be called as though they were a function pointer with a very special calling convention. The frame pointer of the parent frame is passed into the funclet either using the standard EBP register or as the first parameter register, depending on the architecture. The funclet implements the EH action by accessing local variables in memory through the frame pointer, and returning some appropriate value, continuing the EH process. No variables live in to or out of the funclet can be allocated in registers.

The C++ personality also uses funclets to contain the code for catch blocks (i.e. all user code between the braces in `catch (Type obj) { ... }`). The runtime must use funclets for catch bodies because the C++ exception object is allocated in a child stack frame of the function handling the exception. If the runtime rewound the stack back to frame of the catch, the memory holding the exception would be overwritten quickly by subsequent function calls. The use of funclets also allows `__CxxFrameHandler3` to implement rethrow without resorting to TLS. Instead, the runtime throws a special exception, and then uses SEH (`__try` / `__except`) to resume execution with new information in the child frame.

In other words, the successive unwinding approach is incompatible with Visual C++ exceptions and general purpose Windows exception handling. Because the C++ exception object lives in stack memory, LLVM cannot provide a custom personality function that uses landingpads. Similarly, SEH does not provide any mechanism to rethrow an exception or continue unwinding. Therefore, LLVM must use the IR constructs described later in this document to implement compatible exception handling.

SEH filter expressions

The SEH personality functions also use funclets to implement filter expressions, which allow executing arbitrary user code to decide which exceptions to catch. Filter expressions should not be confused with the `filter` clause of the LLVM `landingpad` instruction. Typically filter expressions are used to determine if the exception came from a particular DLL or code region, or if code faulted while accessing a particular memory address range. LLVM does not currently have IR to represent filter expressions because it is difficult to represent their control dependencies. Filter expressions run during the first phase of EH, before cleanups run, making it very difficult to build a faithful control flow graph. For now, the new EH instructions cannot represent SEH filter expressions, and frontends must outline them ahead of time. Local variables of the parent function can be escaped and accessed using the `llvm.localescope` and `llvm.localrecover` intrinsics.

New exception handling instructions

The primary design goal of the new EH instructions is to support funclet generation while preserving information about the CFG so that SSA formation still works. As a secondary goal, they are designed to be generic across MSVC and Itanium C++ exceptions. They make very few assumptions about the data required by the personality, so long as it uses the familiar core EH actions: `catch`, `cleanup`, and `terminate`. However, the new instructions are hard to modify without knowing details of the EH personality. While they can be used to represent Itanium EH, the `landingpad` model is strictly better for optimization purposes.

The following new instructions are considered "exception handling pads", in that they must be the first non-phi instruction of a basic block that may be the unwind destination of an EH flow edge: `catchswitch`, `catchpad`, and `cleanuppad`. As with `landingpads`, when entering a try scope, if the frontend encounters a call site that may throw an exception, it should emit an `invoke` that unwinds to a `catchswitch` block. Similarly, inside the scope of a C++ object with a destructor, `invokes` should unwind to a `cleanuppad`.

New instructions are also used to mark the points where control is transferred out of a catch/cleanup handler (which will correspond to exits from the generated funclet). A catch handler which reaches its end by normal execution executes a `catchret` instruction, which is a terminator indicating where in the function control is returned to. A cleanup handler which reaches its end by normal execution executes a `cleanupret` instruction, which is a terminator indicating where the active exception will unwind to next.

Each of these new EH pad instructions has a way to identify which action should be considered after this action. The `catchswitch` instruction is a terminator and has an unwind destination operand analogous to the unwind destination of an `invoke`. The `cleanuppad` instruction is not a terminator, so the unwind destination is stored on the `cleanupret` instruction instead. Successfully executing a catch handler should resume normal control flow, so neither `catchpad` nor `catchret` instructions can unwind. All of these "unwind edges" may refer to a basic block that contains an EH pad instruction, or they may unwind to the caller. Unwinding to the caller has roughly the same semantics as the `resume` instruction in the `landingpad` model. When inlining through an `invoke`, instructions that unwind to the caller are hooked up to unwind to the unwind destination of the call site.

Putting things together, here is a hypothetical lowering of some C++ that uses all of the new IR instructions:

```
struct Cleanup {
    Cleanup();
    ~Cleanup();
    int m;
};

void may_throw();
int f() noexcept {
    try {
        Cleanup obj;
        may_throw();
    } catch (int e) {
        may_throw();
    }
}
```

(continues on next page)

(continued from previous page)

```

    return e;
}
return 0;
}

```

```

define i32 @f() nounwind personality i32 (...)@__CxxFrameHandler3 {
entry:
    %obj = alloca %struct.Cleanup, align 4
    %e = alloca i32, align 4
    %call = invoke %struct.Cleanup* @"\01??0Cleanup@@QEAA@XZ"(%struct.Cleanup* nonnull
↳%obj)
        to label %invoke.cont unwind label %lpad.catch

invoke.cont:
    ; preds = %entry
    invoke void @"\01?may_throw@@YAXXZ"()
        to label %invoke.cont.2 unwind label %lpad.cleanup

invoke.cont.2:
    ; preds = %invoke.cont
    call void @"\01??_DCleanup@@QEAA@XZ"(%struct.Cleanup* nonnull %obj) nounwind
    br label %return

return:
    ; preds = %invoke.cont.3, %invoke.
↳cont.2
    %retval.0 = phi i32 [ 0, %invoke.cont.2 ], [ %3, %invoke.cont.3 ]
    ret i32 %retval.0

lpad.cleanup:
    ; preds = %invoke.cont.2
    %0 = cleanuppadd within none []
    call void @"\01??_lCleanup@@QEAA@XZ"(%struct.Cleanup* nonnull %obj) nounwind
    cleanupret %0 unwind label %lpad.catch

lpad.catch:
    ; preds = %lpad.cleanup, %entry
    %1 = catchswitch within none [label %catch.body] unwind label %lpad.terminate

catch.body:
    ; preds = %lpad.catch
    %catch = catchpad within %1 [%rtti.TypeDescriptor2* @"\01??_R0H@8", i32 0, i32* %e]
    invoke void @"\01?may_throw@@YAXXZ"()
        to label %invoke.cont.3 unwind label %lpad.terminate

invoke.cont.3:
    ; preds = %catch.body
    %3 = load i32, i32* %e, align 4
    catchret from %catch to label %return

lpad.terminate:
    ; preds = %catch.body, %lpad.catch
    cleanuppadd within none []
    call void @"\01?terminate@@YAXXZ"
    unreachable
}

```

Funclet parent tokens

In order to produce tables for EH personalities that use funclets, it is necessary to recover the nesting that was present in the source. This funclet parent relationship is encoded in the IR using tokens produced by the new "pad" instructions. The token operand of a "pad" or "ret" instruction indicates which funclet it is in, or "none" if it is not nested within another funclet.

The `catchpad` and `cleanuppadd` instructions establish new funclets, and their tokens are consumed by other "pad" instructions to establish membership. The `catchswitch` instruction does not create a funclet, but it produces a token that is always consumed by its immediate successor `catchpad` instructions. This ensures that every catch handler modelled by a `catchpad` belongs to exactly one `catchswitch`, which models the dispatch point after a C++ try.

Here is an example of what this nesting looks like using some hypothetical C++ code:

```
void f() {
  try {
    throw;
  } catch (...) {
    try {
      throw;
    } catch (...) {
    }
  }
}
```

```
define void @f() #0 personality i8* bitcast (i32 (...) * @__CxxFrameHandler3 to i8*) {
entry:
  invoke void @_CxxThrowException(i8* null, %eh.ThrowInfo* null) #1
    to label %unreachable unwind label %catch.dispatch

catch.dispatch:
    ; preds = %entry
  %0 = catchswitch within none [label %catch] unwind to caller

catch:
    ; preds = %catch.dispatch
  %1 = catchpad within %0 [i8* null, i32 64, i8* null]
  invoke void @_CxxThrowException(i8* null, %eh.ThrowInfo* null) #1
    to label %unreachable unwind label %catch.dispatch2

catch.dispatch2:
    ; preds = %catch
  %2 = catchswitch within %1 [label %catch3] unwind to caller

catch3:
    ; preds = %catch.dispatch2
  %3 = catchpad within %2 [i8* null, i32 64, i8* null]
  catchret from %3 to label %try.cont

try.cont:
    ; preds = %catch3
  catchret from %1 to label %try.cont6

try.cont6:
    ; preds = %try.cont
  ret void

unreachable:
    ; preds = %catch, %entry
  unreachable
}
```

The "inner" catchswitch consumes %1 which is produced by the outer catchswitch.

Funclet transitions

The EH tables for personalities that use funclets make implicit use of the funclet nesting relationship to encode unwind destinations, and so are constrained in the set of funclet transitions they can represent. The related LLVM IR instructions accordingly have constraints that ensure encodability of the EH edges in the flow graph.

A `catchswitch`, `catchpad`, or `cleanuppad` is said to be "entered" when it executes. It may subsequently be "exited" by any of the following means:

- A `catchswitch` is immediately exited when none of its constituent `catchpads` are appropriate for the in-flight exception and it unwinds to its unwind destination or the caller.
- A `catchpad` and its parent `catchswitch` are both exited when a `catchret` from the `catchpad` is executed.
- A `cleanuppad` is exited when a `cleanupret` from it is executed.
- Any of these pads is exited when control unwinds to the function's caller, either by a `call` which unwinds all the way to the function's caller, a nested `catchswitch` marked "unwinds to caller", or a nested `cleanuppad`'s `cleanupret` marked "unwinds to caller".
- Any of these pads is exited when an unwind edge (from an `invoke`, nested `catchswitch`, or nested `cleanuppad`'s `cleanupret`) unwinds to a destination pad that is not a descendant of the given pad.

Note that the `ret` instruction is *not* a valid way to exit a funclet pad; it is undefined behavior to execute a `ret` when a pad has been entered but not exited.

A single unwind edge may exit any number of pads (with the restrictions that the edge from a `catchswitch` must exit at least itself, and the edge from a `cleanupret` must exit at least its `cleanuppad`), and then must enter exactly one pad, which must be distinct from all the exited pads. The parent of the pad that an unwind edge enters must be the most-recently-entered not-yet-exited pad (after exiting from any pads that the unwind edge exits), or "none" if there is no such pad. This ensures that the stack of executing funclets at run-time always corresponds to some path in the funclet pad tree that the parent tokens encode.

All unwind edges which exit any given funclet pad (including `cleanupret` edges exiting their `cleanuppad` and `catchswitch` edges exiting their `catchswitch`) must share the same unwind destination. Similarly, any funclet pad which may be exited by unwind to caller must not be exited by any exception edges which unwind anywhere other than the caller. This ensures that each funclet as a whole has only one unwind destination, which EH tables for funclet personalities may require. Note that any unwind edge which exits a `catchpad` also exits its parent `catchswitch`, so this implies that for any given `catchswitch`, its unwind destination must also be the unwind destination of any unwind edge that exits any of its constituent `catchpads`. Because `catchswitch` has no `nounwind` variant, and because IR producers are not *required* to annotate calls which will not unwind as `nounwind`, it is legal to nest a `call` or an "unwind to caller" `catchswitch` within a funclet pad that has an unwind destination other than caller; it is undefined behavior for such a `call` or `catchswitch` to unwind.

Finally, the funclet pads' unwind destinations cannot form a cycle. This ensures that EH lowering can construct "try regions" with a tree-like structure, which funclet-based personalities may require.

4.8.6 Exception Handling support on the target

In order to support exception handling on particular target, there are a few items need to be implemented.

- CFI directives

First, you have to assign each target register with a unique DWARF number. Then in `TargetFrameLowering`'s `emitPrologue`, you have to emit CFI directives to specify how to calculate the CFA (Canonical Frame Address) and how register is restored from the address pointed by the CFA with an offset. The assembler is instructed by CFI directives to build `.eh_frame` section, which is used by the unwinder to unwind stack during exception handling.

- `getExceptionPointerRegister` and `getExceptionSelectorRegister`

`TargetLowering` must implement both functions. The *personality function* passes the *exception structure* (a pointer) and *selector value* (an integer) to the landing pad through the registers specified by `getExceptionPointerRegister` and `getExceptionSelectorRegister` respectively. On most platforms, they will be GPRs and will be the same as the ones specified in the calling convention.

- `EH_RETURN`

The ISD node represents the undocumented GCC extension `__builtin_eh_return (offset, handler)`, which adjusts the stack by offset and then jumps to the handler. `__builtin_eh_return` is used in GCC unwinder (`libgcc`), but not in LLVM unwinder (`libunwind`). If you are on the top of `libgcc` and have particular requirement on your target, you have to handle `EH_RETURN` in `TargetLowering`.

If you don't leverage the existing runtime (`libstdc++` and `libgcc`), you have to take a look on `libc++` and `libunwind` to see what have to be done there. For `libunwind`, you have to do the following

- `__libunwind_config.h`

Define macros for your target.

- `include/libunwind.h`

Define enum for the target registers.

- `src/Registers.hpp`

Define `Registers` class for your target, implement setter and getter functions.

- `src/UnwindCursor.hpp`

Define `dwarfEncoding` and `stepWithCompactEncoding` for your `Registers` class.

- `src/UnwindRegistersRestore.S`

Write an assembly function to restore all your target registers from the memory.

- `src/UnwindRegistersSave.S`

Write an assembly function to save all your target registers on the memory.

4.9 How To Add A Constrained Floating-Point Intrinsic

- *Add the intrinsic*
- *Add SelectionDAG node types*
 - *Building the SelectionDAG*
- *Add documentation and tests*

Warning: This is a work in progress.

4.9.1 Add the intrinsic

Multiple files need to be updated when adding a new constrained intrinsic.

Add the new intrinsic to the table of intrinsics.:

```
include/llvm/IR/Intrinsics.td
```

Update class `ConstrainedFPIntrinsic` to know about the intrinsics.:

```
include/llvm/IR/IntrinsicInst.h
```

Functions like `ConstrainedFPIntrinsic::isUnaryOp()` or `ConstrainedFPIntrinsic::isTernaryOp()` may need to know about the new intrinsic.:

```
lib/IR/IntrinsicInst.cpp
```

Update the IR verifier:

```
lib/IR/Verifier.cpp
```

4.9.2 Add SelectionDAG node types

Add the new STRICT version of the node type to the `ISD::NodeType` enum.:

```
include/llvm/CodeGen/ISDOpcodes.h
```

In class `SDNode` update `isStrictFPOpcode()`:

```
include/llvm/CodeGen/SelectionDAGNodes.h
```

A mapping from the STRICT SDnode type to the non-STRICT is done in `TargetLowering-Base::getStrictFPOperationAction()`. This allows STRICT nodes to be legalized similarly to the non-STRICT node type.:

```
include/llvm/CodeGen/TargetLowering.h
```

Building the SelectionDAG

The switch statement in `SelectionDAGBuilder::visitIntrinsicCall()` needs to be updated to call `SelectionDAGBuilder::visitConstrainedFPIntrinsic()`. That function, in turn, needs to be updated to know how to create the `SDNode` for the intrinsic. The new STRICT node will eventually be converted to the matching non-STRICT node. For this reason it should have the same operands and values as the non-STRICT version but should also use the chain. This makes subsequent sharing of code for STRICT and non-STRICT code paths easier.:

```
lib/CodeGen/SelectionDAG/SelectionDAGBuilder.cpp
```

Most of the STRICT nodes get legalized the same as their matching non-STRICT counterparts. A new STRICT node with this property must get added to the switch in `SelectionDAGLegalize::LegalizeOp()`.:

```
lib/CodeGen/SelectionDAG/LegalizeDAG.cpp
```

Other parts of the legalizer may need to be updated as well. Look for places where the non-STRICT counterpart is legalized and update as needed. Be careful of the chain since STRICT nodes use it but their counterparts often don't.

The code to do the conversion or mutation of the STRICT node to a non-STRICT version of the node happens in `SelectionDAG::mutateStrictFPToFP()`. Be careful updating this function since some nodes have the same return type as their input operand, but some are different. Both of these cases must be properly handled.:

```
lib/CodeGen/SelectionDAG/SelectionDAG.cpp
```

However, the mutation may not happen if the new node has not been registered in `TargetLoweringBase::initActions()`. If the corresponding non-STRICT node is Legal but a target does not know about STRICT nodes then the STRICT node will default to Legal and mutation will be bypassed with a "Cannot select" error. Register the new STRICT node as Expand to avoid this bug.:

```
lib/CodeGen/TargetLoweringBase.cpp
```

To make debug logs readable it is helpful to update the SelectionDAG's debug logger.:

```
lib/CodeGen/SelectionDAG/SelectionDAGDumper.cpp
```

4.9.3 Add documentation and tests

```
docs/LangRef.rst
```

4.10 LLVM Link Time Optimization: Design and Implementation

- *Description*
- *Design Philosophy*
 - *Example of link time optimization*
 - *Alternative Approaches*
- *Multi-phase communication between libLTO and linker*
 - *Phase 1 : Read LLVM Bitcode Files*
 - *Phase 2 : Symbol Resolution*
 - *Phase 3 : Optimize Bitcode Files*
 - *Phase 4 : Symbol Resolution after optimization*
- *libLTO*
 - *lto_module_t*
 - *lto_code_gen_t*

4.10.1 Description

LLVM features powerful intermodular optimizations which can be used at link time. Link Time Optimization (LTO) is another name for intermodular optimization when performed during the link stage. This document describes the interface and design between the LTO optimizer and the linker.

4.10.2 Design Philosophy

The LLVM Link Time Optimizer provides complete transparency, while doing intermodular optimization, in the compiler tool chain. Its main goal is to let the developer take advantage of intermodular optimizations without making any significant changes to the developer's makefiles or build system. This is achieved through tight integration with the linker. In this model, the linker treats LLVM bitcode files like native object files and allows mixing and matching among them. The linker uses *libLTO*, a shared object, to handle LLVM bitcode files. This tight integration between the linker and LLVM optimizer helps to do optimizations that are not possible in other models. The linker input allows the optimizer to avoid relying on conservative escape analysis.

Example of link time optimization

The following example illustrates the advantages of LTO's integrated approach and clean interface. This example requires a system linker which supports LTO through the interface described in this document. Here, clang transparently invokes system linker.

- Input source file `a.c` is compiled into LLVM bitcode form.
- Input source file `main.c` is compiled into native object code.

```

--- a.h ---
extern int  foo1(void);
extern void foo2(void);
extern void foo4(void);

--- a.c ---
#include "a.h"

static signed int i = 0;

void foo2(void) {
    i = -1;
}

static int foo3() {
    foo4();
    return 10;
}

int foo1(void) {
    int data = 0;

    if (i < 0)
        data = foo3();

    data = data + 42;
    return data;
}

```

(continues on next page)

(continued from previous page)

```

--- main.c ---
#include <stdio.h>
#include "a.h"

void foo4(void) {
    printf("Hi\n");
}

int main() {
    return foo1();
}

```

To compile, run:

```

% clang -flto -c a.c -o a.o           # <-- a.o is LLVM bitcode file
% clang -c main.c -o main.o          # <-- main.o is native object file
% clang -flto a.o main.o -o main     # <-- standard link command with -flto

```

- In this example, the linker recognizes that `foo2()` is an externally visible symbol defined in LLVM bitcode file. The linker completes its usual symbol resolution pass and finds that `foo2()` is not used anywhere. This information is used by the LLVM optimizer and it removes `foo2()`.
- As soon as `foo2()` is removed, the optimizer recognizes that condition `i < 0` is always false, which means `foo3()` is never used. Hence, the optimizer also removes `foo3()`.
- And this in turn, enables linker to remove `foo4()`.

This example illustrates the advantage of tight integration with the linker. Here, the optimizer can not remove `foo3()` without the linker's input.

Alternative Approaches

Compiler driver invokes link time optimizer separately. In this model the link time optimizer is not able to take advantage of information collected during the linker's normal symbol resolution phase. In the above example, the optimizer can not remove `foo2()` without the linker's input because it is externally visible. This in turn prohibits the optimizer from removing `foo3()`.

Use separate tool to collect symbol information from all object files. In this model, a new, separate, tool or library replicates the linker's capability to collect information for link time optimization. Not only is this code duplication difficult to justify, but it also has several other disadvantages. For example, the linking semantics and the features provided by the linker on various platform are not unique. This means, this new tool needs to support all such features and platforms in one super tool or a separate tool per platform is required. This increases maintenance cost for link time optimizer significantly, which is not necessary. This approach also requires staying synchronized with linker developments on various platforms, which is not the main focus of the link time optimizer. Finally, this approach increases end user's build time due to the duplication of work done by this separate tool and the linker itself.

4.10.3 Multi-phase communication between libLTO and linker

The linker collects information about symbol definitions and uses in various link objects which is more accurate than any information collected by other tools during typical build cycles. The linker collects this information by looking at the definitions and uses of symbols in native .o files and using symbol visibility information. The linker also uses user-supplied information, such as a list of exported symbols. LLVM optimizer collects control flow information, data flow information and knows much more about program structure from the optimizer's point of view. Our goal is to take advantage of tight integration between the linker and the optimizer by sharing this information during various linking phases.

Phase 1 : Read LLVM Bitcode Files

The linker first reads all object files in natural order and collects symbol information. This includes native object files as well as LLVM bitcode files. To minimize the cost to the linker in the case that all .o files are native object files, the linker only calls `lto_module_create()` when a supplied object file is found to not be a native object file. If `lto_module_create()` returns that the file is an LLVM bitcode file, the linker then iterates over the module using `lto_module_get_symbol_name()` and `lto_module_get_symbol_attribute()` to get all symbols defined and referenced. This information is added to the linker's global symbol table.

The `lto*` functions are all implemented in a shared object `libLTO`. This allows the LLVM LTO code to be updated independently of the linker tool. On platforms that support it, the shared object is lazily loaded.

Phase 2 : Symbol Resolution

In this stage, the linker resolves symbols using global symbol table. It may report undefined symbol errors, read archive members, replace weak symbols, etc. The linker is able to do this seamlessly even though it does not know the exact content of input LLVM bitcode files. If dead code stripping is enabled then the linker collects the list of live symbols.

Phase 3 : Optimize Bitcode Files

After symbol resolution, the linker tells the LTO shared object which symbols are needed by native object files. In the example above, the linker reports that only `foo1()` is used by native object files using `lto_codegen_add_must_preserve_symbol()`. Next the linker invokes the LLVM optimizer and code generators using `lto_codegen_compile()` which returns a native object file creating by merging the LLVM bitcode files and applying various optimization passes.

Phase 4 : Symbol Resolution after optimization

In this phase, the linker reads optimized a native object file and updates the internal global symbol table to reflect any changes. The linker also collects information about any changes in use of external symbols by LLVM bitcode files. In the example above, the linker notes that `foo4()` is not used any more. If dead code stripping is enabled then the linker refreshes the live symbol information appropriately and performs dead code stripping.

After this phase, the linker continues linking as if it never saw LLVM bitcode files.

4.10.4 libLTO

libLTO is a shared object that is part of the LLVM tools, and is intended for use by a linker. libLTO provides an abstract C interface to use the LLVM interprocedural optimizer without exposing details of LLVM's internals. The intention is to keep the interface as stable as possible even when the LLVM optimizer continues to evolve. It should even be possible for a completely different compilation technology to provide a different libLTO that works with their object files and the standard linker tool.

`lto_module_t`

A non-native object file is handled via an `lto_module_t`. The following functions allow the linker to check if a file (on disk or in a memory buffer) is a file which libLTO can process:

```
lto_module_is_object_file(const char*)
lto_module_is_object_file_for_target(const char*, const char*)
lto_module_is_object_file_in_memory(const void*, size_t)
lto_module_is_object_file_in_memory_for_target(const void*, size_t, const char*)
```

If the object file can be processed by libLTO, the linker creates a `lto_module_t` by using one of:

```
lto_module_create(const char*)
lto_module_create_from_memory(const void*, size_t)
```

and when done, the handle is released via

```
lto_module_dispose(lto_module_t)
```

The linker can introspect the non-native object file by getting the number of symbols and getting the name and attributes of each symbol via:

```
lto_module_get_num_symbols(lto_module_t)
lto_module_get_symbol_name(lto_module_t, unsigned int)
lto_module_get_symbol_attribute(lto_module_t, unsigned int)
```

The attributes of a symbol include the alignment, visibility, and kind.

`lto_code_gen_t`

Once the linker has loaded each non-native object files into an `lto_module_t`, it can request libLTO to process them all and generate a native object file. This is done in a couple of steps. First, a code generator is created with:

```
lto_codegen_create()
```

Then, each non-native object file is added to the code generator with:

```
lto_codegen_add_module(lto_code_gen_t, lto_module_t)
```

The linker then has the option of setting some codegen options. Whether or not to generate DWARF debug info is set with:

```
lto_codegen_set_debug_model(lto_code_gen_t)
```

which kind of position independence is set with:

```
lto_codegen_set_pic_model(lto_code_gen_t)
```

And each symbol that is referenced by a native object file or otherwise must not be optimized away is set with:

```
lto_codegen_add_must_preserve_symbol(lto_code_gen_t, const char*)
```

After all these settings are done, the linker requests that a native object file be created from the modules with the settings using:

```
lto_codegen_compile(lto_code_gen_t, size*)
```

which returns a pointer to a buffer containing the generated native object file. The linker then parses that and links it with the rest of the native object files.

4.11 Segmented Stacks in LLVM

- *Introduction*
- *Implementation Details*
 - *Allocating Stacklets*
 - *Variable Sized Allocas*

4.11.1 Introduction

Segmented stack allows stack space to be allocated incrementally than as a monolithic chunk (of some worst case size) at thread initialization. This is done by allocating stack blocks (henceforth called *stacklets*) and linking them into a doubly linked list. The function prologue is responsible for checking if the current stacklet has enough space for the function to execute; and if not, call into the libgcc runtime to allocate more stack space. Segmented stacks are enabled with the "split-stack" attribute on LLVM functions.

The runtime functionality is [already there in libgcc](#).

4.11.2 Implementation Details

Allocating Stacklets

As mentioned above, the function prologue checks if the current stacklet has enough space. The current approach is to use a slot in the TCB to store the current stack limit (minus the amount of space needed to allocate a new block) - this slot's offset is again dictated by libgcc. The generated assembly looks like this on x86-64:

```
leaq    -8(%rsp), %r10
cmpq    %fs:112, %r10
jg      .LBB0_2

# More stack space needs to be allocated
movabsq $8, %r10    # The amount of space needed
movabsq $0, %r11    # The total size of arguments passed on stack
callq   __morestack
```

(continues on next page)

(continued from previous page)

```
ret                # The reason for this extra return is explained below
.LBB0_2:
  # Usual prologue continues here
```

The size of function arguments on the stack needs to be passed to `__morestack` (this function is implemented in `libgcc`) since that number of bytes has to be copied from the previous stacklet to the current one. This is so that SP (and FP) relative addressing of function arguments work as expected.

The unusual `ret` is needed to have the function which made a call to `__morestack` return correctly. `__morestack`, instead of returning, calls into `.LBB0_2`. This is possible since both, the size of the `ret` instruction and the PC of call to `__morestack` are known. When the function body returns, control is transferred back to `__morestack`. `__morestack` then de-allocates the new stacklet, restores the correct SP value, and does a second return, which returns control to the correct caller.

Variable Sized Allocas

The section on *allocating stacklets* automatically assumes that every stack frame will be of fixed size. However, LLVM allows the use of the `llvm.alloca` intrinsic to allocate dynamically sized blocks of memory on the stack. When faced with such a variable-sized `alloca`, code is generated to:

- Check if the current stacklet has enough space. If yes, just bump the SP, like in the normal case.
- If not, generate a call to `libgcc`, which allocates the memory from the heap.

The memory allocated from the heap is linked into a list in the current stacklet, and freed along with the same. This prevents a memory leak.

Introduction

TableGen backends are at the core of TableGen's functionality. The source files provide the semantics to a generated (in memory) structure, but it's up to the backend to print this out in a way that is meaningful to the user (normally a C program including a file or a textual list of warnings, options and error messages).

TableGen is used by both LLVM and Clang with very different goals. LLVM uses it as a way to automate the generation of massive amounts of information regarding instructions, schedules, cores and architecture features. Some backends generate output that is consumed by more than one source file, so they need to be created in a way that is easy to use pre-processor tricks. Some backends can also print C code structures, so that they can be directly included as-is.

Clang, on the other hand, uses it mainly for diagnostic messages (errors, warnings, tips) and attributes, so more on the textual end of the scale.

LLVM BackEnds

Warning: This document is raw. Each section below needs three sub-sections: description of its purpose with a list of users, output generated from generic input, and finally why it needed a new backend (in case there's something similar).

Overall, each backend will take the same TableGen file type and transform into similar output for different targets/uses. There is an implicit contract between the TableGen files, the back-ends and their users.

For instance, a global contract is that each back-end produces macro-guarded sections. Based on whether the file is included by a header or a source file, or even in which context of each file the include is being used, you have to define a macro just before including it, to get the right output:

```
#define GET_REGINFO_TARGET_DESC
#include "ARMGenRegisterInfo.inc"
```

And just part of the generated file would be included. This is useful if you need the same information in multiple formats (instantiation, initialization, getter/setter functions, etc) from the same source TableGen file without having to re-compile the TableGen file multiple times.

Sometimes, multiple macros might be defined before the same include file to output multiple blocks:

```
#define GET_REGISTER_MATCHER
#define GET_SUBTARGET_FEATURE_NAME
#define GET_MATCHER_IMPLEMENTATION
#include "ARMGenAsmMatcher.inc"
```

The macros will be undef'd automatically as they're used, in the include file.

On all LLVM back-ends, the `llvm-tblgen` binary will be executed on the root TableGen file `<Target>.td`, which should include all others. This guarantees that all information needed is accessible, and that no duplication is needed in the TableGen files.

CodeEmitter

Purpose: CodeEmitterGen uses the descriptions of instructions and their fields to construct an automated code emitter: a function that, given a `MachineInstr`, returns the (currently, 32-bit unsigned) value of the instruction.

Output: C++ code, implementing the target's `CodeEmitter` class by overriding the virtual functions as `<Target>CodeEmitter::function()`.

Usage: Used to include directly at the end of `<Target>MCCodeEmitter.cpp`.

RegisterInfo

Purpose: This tablegen backend is responsible for emitting a description of a target register file for a code generator. It uses instances of the `Register`, `RegisterAliases`, and `RegisterClass` classes to gather this information.

Output: C++ code with enums and structures representing the register mappings, properties, masks, etc.

Usage: Both on `<Target>BaseRegisterInfo` and `<Target>MCTargetDesc` (headers and source files) with macros defining in which they are for declaration vs. initialization issues.

InstrInfo

Purpose: This tablegen backend is responsible for emitting a description of the target instruction set for the code generator. (what are the differences from CodeEmitter?)

Output: C++ code with enums and structures representing the instruction mappings, properties, masks, etc.

Usage: Both on `<Target>BaseInstrInfo` and `<Target>MCTargetDesc` (headers and source files) with macros defining in which they are for declaration vs. initialization issues.

AsmWriter

Purpose: Emits an assembly printer for the current target.

Output: Implementation of `<Target>InstPrinter::printInstruction()`, among other things.

Usage: Included directly into `InstPrinter/<Target>InstPrinter.cpp`.

AsmMatcher

Purpose: Emits a target specifier matcher for converting parsed assembly operands in the `MCIInst` structures. It also emits a matcher for custom operand parsing. Extensive documentation is written on the `AsmMatcherEmitter.cpp` file.

Output: Assembler parsers' matcher functions, declarations, etc.

Usage: Used in back-ends' `AsmParser/<Target>AsmParser.cpp` for building the `AsmParser` class.

Disassembler

Purpose: Contains disassembler table emitters for various architectures. Extensive documentation is written on the `DisassemblerEmitter.cpp` file.

Output: Decoding tables, static decoding functions, etc.

Usage: Directly included in `Disassembler/<Target>Disassembler.cpp` to cater for all default decodings, after all hand-made ones.

PseudoLowering

Purpose: Generate pseudo instruction lowering.

Output: Implements `<Target>AsmPrinter::emitPseudoExpansionLowering()`.

Usage: Included directly into `<Target>AsmPrinter.cpp`.

CallingConv

Purpose: Responsible for emitting descriptions of the calling conventions supported by this target.

Output: Implement static functions to deal with calling conventions chained by matching styles, returning false on no match.

Usage: Used in `ISelLowering` and `FastISel` as function pointers to implementation returned by a CC selection function.

DAGISel

Purpose: Generate a DAG instruction selector.

Output: Creates huge functions for automating DAG selection.

Usage: Included in `<Target>ISelDAGToDAG.cpp` inside the target's implementation of `SelectionDAGISel`.

DFAPacketizer

Purpose: This class parses the `Schedule.td` file and produces an API that can be used to reason about whether an instruction can be added to a packet on a VLIW architecture. The class internally generates a deterministic finite automaton (DFA) that models all possible mappings of machine instructions to functional units as instructions are added to a packet.

Output: Scheduling tables for GPU back-ends (Hexagon, AMD).

Usage: Included directly on `<Target>InstrInfo.cpp`.

FastISel

Purpose: This tablegen backend emits code for use by the "fast" instruction selection algorithm. See the comments at the top of `lib/CodeGen/SelectionDAG/FastISel.cpp` for background. This file scans through the target's tablegen instruction-info files and extracts instructions with obvious-looking patterns, and it emits code to look up these instructions by type and operator.

Output: Generates `Predicate` and `FastEmit` methods.

Usage: Implements private methods of the targets' implementation of `FastISel` class.

Subtarget

Purpose: Generate subtarget enumerations.

Output: Enums, globals, local tables for sub-target information.

Usage: Populates `<Target>Subtarget` and `MCTargetDesc/<Target>MCTargetDesc` files (both headers and source).

Intrinsic

Purpose: Generate (target) intrinsic information.

OptParserDefs

Purpose: Print enum values for a class.

SearchableTables

Purpose: Generate custom searchable tables.

Output: Enums, global tables and lookup helper functions.

Usage: This backend allows generating free-form, target-specific tables from TableGen records. The ARM and AArch64 targets use this backend to generate tables of system registers; the AMDGPU target uses it to generate meta-data about complex image and memory buffer instructions.

More documentation is available in `include/llvm/TableGen/SearchableTable.td`, which also contains the definitions of TableGen classes which must be instantiated in order to define the enums and tables emitted by this backend.

CTags

Purpose: This tablegen backend emits an index of definitions in `ctags(1)` format. A helper script, `utils/TableGen/tdtags`, provides an easier-to-use interface; run `'tdtags -H'` for documentation.

X86EVEX2VEX

Purpose: This X86 specific tablegen backend emits tables that map EVEX encoded instructions to their VEX encoded identical instruction.

Clang BackEnds

ClangAttrClasses

Purpose: Creates `Attrs.inc`, which contains semantic attribute class declarations for any attribute in `Attr.td` that has not set `ASTNode = 0`. This file is included as part of `Attr.h`.

ClangAttrParserStringSwitches

Purpose: Creates `AttrParserStringSwitches.inc`, which contains `StringSwitch::Case` statements for parser-related string switches. Each switch is given its own macro (such as `CLANG_ATTR_ARG_CONTEXT_LIST`, or `CLANG_ATTR_IDENTIFIER_ARG_LIST`), which is expected to be defined before including `AttrParserStringSwitches.inc`, and undefined after.

ClangAttrImpl

Purpose: Creates `AttrImpl.inc`, which contains semantic attribute class definitions for any attribute in `Attr.td` that has not set `ASTNode = 0`. This file is included as part of `AttrImpl.cpp`.

ClangAttrList

Purpose: Creates `AttrList.inc`, which is used when a list of semantic attribute identifiers is required. For instance, `AttrKinds.h` includes this file to generate the list of `attr::Kind` enumeration values. This list is separated out into multiple categories: attributes, inheritable attributes, and inheritable parameter attributes. This categorization happens automatically based on information in `Attr.td` and is used to implement the `classof` functionality required for `dyn_cast` and similar APIs.

ClangAttrPCHRead

Purpose: Creates `AttrPCHRead.inc`, which is used to deserialize attributes in the `ASTReader::ReadAttributes` function.

ClangAttrPCHWrite

Purpose: Creates `AttrPCHWrite.inc`, which is used to serialize attributes in the `ASTWriter::WriteAttributes` function.

ClangAttrSpellings

Purpose: Creates `AttrSpellings.inc`, which is used to implement the `__has_attribute` feature test macro.

ClangAttrSpellingListIndex

Purpose: Creates `AttrSpellingListIndex.inc`, which is used to map parsed attribute spellings (including which syntax or scope was used) to an attribute spelling list index. These spelling list index values are internal implementation details exposed via `AttributeList::getAttributeSpellingListIndex`.

ClangAttrVisitor

Purpose: Creates `AttrVisitor.inc`, which is used when implementing recursive AST visitors.

ClangAttrTemplateInstantiate

Purpose: Creates `AttrTemplateInstantiate.inc`, which implements the `instantiateTemplateAttribute` function, used when instantiating a template that requires an attribute to be cloned.

ClangAttrParsedAttrList

Purpose: Creates `AttrParsedAttrList.inc`, which is used to generate the `AttributeList::Kind` parsed attribute enumeration.

ClangAttrParsedAttrImpl

Purpose: Creates `AttrParsedAttrImpl.inc`, which is used by `AttributeList.cpp` to implement several functions on the `AttributeList` class. This functionality is implemented via the `AttrInfoMap` `ParsedAttrInfo` array, which contains one element per parsed attribute object.

ClangAttrParsedAttrKinds

Purpose: Creates `AttrParsedAttrKinds.inc`, which is used to implement the `AttributeList::getKind` function, mapping a string (and syntax) to a parsed attribute `AttributeList::Kind` enumeration.

ClangAttrDump

Purpose: Creates `AttrDump.inc`, which dumps information about an attribute. It is used to implement `ASTDumper::dumpAttr`.

ClangDiagsDefs

Generate Clang diagnostics definitions.

ClangDiagGroups

Generate Clang diagnostic groups.

ClangDiagsIndexName

Generate Clang diagnostic name index.

ClangCommentNodes

Generate Clang AST comment nodes.

ClangDeclNodes

Generate Clang AST declaration nodes.

ClangStmtNodes

Generate Clang AST statement nodes.

ClangSACheckers

Generate Clang Static Analyzer checkers.

ClangCommentHTMLTags

Generate efficient matchers for HTML tag names that are used in documentation comments.

ClangCommentHTMLTagsProperties

Generate efficient matchers for HTML tag properties.

ClangCommentHTMLNamedCharacterReferences

Generate function to translate named character references to UTF-8 sequences.

ClangCommentCommandInfo

Generate command properties for commands that are used in documentation comments.

ClangCommentCommandList

Generate list of commands that are used in documentation comments.

ArmNeon

Generate arm_neon.h for clang.

ArmNeonSema

Generate ARM NEON sema support for clang.

ArmNeonTest

Generate ARM NEON tests for clang.

AttrDocs

Purpose: Creates `AttributeReference.rst` from `AttrDocs.td`, and is used for documenting user-facing attributes.

General BackEnds

JSON

Purpose: Output all the values in every `def`, as a JSON data structure that can be easily parsed by a variety of languages. Useful for writing custom backends without having to modify TableGen itself, or for performing auxiliary analysis on the same TableGen data passed to a built-in backend.

Output:

The root of the output file is a JSON object (i.e. dictionary), containing the following fixed keys:

- `!tablegen_json_version`: a numeric version field that will increase if an incompatible change is ever made to the structure of this data. The format described here corresponds to version 1.
- `!instanceof`: a dictionary whose keys are the class names defined in the TableGen input. For each key, the corresponding value is an array of strings giving the names of `def` records that derive from that class. So `root["!instanceof"]["Instruction"]`, for example, would list the names of all the records deriving from the class `Instruction`.

For each `def` record, the root object also has a key for the record name. The corresponding value is a subsidiary object containing the following fixed keys:

- `!superclasses`: an array of strings giving the names of all the classes that this record derives from.
- `!fields`: an array of strings giving the names of all the variables in this record that were defined with the `field` keyword.
- `!name`: a string giving the name of the record. This is always identical to the key in the JSON root object corresponding to this record's dictionary. (If the record is anonymous, the name is arbitrary.)
- `!anonymous`: a boolean indicating whether the record's name was specified by the TableGen input (if it is `false`), or invented by TableGen itself (if `true`).

For each variable defined in a record, the `def` object for that record also has a key for the variable name. The corresponding value is a translation into JSON of the variable's value, using the conventions described below.

Some TableGen data types are translated directly into the corresponding JSON type:

- A completely undefined value (e.g. for a variable declared without initializer in some superclass of this record, and never initialized by the record itself or any other superclass) is emitted as the JSON `null` value.

- `int` and `bit` values are emitted as numbers. Note that TableGen `int` values are capable of holding integers too large to be exactly representable in IEEE double precision. The integer literal in the JSON output will show the full exact integer value. So if you need to retrieve large integers with full precision, you should use a JSON reader capable of translating such literals back into 64-bit integers without losing precision, such as Python's standard `json` module.
- `string` and `code` values are emitted as JSON strings.
- `list<T>` values, for any element type `T`, are emitted as JSON arrays. Each element of the array is represented in turn using these same conventions.
- `bits` values are also emitted as arrays. A `bits` array is ordered from least-significant bit to most-significant. So the element with index `i` corresponds to the bit described as `x{i}` in TableGen source. However, note that this means that scripting languages are likely to *display* the array in the opposite order from the way it appears in the TableGen source or in the diagnostic `-print-records` output.

All other TableGen value types are emitted as a JSON object, containing two standard fields: `kind` is a discriminator describing which kind of value the object represents, and `printable` is a string giving the same representation of the value that would appear in `-print-records`.

- A reference to a `def` object has `kind=="def"`, and has an extra field `def` giving the name of the object referred to.
- A reference to another variable in the same record has `kind=="var"`, and has an extra field `var` giving the name of the variable referred to.
- A reference to a specific bit of a `bits`-typed variable in the same record has `kind=="varbit"`, and has two extra fields: `var` gives the name of the variable referred to, and `index` gives the index of the bit.
- A value of type `dag` has `kind=="dag"`, and has two extra fields. `operator` gives the initial value after the opening parenthesis of the `dag` initializer; `args` is an array giving the following arguments. The elements of `args` are arrays of length 2, giving the value of each argument followed by its colon-suffixed name (if any). For example, in the JSON representation of the `dag` value `(Op 22, "hello":$foo)` (assuming that `Op` is the name of a record defined elsewhere with a `def` statement):
 - `operator` will be an object in which `kind=="def"` and `def=="Op"`
 - `args` will be the array `[[22, null], ["hello", "foo"]]`.
- If any other kind of value or complicated expression appears in the output, it will have `kind=="complex"`, and no additional fields. These values are not expected to be needed by backends. The standard `printable` field can be used to extract a representation of them in TableGen source syntax if necessary.

How to write a back-end

TODO.

Until we get a step-by-step *HowTo* for writing TableGen backends, you can at least grab the boilerplate (build system, new files, etc.) from Clang's r173931.

TODO: How they work, how to write one. This section should not contain details about any particular backend, except maybe `-print-enums` as an example. This should highlight the APIs in `TableGen/Record.h`.

4.13.2 TableGen Language Reference

- *Introduction*
- *Notation*
- *Lexical Analysis*
- *Syntax*
 - *classes*
 - *Declarations*
 - *Types*
 - *Values*
 - *Bodies*
 - *def*
 - *defm*
 - *defset*
 - *foreach*
 - *Top-Level let*
 - *multiclass*
- *Preprocessing Support*

Warning: This document is extremely rough. If you find something lacking, please fix it, file a documentation bug, or ask about it on llvm-dev.

Introduction

This document is meant to be a normative spec about the TableGen language in and of itself (i.e. how to understand a given construct in terms of how it affects the final set of records represented by the TableGen file). If you are unsure if this document is really what you are looking for, please read the *introduction to TableGen* first.

Notation

The lexical and syntax notation used here is intended to imitate [Python's](#). In particular, for lexical definitions, the productions operate at the character level and there is no implied whitespace between elements. The syntax definitions operate at the token level, so there is implied whitespace between tokens.

Lexical Analysis

TableGen supports BCPL (`// ...`) and nestable C-style (`/* ... */`) comments. TableGen also provides simple *Preprocessing Support*.

The following is a listing of the basic punctuation tokens:

```
- + [ ] { } ( ) < > : ; . = ? #
```

Numeric literals take one of the following forms:

```
TokInteger      ::=  DecimalInteger | HexInteger | BinInteger
DecimalInteger  ::=  ["+" | "-"] ("0"..."9")+
HexInteger      ::=  "0x" ("0"..."9" | "a"..."f" | "A"..."F")+
BinInteger      ::=  "0b" ("0" | "1")+
```

One aspect to note is that the *DecimalInteger* token *includes* the + or -, as opposed to having + and - be unary operators as most languages do.

Also note that *BinInteger* creates a value of type `bits<n>` (where `n` is the number of bits). This will implicitly convert to integers when needed.

TableGen has identifier-like tokens:

```
ualpha          ::=  "a"..."z" | "A"..."Z" | "_"
TokIdentifier    ::=  ("0"..."9")* ualpha (ualpha | "0"..."9")*
TokVarName       ::=  "$" ualpha (ualpha | "0"..."9")*
```

Note that unlike most languages, TableGen allows *TokIdentifier* to begin with a number. In case of ambiguity, a token will be interpreted as a numeric literal rather than an identifier.

TableGen also has two string-like literals:

```
TokString        ::=  "'" <non-' characters and C-like escapes> "'"
TokCodeFragment  ::=  "[{" <shortest text not containing "> "]"
```

TokCodeFragment is essentially a multiline string literal delimited by `[{` and `}]`.

Note: The current implementation accepts the following C-like escapes:

```
\\ \' \" \t \n
```

TableGen also has the following keywords:

bit	bits	class	code	dag
def	foreach	defm	field	in
int	let	list	multiclass	string

TableGen also has "bang operators" which have a wide variety of meanings:

```
BangOperator ::= one of
               !eq !if !head !tail !con
               !add !shl !sra !srl !and
               !or !empty !subst !foreach !strconcat
               !cast !listconcat !size !foldl
               !isa !dag !le !lt !ge
               !gt !ne !mul !listsplat
```

TableGen also has !cond operator that needs a slightly different syntax compared to other "bang operators":

```
CondOperator ::= !cond
```

Syntax

TableGen has an `include` mechanism. It does not play a role in the syntax per se, since it is lexically replaced with the contents of the included file.

```
IncludeDirective ::= "include" TokString
```

TableGen's top-level production consists of "objects".

```
TableGenFile ::= Object*
Object       ::= Class | Def | Defm | Defset | Let | MultiClass |
```

classes

```
Class           ::= "class" TokIdentifier [TemplateArgList] ObjectBody
TemplateArgList ::= "<" Declaration ("," Declaration)* ">"
```

A `class` declaration creates a record which other records can inherit from. A class can be parametrized by a list of "template arguments", whose values can be used in the class body.

A given class can only be defined once. A `class` declaration is considered to define the class if any of the following is true:

1. The *TemplateArgList* is present.
2. The *Body* in the *ObjectBody* is present and is not empty.
3. The *BaseClassList* in the *ObjectBody* is present.

You can declare an empty class by giving an empty *TemplateArgList* and an empty *ObjectBody*. This can

serve as a restricted form of forward declaration: note that records deriving from the forward-declared class will inherit no fields from it since the record expansion is done when the record is parsed.

Every class has an implicit template argument called `NAME`, which is set to the name of the instantiating `def` or `defn`. The result is undefined if the class is instantiated by an anonymous record.

Declarations

The declaration syntax is pretty much what you would expect as a C++ programmer.

```
Declaration ::= Type TokIdentifier ["=" Value]
```

It assigns the value to the identifier.

Types

```
Type ::= "string" | "code" | "bit" | "int" | "dag"
      | "bits" "<" TokInteger ">"
      | "list" "<" Type ">"
      | ClassID
ClassID ::= TokIdentifier
```

Both `string` and `code` correspond to the `string` type; the difference is purely to indicate programmer intention.

The `ClassID` must identify a class that has been previously declared or defined.

Values

```
Value ::= SimpleValue ValueSuffix*
ValueSuffix ::= "{" RangeList "}"
              | "[" RangeList "]"
              | "." TokIdentifier
RangeList ::= RangePiece ("," RangePiece)*
RangePiece ::= TokInteger
              | TokInteger "-" TokInteger
              | TokInteger TokInteger
```

The peculiar last form of `RangePiece` is due to the fact that the `"-"` is included in the `TokInteger`, hence `1-5` gets lexed as two consecutive `TokInteger`'s, with values `1` and `-5`, instead of `"1"`, `"-"`, and `"5"`. The `RangeList` can be thought of as specifying "list slice" in some contexts.

`SimpleValue` has a number of forms:

```
SimpleValue ::= TokIdentifier
```

The value will be the variable referenced by the identifier. It can be one of:

- name of a `def`, such as the use of `Bar` in:

```
def Bar : SomeClass {  
    int X = 5;  
}  
  
def Foo {  
    SomeClass Baz = Bar;  
}
```

- value local to a def, such as the use of Bar in:

```
def Foo {  
    int Bar = 5;  
    int Baz = Bar;  
}
```

Values defined in superclasses can be accessed the same way.

- a template arg of a class, such as the use of Bar in:

```
class Foo<int Bar> {  
    int Baz = Bar;  
}
```

- value local to a class, such as the use of Bar in:

```
class Foo {  
    int Bar = 5;  
    int Baz = Bar;  
}
```

- a template arg to a multiclass, such as the use of Bar in:

```
multiclass Foo<int Bar> {  
    def : SomeClass<Bar>;  
}
```

- the iteration variable of a foreach, such as the use of i in:

```
foreach i = 0-5 in  
def Foo#i;
```

- a variable defined by defset
- the implicit template argument NAME in a class or multiclass

`SimpleValue ::= TokInteger`

This represents the numeric value of the integer.

`SimpleValue ::= TokString+`

Multiple adjacent string literals are concatenated like in C/C++. The value is the concatenation of the strings.

`SimpleValue ::= TokCodeFragment`

The value is the string value of the code fragment.

```
SimpleValue ::= "?"
```

? represents an "unset" initializer.

```
SimpleValue ::= "{" ValueList "}"
ValueList  ::= [ValueListNE]
ValueListNE ::= Value ("," Value) *
```

This represents a sequence of bits, as would be used to initialize a `bits<n>` field (where `n` is the number of bits).

```
SimpleValue ::= ClassID "<" ValueListNE ">"
```

This generates a new anonymous record definition (as would be created by an unnamed `def` inheriting from the given class with the given template arguments) and the value is the value of that record definition.

```
SimpleValue ::= "[" ValueList "]" ["<" Type ">"]
```

A list initializer. The optional *Type* can be used to indicate a specific element type, otherwise the element type will be deduced from the given values.

```
SimpleValue ::= "(" DagArg [DagArgList] ")"
DagArgList  ::= DagArg ("," DagArg) *
DagArg      ::= Value [":" TokVarName] | TokVarName
```

The initial *DagArg* is called the "operator" of the dag.

```
SimpleValue ::= BangOperator ["<" Type ">"] "(" ValueListNE ")"
              | CondOperator "(" CondVal ("," CondVal) * ")"
CondVal      ::= Value ":" Value
```

Bodies

```
ObjectBody    ::= BaseClassList Body
BaseClassList ::= [":" BaseClassListNE]
BaseClassListNE ::= SubClassRef ("," SubClassRef) *
SubClassRef    ::= (ClassID | MultiClassID) ["<" ValueList ">"]
DefmID         ::= TokIdentifier
```

The version with the *MultiClassID* is only valid in the *BaseClassList* of a *defm*. The *MultiClassID* should be the name of a multiclass.

It is after parsing the base class list that the "let stack" is applied.

```
Body      ::=  ";" | "{" BodyList "}"
BodyList  ::=  BodyItem*
BodyItem  ::=  Declaration ";"
              | "let" TokIdentifier [ "{" RangeList "}" ] "=" Value ";"
```

The `let` form allows overriding the value of an inherited field.

def

```
Def ::= "def" [Value] ObjectBody
```

Defines a record whose name is given by the optional *Value*. The value is parsed in a special mode where global identifiers (records and variables defined by `defset`) are not recognized, and all unrecognized identifiers are interpreted as strings.

If no name is given, the record is anonymous. The final name of anonymous records is undefined, but globally unique.

Special handling occurs if this `def` appears inside a `multiclass` or a `foreach`.

When a non-anonymous record is defined in a `multiclass` and the given name does not contain a reference to the implicit template argument `NAME`, such a reference will automatically be prepended. That is, the following are equivalent inside a `multiclass`:

```
def Foo;
def NAME#Foo;
```

defm

```
Defm ::= "defm" [Value] ":" BaseClassListNE ";"
```

The *BaseClassList* is a list of at least one `multiclass` and any number of `class`'s. The `multiclass`'s must occur before any `class`'s.

Instantiates all records defined in all given `multiclass`'s and adds the given `class`'s as superclasses.

The name is parsed in the same special mode used by `def`. If the name is missing, a globally unique string is used instead (but instantiated records are not considered to be anonymous, unless they were originally defined by an anonymous `def`) That is, the following have different semantics:

```
defm : SomeMultiClass<...>; // some globally unique name
defm "" : SomeMultiClass<...>; // empty name string
```

When it occurs inside a `multiclass`, the second variant is equivalent to `defm NAME : ...`. More generally, when `defm` occurs in a `multiclass` and its name does not contain a reference to the implicit template argument `NAME`, such a reference will automatically be prepended. That is, the following are equivalent inside a `multiclass`:

```
defm Foo : SomeMultiClass<...>;
defm NAME#Foo : SomeMultiClass<...>;
```

defset

```
Defset ::= "defset" Type TokIdentifier "=" "{" Object* "}"
```

All records defined inside the braces via `def` and `defm` are collected in a globally accessible list of the given name (in addition to being added to the global collection of records as usual). Anonymous records created inside initializer expressions using the `Class<args...>` syntax are never collected in a `defset`.

The given type must be `list<A>`, where `A` is some class. It is an error to define a record (via `def` or `defm`) inside the braces which doesn't derive from `A`.

foreach

```
Foreach ::= "foreach" ForeachDeclaration "in" "{" Object* "}"
          | "foreach" ForeachDeclaration "in" Object
ForeachDeclaration ::= ID "=" ( "{" RangeList "}" | RangePiece | Value )
```

The value assigned to the variable in the declaration is iterated over and the object or object list is reevaluated with the variable set at each iterated value.

Note that the productions involving `RangeList` and `RangePiece` have precedence over the more generic value parsing based on the first token.

Top-Level let

```
Let ::= "let" LetList "in" "{" Object* "}"
      | "let" LetList "in" Object
LetList ::= LetItem ("," LetItem)*
LetItem ::= TokIdentifier [RangeList] "=" Value
```

This is effectively equivalent to `let` inside the body of a record except that it applies to multiple records at a time. The bindings are applied at the end of parsing the base classes of a record.

multiclass

```
MultiClass ::= "multiclass" TokIdentifier [TemplateArgList]
              [ ":" BaseMultiClassList ] "{" MultiClassObject+ "}"
BaseMultiClassList ::= MultiClassID ("," MultiClassID)*
MultiClassID ::= TokIdentifier
MultiClassObject ::= Def | Defm | Let | Foreach
```

Preprocessing Support

TableGen's embedded preprocessor is only intended for conditional compilation. It supports the following directives:

```

LineBegin      ::=  ^
LineEnd        ::=  "\n" | "\r" | EOF
WhiteSpace     ::=  " " | "\t"
CStyleComment  ::=  "/*" (.* - "*/") "*/"
BCPLComment    ::=  "//" (.* - LineEnd) LineEnd
WhiteSpaceOrCStyleComment ::= WhiteSpace | CStyleComment
WhiteSpaceOrAnyComment ::= WhiteSpace | CStyleComment | BCPLComment
MacroName      ::=  ualpha (ualpha | "0"..."9")*
PrepDefine     ::=  LineBegin (WhiteSpaceOrCStyleComment)*
                  "#define" (WhiteSpace)+ MacroName
                  (WhiteSpaceOrAnyComment)* LineEnd
PrepIfdef      ::=  LineBegin (WhiteSpaceOrCStyleComment)*
                  "#ifdef" (WhiteSpace)+ MacroName
                  (WhiteSpaceOrAnyComment)* LineEnd
PrepElse       ::=  LineBegin (WhiteSpaceOrCStyleComment)*
                  "#else" (WhiteSpaceOrAnyComment)* LineEnd
PrepEndif      ::=  LineBegin (WhiteSpaceOrCStyleComment)*
                  "#endif" (WhiteSpaceOrAnyComment)* LineEnd
PrepRegContentException ::= PrepIfdef | PrepElse | PrepEndif | EOF
PrepRegion     ::=  .* - PrepRegContentException
                  | PrepIfdef
                  (PrepRegion)*
                  [PrepElse]
                  (PrepRegion)*
                  PrepEndif

```

PrepRegion may occur anywhere in a TD file, as long as it matches the grammar specification.

PrepDefine allows defining a *MacroName* so that any following *PrepIfdef* - *PrepElse* preprocessing region part and *PrepIfdef* - *PrepEndif* preprocessing region are enabled for TableGen tokens parsing.

A preprocessing region, starting (i.e. having its *PrepIfdef*) in a file, must end (i.e. have its *PrepEndif*) in the same file.

A *MacroName* may be defined externally by using { -D<NAME> } option of TableGen.

Warning: This document is extremely rough. If you find something lacking, please fix it, file a documentation bug, or ask about it on llvm-dev.

Introduction

This document is not meant to be a normative spec about the TableGen language in and of itself (i.e. how to understand a given construct in terms of how it affects the final set of records represented by the TableGen file). For the formal language specification, see *TableGen Language Reference*.

TableGen syntax

TableGen doesn't care about the meaning of data (that is up to the backend to define), but it does care about syntax, and it enforces a simple type system. This section describes the syntax and the constructs allowed in a TableGen file.

TableGen primitives

TableGen comments

TableGen supports C++ style `"/"/` comments, which run to the end of the line, and it also supports **nestable** `"/ * */` comments.

The TableGen type system

TableGen files are strongly typed, in a simple (but complete) type-system. These types are used to perform automatic conversions, check for errors, and to help interface designers constrain the input that they allow. Every *value definition* is required to have an associated type.

TableGen supports a mixture of very low-level types (such as `bit`) and very high-level types (such as `dag`). This flexibility is what allows it to describe a wide range of information conveniently and compactly. The TableGen types are:

bit A 'bit' is a boolean value that can hold either 0 or 1.

int The 'int' type represents a simple 32-bit integer value, such as 5.

string The 'string' type represents an ordered sequence of characters of arbitrary length.

code The *code* type represents a code fragment, which can be single/multi-line string literal.

bits<n> A 'bits' type is an arbitrary, but fixed, size integer that is broken up into individual bits. This type is useful because it can handle some bits being defined while others are undefined.

list<ty> This type represents a list whose elements are some other type. The contained type is arbitrary: it can even be another list type.

Class type Specifying a class name in a type context means that the defined value must be a subclass of the specified class. This is useful in conjunction with the `list` type, for example, to constrain the elements of the list to a common base class (e.g., a `list<Register>` can only contain definitions derived from the "Register" class).

dag This type represents a nestable directed graph of elements.

To date, these types have been sufficient for describing things that TableGen has been used for, but it is straight-forward to extend this list if needed.

TableGen values and expressions

TableGen allows for a pretty reasonable number of different expression forms when building up values. These forms allow the TableGen file to be written in a natural syntax and flavor for the application. The current expression forms supported include:

? uninitialized field

0b1001011 binary integer value. Note that this is sized by the number of bits given and will not be silently extended/truncated.

7 decimal integer value

0x7F hexadecimal integer value

"foo" a single-line string value, can be assigned to `string` or `code` variable.

[{ ... }] usually called a "code fragment", but is just a multiline string literal

[**X**, **Y**, **Z**]<**type**> list value. <type> is the type of the list element and is usually optional. In rare cases, TableGen is unable to deduce the element type in which case the user must specify it explicitly.

{ **a**, **b**, **0b10** } initializer for a "bits<4>" value. 1-bit from "a", 1-bit from "b", 2-bits from 0b10.

value value reference

value{17} access to one bit of a value

value{15-17} access to an ordered sequence of bits of a value, in particular `value{15-17}` produces an order that is the reverse of `value{17-15}`.

DEF reference to a record definition

CLASS<val list> reference to a new anonymous definition of CLASS with the specified template arguments.

X.Y reference to the subfield of a value

list[4-7,17,2-3] A slice of the 'list' list, including elements 4,5,6,7,17,2, and 3 from it. Elements may be included multiple times.

foreach <var> = [<list>] in { <body> }

foreach *<var>* = [*<list>*] **in** *<def>* Replicate *<body>* or *<def>*, replacing instances of *<var>* with each value in *<list>*. *<var>* is scoped at the level of the `foreach` loop and must not conflict with any other object introduced in *<body>* or *<def>*. Only `defs` and `defms` are expanded within *<body>*.

```
foreach <var> = 0-15 in ...
```

foreach *<var>* = {0-15, 32-47} **in** ... Loop over ranges of integers. The braces are required for multiple ranges.

(DEF a, b) a dag value. The first element is required to be a record definition, the remaining elements in the list may be arbitrary other values, including nested ``dag'` values.

!con(a, b, ...) Concatenate two or more DAG nodes. Their operations must equal.

Example: `!con((op a1:$name1, a2:$name2), (op b1:$name3))` results in the DAG node `(op a1:$name1, a2:$name2, b1:$name3)`.

!dag(op, children, names) Generate a DAG node programmatically. 'children' and 'names' must be lists of equal length or unset ('?'). 'names' must be a 'list<string>'.

Due to limitations of the type system, 'children' must be a list of items of a common type. In practice, this means that they should either have the same type or be records with a common superclass. Mixing dag and non-dag items is not possible. However, '?' can be used.

Example: `!dag(op, [a1, a2, ?], ["name1", "name2", "name3"])` results in `(op a1:$name1, a2:$name2, ?:$name3)`.

!listconcat(a, b, ...) A list value that is the result of concatenating the 'a' and 'b' lists. The lists must have the same element type. More than two arguments are accepted with the result being the concatenation of all the lists given.

!listsplat(a, size) A list value that contains the value *a* *size* times. Example: `!listsplat(0, 2)` results in `[0, 0]`.

!strconcat(a, b, ...) A string value that is the result of concatenating the 'a' and 'b' strings. More than two arguments are accepted with the result being the concatenation of all the strings given.

str1#str2 `"#"` (paste) is a shorthand for `!strconcat`. It may concatenate things that are not quoted strings, in which case an implicit `!cast<string>` is done on the operand of the paste.

!cast<type>(a) If 'a' is a string, a record of type *type* obtained by looking up the string 'a' in the list of all records defined by the time that all template arguments in 'a' are fully resolved.

For example, if `!cast<type>(a)` appears in a multiclass definition, or in a class instantiated inside of a multiclass definition, and 'a' does not reference any template arguments of the multiclass, then a record of name 'a' must be instantiated earlier in the source file. If 'a' does reference a template argument, then the lookup is delayed until `defm` statements instantiating the multiclass (or later, if the `defm` occurs in another multiclass and template arguments of the inner multiclass that are referenced by 'a' are substituted by values that themselves contain references to template arguments of the outer multiclass).

If the type of 'a' does not match *type*, TableGen aborts with an error.

Otherwise, perform a normal type cast e.g. between an int and a bit, or between record types. This allows casting a record to a subclass, though if the types do not match, constant folding will be inhibited. `!cast<string>` is a special case in that the argument can be an int or a record. In the latter case, the record's name is returned.

!isa<type>(a) Returns an integer: 1 if 'a' is dynamically of the given type, 0 otherwise.

!subst(a, b, c) If 'a' and 'b' are of string type or are symbol references, substitute 'b' for 'a' in 'c'. This operation is analogous to `$(subst)` in GNU make.

!foreach(a, b, c) For each member of dag or list 'b' apply operator 'c'. 'a' is the name of a variable that will be substituted by members of 'b' in 'c'. This operation is analogous to `$(foreach)` in GNU make.

!foldl(start, lst, a, b, expr) Perform a left-fold over 'lst' with the given starting value. 'a' and 'b' are variable names which will be substituted in 'expr'. If you think of expr as a function f(a,b), the fold will compute 'f(...f(f(start, lst[0]), lst[1]), ...), lst[n-1])' for a list of length n. As usual, 'a' will be of the type of 'start', and 'b' will be of the type of elements of 'lst'. These types need not be the same, but 'expr' must be of the same type as 'start'.

!head(a) The first element of list 'a'.

!tail(a) The 2nd-N elements of list 'a'.

!empty(a) An integer {0,1} indicating whether list 'a' is empty.

!size(a) An integer indicating the number of elements in list 'a'.

!if(a,b,c) 'b' if the result of 'int' or 'bit' operator 'a' is nonzero, 'c' otherwise.

!cond(condition_1 : val1, condition_2 : val2, ..., condition_n : valn)

Instead of embedding !if inside !if which can get cumbersome, one can use !cond. !cond returns 'val1' if the result of 'int' or 'bit' operator 'condition1' is nonzero. Otherwise, it checks 'condition2'. If 'condition2' is nonzero, returns 'val2', and so on. If all conditions are zero, it reports an error.

For example, to convert an integer 'x' into a string: !cond(!lt(x,0) : "negative", !eq(x,0) : "zero", 1 : "positive")

!eq(a,b) 'bit 1' if string a is equal to string b, 0 otherwise. This only operates on string, int and bit objects. Use !cast<string> to compare other types of objects.

!ne(a,b) The negation of !eq(a,b).

!le(a,b), !lt(a,b), !ge(a,b), !gt(a,b) (Signed) comparison of integer values that returns bit 1 or 0 depending on the result of the comparison.

!shl(a,b) !srl(a,b) !sra(a,b) The usual shift operators. Operations are on 64-bit integers, the result is undefined for shift counts outside [0, 63].

!add(a,b,...) !mul(a,b,...) !and(a,b,...) !or(a,b,...) The usual arithmetic and binary operators.

Note that all of the values have rules specifying how they convert to values for different types. These rules allow you to assign a value like "7" to a "bits<4>" value, for example.

Classes and definitions

As mentioned in the [introduction](#), classes and definitions (collectively known as 'records') in TableGen are the main high-level unit of information that TableGen collects. Records are defined with a `def` or `class` keyword, the record name, and an optional list of *"template arguments"*. If the record has superclasses, they are specified as a comma separated list that starts with a colon character (":"). If *value definitions* or *let expressions* are needed for the class, they are enclosed in curly braces ("{}"); otherwise, the record ends with a semicolon.

Here is a simple TableGen file:

```
class C { bit V = 1; }
def X : C;
def Y : C {
  string Greeting = "hello";
}
```

This example defines two definitions, X and Y, both of which derive from the C class. Because of this, they both get the V bit value. The Y definition also gets the Greeting member as well.

In general, classes are useful for collecting together the commonality between a group of records and isolating it in a single place. Also, classes permit the specification of default values for their subclasses, allowing the subclasses to override them as they wish.

Value definitions

Value definitions define named entries in records. A value must be defined before it can be referred to as the operand for another value definition or before the value is reset with a *let expression*. A value is defined by specifying a *TableGen type* and a name. If an initial value is available, it may be specified after the type with an equal sign. Value definitions require terminating semicolons.

'let' expressions

A record-level let expression is used to change the value of a value definition in a record. This is primarily useful when a superclass defines a value that a derived class or definition wants to override. Let expressions consist of the 'let' keyword followed by a value name, an equal sign ("="), and a new value. For example, a new class could be added to the example above, redefining the `V` field for all of its subclasses:

```
class D : C { let V = 0; }
def Z : D;
```

In this case, the `Z` definition will have a zero value for its `V` value, despite the fact that it derives (indirectly) from the `C` class, because the `D` class overrode its value.

References between variables in a record are substituted late, which gives `let` expressions unusual power. Consider this admittedly silly example:

```
class A<int x> {
  int Y = x;
  int Yplus1 = !add(Y, 1);
  int xplus1 = !add(x, 1);
}
def Z : A<5> {
  let Y = 10;
}
```

The value of `Z.xplus1` will be 6, but the value of `Z.Yplus1` is 11. Use this power wisely.

Class template arguments

TableGen permits the definition of parameterized classes as well as normal concrete classes. Parameterized TableGen classes specify a list of variable bindings (which may optionally have defaults) that are bound when used. Here is a simple example:

```
class FPFormat<bits<3> val> {
  bits<3> Value = val;
}
def NotFP      : FPFormat<0>;
def ZeroArgFP  : FPFormat<1>;
def OneArgFP   : FPFormat<2>;
def OneArgFPRW : FPFormat<3>;
def TwoArgFP   : FPFormat<4>;
def CompareFP  : FPFormat<5>;
```

(continues on next page)

(continued from previous page)

```
def CondMovFP : FPFormat<6>;
def SpecialFP : FPFormat<7>;
```

In this case, template arguments are used as a space efficient way to specify a list of "enumeration values", each with a "Value" field set to the specified integer.

The more esoteric forms of *TableGen expressions* are useful in conjunction with template arguments. As an example:

```
class ModRefVal<bits<2> val> {
  bits<2> Value = val;
}

def None      : ModRefVal<0>;
def Mod       : ModRefVal<1>;
def Ref       : ModRefVal<2>;
def ModRef    : ModRefVal<3>;

class Value<ModRefVal MR> {
  // Decode some information into a more convenient format, while providing
  // a nice interface to the user of the "Value" class.
  bit isMod = MR.Value{0};
  bit isRef = MR.Value{1};

  // other stuff...
}

// Example uses
def bork : Value<Mod>;
def zork : Value<Ref>;
def hork : Value<ModRef>;
```

This is obviously a contrived example, but it shows how template arguments can be used to decouple the interface provided to the user of the class from the actual internal data representation expected by the class. In this case, running `llvm-tblgen` on the example prints the following definitions:

```
def bork {          // Value
  bit isMod = 1;
  bit isRef = 0;
}
def hork {          // Value
  bit isMod = 1;
  bit isRef = 1;
}
def zork {          // Value
  bit isMod = 0;
  bit isRef = 1;
}
```

This shows that TableGen was able to dig into the argument and extract a piece of information that was requested by the designer of the "Value" class. For more realistic examples, please see existing users of TableGen, such as the X86 backend.

Multiclass definitions and instances

While classes with template arguments are a good way to factor commonality between two instances of a definition, multiclass definitions allow a convenient notation for defining multiple definitions at once (instances of implicitly constructed classes). For example, consider an 3-address instruction set whose instructions come in two forms: "reg = reg op reg" and "reg = reg op imm" (e.g. SPARC). In this case, you'd like to specify in one place that this commonality exists, then in a separate place indicate what all the ops are.

Here is an example TableGen fragment that shows this idea:

```
def ops;
def GPR;
def Imm;
class inst<int opc, string asmstr, dag operandlist>;

multiclass ri_inst<int opc, string asmstr> {
  def _rr : inst<opc, !strconcat(asmstr, " $dst, $src1, $src2"),
              (ops GPR:$dst, GPR:$src1, GPR:$src2)>;
  def _ri : inst<opc, !strconcat(asmstr, " $dst, $src1, $src2"),
              (ops GPR:$dst, GPR:$src1, Imm:$src2)>;
}

// Instantiations of the ri_inst multiclass.
defm ADD : ri_inst<0b111, "add">;
defm SUB : ri_inst<0b101, "sub">;
defm MUL : ri_inst<0b100, "mul">;
...
```

The name of the resultant definitions has the multidef fragment names appended to them, so this defines ADD_rr, ADD_ri, SUB_rr, etc. A defm may inherit from multiple multiclass definitions, instantiating definitions from each multiclass. Using a multiclass this way is exactly equivalent to instantiating the classes multiple times yourself, e.g. by writing:

```
def ops;
def GPR;
def Imm;
class inst<int opc, string asmstr, dag operandlist>;

class rrinst<int opc, string asmstr>
  : inst<opc, !strconcat(asmstr, " $dst, $src1, $src2"),
        (ops GPR:$dst, GPR:$src1, GPR:$src2)>;

class riinst<int opc, string asmstr>
  : inst<opc, !strconcat(asmstr, " $dst, $src1, $src2"),
        (ops GPR:$dst, GPR:$src1, Imm:$src2)>;

// Instantiations of the ri_inst multiclass.
def ADD_rr : rrinst<0b111, "add">;
def ADD_ri : riinst<0b111, "add">;
def SUB_rr : rrinst<0b101, "sub">;
def SUB_ri : riinst<0b101, "sub">;
def MUL_rr : rrinst<0b100, "mul">;
def MUL_ri : riinst<0b100, "mul">;
...
```

A defm can also be used inside a multiclass providing several levels of multiclass instantiations.

```
class Instruction<bits<4> opc, string Name> {
```

(continues on next page)

(continued from previous page)

```

    bits<4> opcode = opc;
    string name = Name;
}

multiclass basic_r<bits<4> opc> {
    def rr : Instruction<opc, "rr">;
    def rm : Instruction<opc, "rm">;
}

multiclass basic_s<bits<4> opc> {
    defm SS : basic_r<opc>;
    defm SD : basic_r<opc>;
    def X : Instruction<opc, "x">;
}

multiclass basic_p<bits<4> opc> {
    defm PS : basic_r<opc>;
    defm PD : basic_r<opc>;
    def Y : Instruction<opc, "y">;
}

defm ADD : basic_s<0xf>, basic_p<0xf>;
...

// Results
def ADDPDrm { ...
def ADDPDrr { ...
def ADDPSrm { ...
def ADDPSrr { ...
def ADDSDrm { ...
def ADDSDrr { ...
def ADDY { ...
def ADDX { ...

```

`defm` declarations can inherit from classes too, the rule to follow is that the class list must start after the last multiclass, and there must be at least one multiclass before them.

```

class XD { bits<4> Prefix = 11; }
class XS { bits<4> Prefix = 12; }

class I<bits<4> op> {
    bits<4> opcode = op;
}

multiclass R {
    def rr : I<4>;
    def rm : I<2>;
}

multiclass Y {
    defm SS : R, XD;
    defm SD : R, XS;
}

defm Instr : Y;

```

(continues on next page)

(continued from previous page)

```
// Results
def InstrSDrm {
  bits<4> opcode = { 0, 0, 1, 0 };
  bits<4> Prefix = { 1, 1, 0, 0 };
}
...
def InstrSSrr {
  bits<4> opcode = { 0, 1, 0, 0 };
  bits<4> Prefix = { 1, 0, 1, 1 };
}
```

File scope entities

File inclusion

TableGen supports the 'include' token, which textually substitutes the specified file in place of the include directive. The filename should be specified as a double quoted string immediately after the 'include' keyword. Example:

```
include "foo.td"
```

'let' expressions

"Let" expressions at file scope are similar to *"let" expressions within a record*, except they can specify a value binding for multiple records at a time, and may be useful in certain other cases. File-scope let expressions are really just another way that TableGen allows the end-user to factor out commonality from the records.

File-scope "let" expressions take a comma-separated list of bindings to apply, and one or more records to bind the values in. Here are some examples:

```
let isTerminator = 1, isReturn = 1, isBarrier = 1, hasCtrlDep = 1 in
  def RET : I<0xC3, RawFrm, (outs), (ins), "ret", [(X86retflag 0)]>;

let isCall = 1 in
  // All calls clobber the non-callee saved registers...
  let Defs = [EAX, ECX, EDX, FP0, FP1, FP2, FP3, FP4, FP5, FP6, ST0,
             MM0, MM1, MM2, MM3, MM4, MM5, MM6, MM7,
             XMM0, XMM1, XMM2, XMM3, XMM4, XMM5, XMM6, XMM7, EFLAGS] in {
    def CALLpcrel32 : Ii32<0xE8, RawFrm, (outs), (ins i32imm:$dst,variable_ops),
                     "call\t${dst:call}", []>;

    def CALL32r      : I<0xFF, MRM2r, (outs), (ins GR32:$dst, variable_ops),
                     "call\t{*}$dst", [(X86call GR32:$dst)]>;

    def CALL32m      : I<0xFF, MRM2m, (outs), (ins i32mem:$dst, variable_ops),
                     "call\t{*}$dst", []>;
  }
```

File-scope "let" expressions are often useful when a couple of definitions need to be added to several records, and the records do not otherwise need to be opened, as in the case with the CALL* instructions above.

It's also possible to use "let" expressions inside multiclasses, providing more ways to factor out commonality from the records, specially if using several levels of multiclass instantiations. This also avoids the need of using "let" expressions within subsequent records inside a multiclass.

```
multiclass basic_r<bits<4> opc> {
  let Predicates = [HasSSE2] in {
    def rr : Instruction<opc, "rr">;
    def rm : Instruction<opc, "rm">;
  }
  let Predicates = [HasSSE3] in
    def rx : Instruction<opc, "rx">;
}

multiclass basic_ss<bits<4> opc> {
  let IsDouble = 0 in
    defm SS : basic_r<opc>;

  let IsDouble = 1 in
    defm SD : basic_r<opc>;
}

defm ADD : basic_ss<0xf>;
```

Looping

TableGen supports the 'foreach' block, which textually replicates the loop body, substituting iterator values for iterator references in the body. Example:

```
foreach i = [0, 1, 2, 3] in {
  def R#i : Register<...>;
  def F#i : Register<...>;
}
```

This will create objects R0, R1, R2 and R3. `foreach` blocks may be nested. If there is only one item in the body the braces may be elided:

```
foreach i = [0, 1, 2, 3] in
  def R#i : Register<...>;
```

Code Generator backend info

Expressions used by code generator to describe instructions and isel patterns:

(implicit a) an implicitly defined physical register. This tells the dag instruction selection emitter the input pattern's extra definitions matches implicit physical register definitions.

4.13.4 TableGen Deficiencies

- *Introduction*
- *Known Problems*

Introduction

Despite being very generic, TableGen has some deficiencies that have been pointed out numerous times. The common theme is that, while TableGen allows you to build Domain-Specific-Languages, the final languages that you create lack the power of other DSLs, which in turn increase considerably the size and complexity of TableGen files.

At the same time, TableGen allows you to create virtually any meaning of the basic concepts via custom-made back-ends, which can pervert the original design and make it very hard for newcomers to understand it.

There are some in favour of extending the semantics even more, but making sure back-ends adhere to strict rules. Others suggesting we should move to more powerful DSLs designed with specific purposes, or even re-using existing DSLs.

Known Problems

TODO: Add here frequently asked questions about why TableGen doesn't do what you want, how it might, and how we could extend/restrict it to be more use friendly.

4.13.5 Introduction

TableGen's purpose is to help a human develop and maintain records of domain-specific information. Because there may be a large number of these records, it is specifically designed to allow writing flexible descriptions and for common features of these records to be factored out. This reduces the amount of duplication in the description, reduces the chance of error, and makes it easier to structure domain specific information.

The core part of TableGen parses a file, instantiates the declarations, and hands the result off to a domain-specific *backend* for processing.

The current major users of TableGen are *The LLVM Target-Independent Code Generator* and the *Clang diagnostics and attributes*.

Note that if you work on TableGen much, and use emacs or vim, that you can find an emacs "TableGen mode" and a vim language file in the `llvm/utils/emacs` and `llvm/utils/vim` directories of your LLVM distribution, respectively.

4.13.6 The TableGen program

TableGen files are interpreted by the TableGen program: *llvm-tblgen* available on your build directory under *bin*. It is not installed in the system (or where your `sysroot` is set to), since it has no use beyond LLVM's build process.

Running TableGen

TableGen runs just like any other LLVM tool. The first (optional) argument specifies the file to read. If a filename is not specified, `llvm-tblgen` reads from standard input.

To be useful, one of the *backends* must be used. These backends are selectable on the command line (type '`llvm-tblgen -help`' for a list). For example, to get a list of all of the definitions that subclass a particular type (which can be useful for building up an enum list of these records), use the `-print-enums` option:

```
$ llvm-tblgen X86.td -print-enums -class=Register
AH, AL, AX, BH, BL, BP, BPL, BX, CH, CL, CX, DH, DI, DIL, DL, DX, EAX, EBP, EBX,
ECX, EDI, EDX, EFLAGS, EIP, ESI, ESP, FP0, FP1, FP2, FP3, FP4, FP5, FP6, IP,
MM0, MM1, MM2, MM3, MM4, MM5, MM6, MM7, R10, R10B, R10D, R10W, R11, R11B, R11D,
R11W, R12, R12B, R12D, R12W, R13, R13B, R13D, R13W, R14, R14B, R14D, R14W, R15,
```

(continues on next page)

(continued from previous page)

```
R15B, R15D, R15W, R8, R8B, R8D, R8W, R9, R9B, R9D, R9W, RAX, RBP, RBX, RCX, RDI,
RDX, RIP, RSI, RSP, SI, SIL, SP, SPL, ST0, ST1, ST2, ST3, ST4, ST5, ST6, ST7,
XMM0, XMM1, XMM10, XMM11, XMM12, XMM13, XMM14, XMM15, XMM2, XMM3, XMM4, XMM5,
XMM6, XMM7, XMM8, XMM9,
```

```
$ llvm-tblgen X86.td -print-enums -class=Instruction
ABS_F, ABS_Fp32, ABS_Fp64, ABS_Fp80, ADC32mi, ADC32mi8, ADC32mr, ADC32ri,
ADC32ri8, ADC32rm, ADC32rr, ADC64mi32, ADC64mi8, ADC64mr, ADC64ri32, ADC64ri8,
ADC64rm, ADC64rr, ADD16mi, ADD16mi8, ADD16mr, ADD16ri, ADD16ri8, ADD16rm,
ADD16rr, ADD32mi, ADD32mi8, ADD32mr, ADD32ri, ADD32ri8, ADD32rm, ADD32rr,
ADD64mi32, ADD64mi8, ADD64mr, ADD64ri32, ...
```

The default backend prints out all of the records. There is also a general backend which outputs all the records as a JSON data structure, enabled using the *-dump-json* option.

If you plan to use TableGen, you will most likely have to write a *backend* that extracts the information specific to what you need and formats it in the appropriate way. You can do this by extending TableGen itself in C++, or by writing a script in any language that can consume the JSON output.

Example

With no other arguments, *llvm-tblgen* parses the specified file and prints out all of the classes, then all of the definitions. This is a good way to see what the various definitions expand to fully. Running this on the `X86.td` file prints this (at the time of this writing):

```
...
def ADD32rr { // Instruction X86Inst I
  string Namespace = "X86";
  dag OutOperandList = (outs GR32:$dst);
  dag InOperandList = (ins GR32:$src1, GR32:$src2);
  string AsmString = "add{l}\t{$src2, $dst|$dst, $src2}";
  list<dag> Pattern = [(set GR32:$dst, (add GR32:$src1, GR32:$src2))];
  list<Register> Uses = [];
  list<Register> Defs = [EFLAGS];
  list<Predicate> Predicates = [];
  int CodeSize = 3;
  int AddedComplexity = 0;
  bit isReturn = 0;
  bit isBranch = 0;
  bit isIndirectBranch = 0;
  bit isBarrier = 0;
  bit isCall = 0;
  bit canFoldAsLoad = 0;
  bit mayLoad = 0;
  bit mayStore = 0;
  bit isImplicitDef = 0;
  bit isConvertibleToThreeAddress = 1;
  bit isCommutable = 1;
  bit isTerminator = 0;
  bit isReMaterializable = 0;
  bit isPredicable = 0;
  bit hasDelaySlot = 0;
  bit usesCustomInserter = 0;
  bit hasCtrlDep = 0;
  bit isNotDuplicable = 0;
```

(continues on next page)

(continued from previous page)

```

bit hasSideEffects = 0;
InstrItinClass Itinerary = NoItinerary;
string Constraints = "";
string DisableEncoding = "";
bits<8> Opcode = { 0, 0, 0, 0, 0, 0, 0, 1 };
Format Form = MRMDestReg;
bits<6> FormBits = { 0, 0, 0, 0, 1, 1 };
ImmType ImmT = NoImm;
bits<3> ImmTypeBits = { 0, 0, 0 };
bit hasOpSizePrefix = 0;
bit hasAdSizePrefix = 0;
bits<4> Prefix = { 0, 0, 0, 0 };
bit hasREX_WPrefix = 0;
FPFormat FPForm = ?;
bits<3> FPFormBits = { 0, 0, 0 };
}
...

```

This definition corresponds to the 32-bit register-register add instruction of the x86 architecture. `def ADD32rr` defines a record named `ADD32rr`, and the comment at the end of the line indicates the superclasses of the definition. The body of the record contains all of the data that TableGen assembled for the record, indicating that the instruction is part of the "X86" namespace, the pattern indicating how the instruction is selected by the code generator, that it is a two-address instruction, has a particular encoding, etc. The contents and semantics of the information in the record are specific to the needs of the X86 backend, and are only shown as an example.

As you can see, a lot of information is needed for every instruction supported by the code generator, and specifying it all manually would be unmaintainable, prone to bugs, and tiring to do in the first place. Because we are using TableGen, all of the information was derived from the following definition:

```

let Defs = [EFLAGS],
    isCommutable = 1, // X = ADD Y,Z --> X = ADD Z,Y
    isConvertibleToThreeAddress = 1 in // Can transform into LEA.
def ADD32rr : I<0x01, MRMDestReg, (outs GR32:$dst),
    (ins GR32:$src1, GR32:$src2),
    "add{l}\t{$src2, $dst|$dst, $src2}",
    [(set GR32:$dst, (add GR32:$src1, GR32:$src2))]>;

```

This definition makes use of the custom class `I` (extended from the custom class `X86Inst`), which is defined in the X86-specific TableGen file, to factor out the common features that instructions of its class share. A key feature of TableGen is that it allows the end-user to define the abstractions they prefer to use when describing their information.

4.13.7 Syntax

TableGen has a syntax that is loosely based on C++ templates, with built-in types and specification. In addition, TableGen's syntax introduces some automation concepts like multiclass, foreach, let, etc.

Basic concepts

TableGen files consist of two key parts: 'classes' and 'definitions', both of which are considered 'records'.

TableGen records have a unique name, a list of values, and a list of superclasses. The list of values is the main data that TableGen builds for each record; it is this that holds the domain specific information for the application. The interpretation of this data is left to a specific *backend*, but the structure and format rules are taken care of and are fixed by TableGen.

TableGen definitions are the concrete form of 'records'. These generally do not have any undefined values, and are marked with the 'def' keyword.

```
def FeatureFPARMv8 : SubtargetFeature<"fp-armv8", "HasFPARMv8", "true",  
                                     "Enable ARMv8 FP">;
```

In this example, `FeatureFPARMv8` is `SubtargetFeature` record initialised with some values. The names of the classes are defined via the keyword *class* either on the same file or some other included. Most target TableGen files include the generic ones in `include/llvm/Target`.

TableGen classes are abstract records that are used to build and describe other records. These classes allow the end-user to build abstractions for either the domain they are targeting (such as "Register", "RegisterClass", and "Instruction" in the LLVM code generator) or for the implementor to help factor out common properties of records (such as "FPInst", which is used to represent floating point instructions in the X86 backend). TableGen keeps track of all of the classes that are used to build up a definition, so the backend can find all definitions of a particular class, such as "Instruction".

```
class ProcNoItin<string Name, list<SubtargetFeature> Features>  
    : Processor<Name, NoItineraries, Features>;
```

Here, the class `ProcNoItin`, receiving parameters *Name* of type *string* and a list of target features is specializing the class `Processor` by passing the arguments down as well as hard-coding `NoItineraries`.

TableGen multiclasss are groups of abstract records that are instantiated all at once. Each instantiation can result in multiple TableGen definitions. If a multiclass inherits from another multiclass, the definitions in the sub-multiclass become part of the current multiclass, as if they were declared in the current multiclass.

```
multiclass ro_signed_pats<string T, string Rm, dag Base, dag Offset, dag Extend,  
                        dag address, ValueType sty> {  
def : Pat<(i32 (!cast<SDNode>("sextload" # sty) address)),  
        (!cast<Instruction>("LDRS" # T # "w_" # Rm # "_RegOffset")  
        Base, Offset, Extend)>;  
  
def : Pat<(i64 (!cast<SDNode>("sextload" # sty) address)),  
        (!cast<Instruction>("LDRS" # T # "x_" # Rm # "_RegOffset")  
        Base, Offset, Extend)>;  
}  
  
defm : ro_signed_pats<"B", Rm, Base, Offset, Extend,  
                    !foreach(decls.pattern, address,  
                            !subst(SHIFT, imm_eq0, decls.pattern)),  
                    i8>;
```

See the *TableGen Language Introduction* for more generic information on the usage of the language, and the *TableGen Language Reference* for more in-depth description of the formal language specification.

4.13.8 TableGen backends

TableGen files have no real meaning without a back-end. The default operation of running `llvm-tblgen` is to print the information in a textual format, but that's only useful for debugging of the TableGen files themselves. The power in TableGen is, however, to interpret the source files into an internal representation that can be generated into anything you want.

Current usage of TableGen is to create huge include files with tables that you can either include directly (if the output is in the language you're coding), or be used in pre-processing via macros surrounding the include of the file.

Direct output can be used if the back-end already prints a table in C format or if the output is just a list of strings (for error and warning messages). Pre-processed output should be used if the same information needs to be used in different contexts (like Instruction names), so your back-end should print a meta-information list that can be shaped into different compile-time formats.

See the [TableGen BackEnds](#) for more information.

4.13.9 TableGen Deficiencies

Despite being very generic, TableGen has some deficiencies that have been pointed out numerous times. The common theme is that, while TableGen allows you to build Domain-Specific-Languages, the final languages that you create lack the power of other DSLs, which in turn increase considerably the size and complexity of TableGen files.

At the same time, TableGen allows you to create virtually any meaning of the basic concepts via custom-made back-ends, which can pervert the original design and make it very hard for newcomers to understand the evil TableGen file.

There are some in favour of extending the semantics even more, but making sure back-ends adhere to strict rules. Others are suggesting we should move to less, more powerful DSLs designed with specific purposes, or even re-using existing DSLs.

Either way, this is a discussion that will likely span across several years, if not decades. You can read more in the [TableGen Deficiencies](#) document.

4.14 Debugging JIT-ed Code With GDB

4.14.1 Background

Without special runtime support, debugging dynamically generated code with GDB (as well as most debuggers) can be quite painful. Debuggers generally read debug information from the object file of the code, but for JITed code, there is no such file to look for.

In order to communicate the necessary debug info to GDB, an interface for registering JITed code with debuggers has been designed and implemented for GDB and LLVM MCJIT. At a high level, whenever MCJIT generates new machine code, it does so in an in-memory object file that contains the debug information in DWARF format. MCJIT then adds this in-memory object file to a global list of dynamically generated object files and calls a special function (`__jit_debug_register_code`) marked `noinline` that GDB knows about. When GDB attaches to a process, it puts a breakpoint in this function and loads all of the object files in the global list. When MCJIT calls the registration function, GDB catches the breakpoint signal, loads the new object file from the inferior's memory, and resumes the execution. In this way, GDB can get the necessary debug information.

4.14.2 GDB Version

In order to debug code JIT-ed by LLVM, you need GDB 7.0 or newer, which is available on most modern distributions of Linux. The version of GDB that Apple ships with Xcode has been frozen at 6.3 for a while. LLDB may be a better option for debugging JIT-ed code on macOS.

4.14.3 Debugging MCJIT-ed code

The emerging MCJIT component of LLVM allows full debugging of JIT-ed code with GDB. This is due to MCJIT's ability to use the MC emitter to provide full DWARF debugging information to GDB.

Note that lli has to be passed the `-use-mcjit` flag to JIT the code with MCJIT instead of the old JIT.

Example

Consider the following C code (with line numbers added to make the example easier to follow):

```
1  int compute_factorial(int n)
2  {
3      if (n <= 1)
4          return 1;
5
6      int f = n;
7      while (--n > 1)
8          f *= n;
9      return f;
10 }
11
12
13 int main(int argc, char** argv)
14 {
15     if (argc < 2)
16         return -1;
17     char firstletter = argv[1][0];
18     int result = compute_factorial(firstletter - '0');
19
20     // Returned result is clipped at 255...
21     return result;
22 }
```

Here is a sample command line session that shows how to build and run this code via lli inside GDB:

```
$ $BINPATH/clang -ccl -O0 -g -emit-llvm showdebug.c
$ gdb --quiet --args $BINPATH/lli -use-mcjit showdebug.ll 5
Reading symbols from $BINPATH/lli...done.
(gdb) b showdebug.c:6
No source file named showdebug.c.

4.15 The LLVM gold plugin

4.15.1 Introduction

Building with link time optimization requires cooperation from the system linker. LTO support on Linux systems is available via the [gold linker](#) which supports LTO via plugins. This is the same mechanism used by the [GCC LTO](#) project.

The LLVM gold plugin implements the gold plugin interface on top of [libLTO](#). The same plugin can also be used by other tools such as `ar` and `nm`. Note that `ld.bfd` from `binutils` version 2.21.51.0.2 and above also supports LTO via plugins. However, usage of the LLVM gold plugin with `ld.bfd` is not tested and therefore not officially supported or recommended.

4.15.2 How to build it

You need to have gold with plugin support and build the LLVMgold plugin. The gold linker is installed as `ld.gold`. To see whether gold is the default on your system, run `/usr/bin/ld -v`. It will report "GNU gold" or else "GNU ld" if not. If gold is already installed at `/usr/bin/ld.gold`, one option is to simply make that the default by backing up your existing `/usr/bin/ld` and creating a symbolic link with `ln -s /usr/bin/ld.gold /usr/bin/ld`. Alternatively, you can build with clang's `-fuse-lld=gold` or add `-fuse-lld=gold` to `LDFLAGS`, which will cause the clang driver to invoke `/usr/bin/ld.gold` directly.

If you have gold installed, check for plugin support by running `/usr/bin/ld.gold -plugin`. If it complains "missing argument" then you have plugin support. If not, and you get an error such as "unknown option", then you will either need to build gold or install a version with plugin support.

- Download, configure and build gold with plugin support:

```
$ git clone --depth 1 git://sourceware.org/git/binutils-gdb.git binutils
$ mkdir build
$ cd build
$ ../binutils/configure --enable-gold --enable-plugins --disable-werror
$ make all-gold
```

That should leave you with `build/gold/ld-new` which supports the `-plugin` option. Running `make` will additionally build `build/binutils/ar` and `nm-new` binaries supporting plugins.

Once you're ready to switch to using gold, backup your existing `/usr/bin/ld` then replace it with `ld-new`. Alternatively, install in `/usr/bin/ld.gold` and use `-fuse-lld=gold` as described earlier.

Optionally, add `--enable-gold=default` to the above configure invocation to automatically install the newly built gold as the default linker with `make install`.

- Build the LLVMgold plugin. Run CMake with `-DLLVM_BINUTILS_INCDIR=/path/to/binutils/include`. The correct include path will contain the file `plugin-api.h`.

4.15.3 Usage

You should produce bitcode files from `clang` with the option `-flto`. This flag will also cause `clang` to look for the gold plugin in the `lib` directory under its prefix and pass the `-plugin` option to `ld`. It will not look for an alternate linker without `-fuse-ld=gold`, which is why you otherwise need gold to be the installed system linker in your path.

`ar` and `nm` also accept the `-plugin` option and it's possible to install `LLVMgold.so` to `/usr/lib/bfd-plugins` for a seamless setup. If you built your own gold, be sure to install the `ar` and `nm` new you built to `/usr/bin`.

Example of link time optimization

The following example shows a worked example of the gold plugin mixing LLVM bitcode and native code.

```
--- a.c ---
#include <stdio.h>

extern void foo1(void);
extern void foo4(void);

void foo2(void) {
    printf("Foo2\n");
}

void foo3(void) {
    foo4();
}

int main(void) {
    foo1();
}

--- b.c ---
#include <stdio.h>

extern void foo2(void);

void foo1(void) {
    foo2();
}

void foo4(void) {
    printf("Foo4");
}
```

```
--- command lines ---
$ clang -flto a.c -c -o a.o      # <-- a.o is LLVM bitcode file
$ ar q a.a a.o                 # <-- a.a is an archive with LLVM bitcode
$ clang b.c -c -o b.o          # <-- b.o is native object file
$ clang -flto a.a b.o -o main  # <-- link with LLVMgold plugin
```

Gold informs the plugin that `foo3` is never referenced outside the IR, leading LLVM to delete that function. However, unlike in the [libLTO example](#) gold does not currently eliminate `foo4`.

4.15.4 Quickstart for using LTO with autotooled projects

Once your system `ld`, `ar`, and `nm` all support LLVM bitcode, everything is in place for an easy to use LTO build of autotooled projects:

- Follow the instructions *on how to build LLVMgold.so*.
- Install the newly built binutils to `$PREFIX`
- Copy `Release/lib/LLVMgold.so` to `$PREFIX/lib/bfd-plugins/`
- Set environment variables (`$PREFIX` is where you installed clang and binutils):

```
export CC="$PREFIX/bin/clang -flto"
export CXX="$PREFIX/bin/clang++ -flto"
export AR="$PREFIX/bin/ar"
export NM="$PREFIX/bin/nm"
export RANLIB=/bin/true #ranlib is not needed, and doesn't support .bc files in .a
```

- Or you can just set your path:

```
export PATH="$PREFIX/bin:$PATH"
export CC="clang -flto"
export CXX="clang++ -flto"
export RANLIB=/bin/true
```

- Configure and build the project as usual:

```
% ./configure && make && make check
```

The environment variable settings may work for non-autotooled projects too, but you may need to set the `LD` environment variable as well.

4.15.5 Licensing

Gold is licensed under the GPLv3. LLVMgold uses the interface file `plugin-api.h` from gold which means that the resulting `LLVMgold.so` binary is also GPLv3. This can still be used to link non-GPLv3 programs just as much as gold could without the plugin.

4.16 LLVM's Optional Rich Disassembly Output

- *Introduction*
- *Instruction Annotations*
 - *Contextual markups*
 - *C API Details*

4.16.1 Introduction

LLVM's default disassembly output is raw text. To allow consumers more ability to introspect the instructions' textual representation or to reformat for a more user friendly display there is an optional rich disassembly output.

This optional output is sufficient to reference into individual portions of the instruction text. This is intended for clients like disassemblers, list file generators, and pretty-printers, which need more than the raw instructions and the ability to print them.

To provide this functionality the assembly text is marked up with annotations. The markup is simple enough in syntax to be robust even in the case of version mismatches between consumers and producers. That is, the syntax generally does not carry semantics beyond "this text has an annotation," so consumers can simply ignore annotations they do not understand or do not care about.

After calling `LLVMCreateDisasm()` to create a disassembler context the optional output is enable with this call:

```
LLVMSetDisasmOptions(DC, LLVMDisassembler_Option_UseMarkup);
```

Then subsequent calls to `LLVMDisasmInstruction()` will return output strings with the marked up annotations.

4.16.2 Instruction Annotations

Contextual markups

Annotated assembly display will supply contextual markup to help clients more efficiently implement things like pretty printers. Most markup will be target independent, so clients can effectively provide good display without any target specific knowledge.

Annotated assembly goes through the normal instruction printer, but optionally includes contextual tags on portions of the instruction string. An annotation is any '<'>' delimited section of text(1).

```
annotation: '<' tag-name tag-modifier-list ':' annotated-text '>'
tag-name: identifier
tag-modifier-list: comma delimited identifier list
```

The tag-name is an identifier which gives the type of the annotation. For the first pass, this will be very simple, with memory references, registers, and immediates having the tag names "mem", "reg", and "imm", respectively.

The tag-modifier-list is typically additional target-specific context, such as register class.

Clients should accept and ignore any tag-names or tag-modifiers they do not understand, allowing the annotations to grow in richness without breaking older clients.

For example, a possible annotation of an ARM load of a stack-relative location might be annotated as:

```
ldr <reg gpr:r0>, <mem regoffset:[<reg gpr:sp>, <imm:#4>]>
```

1: For assembly dialects in which '<' and/or '>' are legal tokens, a literal token is escaped by following immediately with a repeat of the character. For example, a literal '<' character is output as '<<' in an annotated assembly string.

C API Details

The intended consumers of this information use the C API, therefore the new C API function for the disassembler will be added to provide an option to produce disassembled instructions with annotations, `LLVMSetDisasmOptions()` and the `LLVMDisassembler_Option_UseMarkup` option (see above).

4.17 System Library

4.17.1 Moved

The System Library has been renamed to Support Library with documentation available at [Support Library](#). Please, change your links to that page.

4.18 Support Library

4.18.1 Abstract

This document provides some details on LLVM's Support Library, located in the source at `lib/Support` and `include/llvm/Support`. The library's purpose is to shield LLVM from the differences between operating systems for the few services LLVM needs from the operating system. Much of LLVM is written using portability features of standard C++. However, in a few areas, system dependent facilities are needed and the Support Library is the wrapper around those system calls.

By centralizing LLVM's use of operating system interfaces, we make it possible for the LLVM tool chain and runtime libraries to be more easily ported to new platforms since (theoretically) only `lib/Support` needs to be ported. This library also unclutters the rest of LLVM from `#ifdef` use and special cases for specific operating systems. Such uses are replaced with simple calls to the interfaces provided in `include/llvm/Support`.

Note that the Support Library is not intended to be a complete operating system wrapper (such as the Adaptive Communications Environment (ACE) or Apache Portable Runtime (APR)), but only provides the functionality necessary to support LLVM.

The Support Library was originally referred to as the System Library, written by Reid Spencer who formulated the design based on similar work originating from the eXtensible Programming System (XPS). Several people helped with the effort; especially, Jeff Cohen and Henrik Bach on the Win32 port.

4.18.2 Keeping LLVM Portable

In order to keep LLVM portable, LLVM developers should adhere to a set of portability rules associated with the Support Library. Adherence to these rules should help the Support Library achieve its goal of shielding LLVM from the variations in operating system interfaces and doing so efficiently. The following sections define the rules needed to fulfill this objective.

Don't Include System Headers

Except in `lib/Support`, no LLVM source code should directly `#include` a system header. Care has been taken to remove all such `#includes` from LLVM while `lib/Support` was being developed. Specifically this means that header files like `"unistd.h"`, `"windows.h"`, `"stdio.h"`, and `"string.h"` are forbidden to be included by LLVM source code outside the implementation of `lib/Support`.

To obtain system-dependent functionality, existing interfaces to the system found in `include/llvm/Support` should be used. If an appropriate interface is not available, it should be added to `include/llvm/Support` and implemented in `lib/Support` for all supported platforms.

Don't Expose System Headers

The Support Library must shield LLVM from **all** system headers. To obtain system level functionality, LLVM source must `#include "llvm/Support/Thing.h"` and nothing else. This means that `Thing.h` cannot expose any system header files. This protects LLVM from accidentally using system specific functionality and only allows it via the `lib/Support` interface.

Use Standard C Headers

The **standard** C headers (the ones beginning with `"c"`) are allowed to be exposed through the `lib/Support` interface. These headers and the things they declare are considered to be platform agnostic. LLVM source files may include them directly or obtain their inclusion through `lib/Support` interfaces.

Use Standard C++ Headers

The **standard** C++ headers from the standard C++ library and standard template library may be exposed through the `lib/Support` interface. These headers and the things they declare are considered to be platform agnostic. LLVM source files may include them or obtain their inclusion through `lib/Support` interfaces.

High Level Interface

The entry points specified in the interface of `lib/Support` must be aimed at completing some reasonably high level task needed by LLVM. We do not want to simply wrap each operating system call. It would be preferable to wrap several operating system calls that are always used in conjunction with one another by LLVM.

For example, consider what is needed to execute a program, wait for it to complete, and return its result code. On Unix, this involves the following operating system calls: `getenv`, `fork`, `execve`, and `wait`. The correct thing for `lib/Support` to provide is a function, say `ExecuteProgramAndWait`, that implements the functionality completely. what we don't want is wrappers for the operating system calls involved.

There must **not** be a one-to-one relationship between operating system calls and the Support library's interface. Any such interface function will be suspicious.

No Unused Functionality

There must be no functionality specified in the interface of `lib/Support` that isn't actually used by LLVM. We're not writing a general purpose operating system wrapper here, just enough to satisfy LLVM's needs. And, LLVM doesn't need much. This design goal aims to keep the `lib/Support` interface small and understandable which should foster its actual use and adoption.

No Duplicate Implementations

The implementation of a function for a given platform must be written exactly once. This implies that it must be possible to apply a function's implementation to multiple operating systems if those operating systems can share the same implementation. This rule applies to the set of operating systems supported for a given class of operating system (e.g. Unix, Win32).

No Virtual Methods

The Support Library interfaces can be called quite frequently by LLVM. In order to make those calls as efficient as possible, we discourage the use of virtual methods. There is no need to use inheritance for implementation differences, it just adds complexity. The `#include` mechanism works just fine.

No Exposed Functions

Any functions defined by system libraries (i.e. not defined by `lib/Support`) must not be exposed through the `lib/Support` interface, even if the header file for that function is not exposed. This prevents inadvertent use of system specific functionality.

For example, the `stat` system call is notorious for having variations in the data it provides. `lib/Support` must not declare `stat` nor allow it to be declared. Instead it should provide its own interface to discovering information about files and directories. Those interfaces may be implemented in terms of `stat` but that is strictly an implementation detail. The interface provided by the Support Library must be implemented on all platforms (even those without `stat`).

No Exposed Data

Any data defined by system libraries (i.e. not defined by `lib/Support`) must not be exposed through the `lib/Support` interface, even if the header file for that function is not exposed. As with functions, this prevents inadvertent use of data that might not exist on all platforms.

Minimize Soft Errors

Operating system interfaces will generally provide error results for every little thing that could go wrong. In almost all cases, you can divide these error results into two groups: normal/good/soft and abnormal/bad/hard. That is, some of the errors are simply information like "file not found", "insufficient privileges", etc. while other errors are much harder like "out of space", "bad disk sector", or "system call interrupted". We'll call the first group "*soft*" errors and the second group "*hard*" errors.

`lib/Support` must always attempt to minimize soft errors. This is a design requirement because the minimization of soft errors can affect the granularity and the nature of the interface. In general, if you find that you're wanting to throw soft errors, you must review the granularity of the interface because it is likely you're trying to implement something that is too low level. The rule of thumb is to provide interface functions that **can't** fail, except when faced with hard errors.

For a trivial example, suppose we wanted to add an "OpenFileForWriting" function. For many operating systems, if the file doesn't exist, attempting to open the file will produce an error. However, `lib/Support` should not simply throw that error if it occurs because it's a soft error. The problem is that the interface function, `OpenFileForWriting` is too low level. It should be `OpenOrCreateFileForWriting`. In the case of the soft "doesn't exist" error, this function would just create it and then open it for writing.

This design principle needs to be maintained in `lib/Support` because it avoids the propagation of soft error handling throughout the rest of LLVM. Hard errors will generally just cause a termination for an LLVM tool so don't be bashful about throwing them.

Rules of thumb:

1. Don't throw soft errors, only hard errors.
2. If you're tempted to throw a soft error, re-think the interface.
3. Handle internally the most common normal/good/soft error conditions so the rest of LLVM doesn't have to.

No throw Specifications

None of the `lib/Support` interface functions may be declared with C++ `throw()` specifications on them. This requirement makes sure that the compiler does not insert additional exception handling code into the interface functions. This is a performance consideration: `lib/Support` functions are at the bottom of many call chains and as such can be frequently called. We need them to be as efficient as possible. However, no routines in the system library should actually throw exceptions.

Code Organization

Implementations of the Support Library interface are separated by their general class of operating system. Currently only Unix and Win32 classes are defined but more could be added for other operating system classifications. To distinguish which implementation to compile, the code in `lib/Support` uses the `LLVM_ON_UNIX` and `_WIN32` `#defines`. Each source file in `lib/Support`, after implementing the generic (operating system independent) functionality needs to include the correct implementation using a set of `#if defined(LLVM_ON_XYZ)` directives. For example, if we had `lib/Support/Path.cpp`, we'd expect to see in that file:

```
#if defined(LLVM_ON_UNIX)
#include "Unix/Path.inc"
#endif
#if defined(_WIN32)
#include "Windows/Path.inc"
#endif
```

The implementation in `lib/Support/Unix/Path.inc` should handle all Unix variants. The implementation in `lib/Support/Windows/Path.inc` should handle all Windows variants. What this does is quickly inc the basic class of operating system that will provide the implementation. The specific details for a given platform must still be determined through the use of `#ifdef`.

Consistent Semantics

The implementation of a `lib/Support` interface can vary drastically between platforms. That's okay as long as the end result of the interface function is the same. For example, a function to create a directory is pretty straight forward on all operating system. System V IPC on the other hand isn't even supported on all platforms. Instead of "supporting" System V IPC, `lib/Support` should provide an interface to the basic concept of inter-process communications. The implementations might use System V IPC if that was available or named pipes, or whatever gets the job done effectively for a given operating system. In all cases, the interface and the implementation must be semantically consistent.

4.19.1 Introduction

This document is the central repository for all information pertaining to debug information in LLVM. It describes the *actual format that the LLVM debug information takes*, which is useful for those interested in creating front-ends or dealing directly with the information. Further, this document provides specific examples of what debug information for C/C++ looks like.

Philosophy behind LLVM debugging information

The idea of the LLVM debugging information is to capture how the important pieces of the source-language's Abstract Syntax Tree map onto LLVM code. Several design aspects have shaped the solution that appears here. The important ones are:

- Debugging information should have very little impact on the rest of the compiler. No transformations, analyses, or code generators should need to be modified because of debugging information.
- LLVM optimizations should interact in *well-defined and easily described ways* with the debugging information.
- Because LLVM is designed to support arbitrary programming languages, LLVM-to-LLVM tools should not need to know anything about the semantics of the source-level-language.
- Source-level languages are often **widely** different from one another. LLVM should not put any restrictions of the flavor of the source-language, and the debugging information should work with any language.
- With code generator support, it should be possible to use an LLVM compiler to compile a program to native machine code and standard debugging formats. This allows compatibility with traditional machine-code level debuggers, like GDB or DBX.

The approach used by the LLVM implementation is to use a small set of *intrinsic functions* to define a mapping between LLVM program objects and the source-level objects. The description of the source-level program is maintained in LLVM metadata in an *implementation-defined format* (the C/C++ front-end currently uses working draft 7 of the [DWARF 3 standard](#)).

When a program is being debugged, a debugger interacts with the user and turns the stored debug information into source-language specific information. As such, a debugger must be aware of the source-language, and is thus tied to a specific language or family of languages.

Debug information consumers

The role of debug information is to provide meta information normally stripped away during the compilation process. This meta information provides an LLVM user a relationship between generated code and the original program source code.

Currently, there are two backend consumers of debug info: DwarfDebug and CodeViewDebug. DwarfDebug produces DWARF suitable for use with GDB, LLDB, and other DWARF-based debuggers. *CodeViewDebug* produces CodeView, the Microsoft debug info format, which is usable with Microsoft debuggers such as Visual Studio and WinDBG. LLVM's debug information format is mostly derived from and inspired by DWARF, but it is feasible to translate into other target debug info formats such as STABS.

It would also be reasonable to use debug information to feed profiling tools for analysis of generated code, or, tools for reconstructing the original source from generated code.

Debug information and optimizations

An extremely high priority of LLVM debugging information is to make it interact well with optimizations and analysis. In particular, the LLVM debug information provides the following guarantees:

- LLVM debug information **always provides information to accurately read the source-level state of the program**, regardless of which LLVM optimizations have been run, and without any modification to the optimizations themselves. However, some optimizations may impact the ability to modify the current state of the program with a debugger, such as setting program variables, or calling functions that have been deleted.
- As desired, LLVM optimizations can be upgraded to be aware of debugging information, allowing them to update the debugging information as they perform aggressive optimizations. This means that, with effort, the LLVM optimizers could optimize debug code just as well as non-debug code.

- LLVM debug information does not prevent optimizations from happening (for example inlining, basic block reordering/merging/cleanup, tail duplication, etc).
- LLVM debug information is automatically optimized along with the rest of the program, using existing facilities. For example, duplicate information is automatically merged by the linker, and unused information is automatically removed.

Basically, the debug information allows you to compile a program with `"-O0 -g"` and get full debug information, allowing you to arbitrarily modify the program as it executes from a debugger. Compiling a program with `"-O3 -g"` gives you full debug information that is always available and accurate for reading (e.g., you get accurate stack traces despite tail call elimination and inlining), but you might lose the ability to modify the program and call functions which were optimized out of the program, or inlined away completely.

The *LLVM test-suite* provides a framework to test the optimizer's handling of debugging information. It can be run like this:

```
% cd llvm/projects/test-suite/MultiSource/Benchmarks # or some other level
% make TEST=dbgopt
```

This will test impact of debugging information on optimization passes. If debugging information influences optimization passes then it will be reported as a failure. See *LLVM Testing Infrastructure Guide* for more information on LLVM test infrastructure and how to run various tests.

4.19.2 Debugging information format

LLVM debugging information has been carefully designed to make it possible for the optimizer to optimize the program and debugging information without necessarily having to know anything about debugging information. In particular, the use of metadata avoids duplicated debugging information from the beginning, and the global dead code elimination pass automatically deletes debugging information for a function if it decides to delete the function.

To do this, most of the debugging information (descriptors for types, variables, functions, source files, etc) is inserted by the language front-end in the form of LLVM metadata.

Debug information is designed to be agnostic about the target debugger and debugging information representation (e.g. DWARF/Stabs/etc). It uses a generic pass to decode the information that represents variables, types, functions, namespaces, etc: this allows for arbitrary source-language semantics and type-systems to be used, as long as there is a module written for the target debugger to interpret the information.

To provide basic functionality, the LLVM debugger does have to make some assumptions about the source-level language being debugged, though it keeps these to a minimum. The only common features that the LLVM debugger assumes exist are *source files*, and *program objects*. These abstract objects are used by a debugger to form stack traces, show information about local variables, etc.

This section of the documentation first describes the representation aspects common to any source-language. *C/C++ front-end specific debug information* describes the data layout conventions used by the C and C++ front-ends.

Debug information descriptors are *specialized metadata nodes*, first-class subclasses of `Metadata`.

Debugger intrinsic functions

LLVM uses several intrinsic functions (name prefixed with "llvm.dbg") to track source local variables through optimization and code generation.

llvm.dbg.addr

```
void @llvm.dbg.addr(metadata, metadata, metadata)
```

This intrinsic provides information about a local element (e.g., variable). The first argument is metadata holding the address of variable, typically a static alloca in the function entry block. The second argument is a [local variable](#) containing a description of the variable. The third argument is a [complex expression](#). An *llvm.dbg.addr* intrinsic describes the *address* of a source variable.

```
%i.addr = alloca i32, align 4
call void @llvm.dbg.addr(metadata i32* %i.addr, metadata !1,
                        metadata !DIExpression()), !dbg !2
!1 = !DILocalVariable(name: "i", ...) ; int i
!2 = !DILocation(...)
...
%buffer = alloca [256 x i8], align 8
; The address of i is buffer+64.
call void @llvm.dbg.addr(metadata [256 x i8]* %buffer, metadata !3,
                        metadata !DIExpression(DW_OP_plus, 64)), !dbg !4
!3 = !DILocalVariable(name: "i", ...) ; int i
!4 = !DILocation(...)
```

A frontend should generate exactly one call to *llvm.dbg.addr* at the point of declaration of a source variable. Optimization passes that fully promote the variable from memory to SSA values will replace this call with possibly multiple calls to *llvm.dbg.value*. Passes that delete stores are effectively partial promotion, and they will insert a mix of calls to *llvm.dbg.value* and *llvm.dbg.addr* to track the source variable value when it is available. After optimization, there may be multiple calls to *llvm.dbg.addr* describing the program points where the variables lives in memory. All calls for the same concrete source variable must agree on the memory location.

llvm.dbg.declare

```
void @llvm.dbg.declare(metadata, metadata, metadata)
```

This intrinsic is identical to *llvm.dbg.addr*, except that there can only be one call to *llvm.dbg.declare* for a given concrete [local variable](#). It is not control-dependent, meaning that if a call to *llvm.dbg.declare* exists and has a valid location argument, that address is considered to be the true home of the variable across its entire lifetime. This makes it hard for optimizations to preserve accurate debug info in the presence of *llvm.dbg.declare*, so we are transitioning away from it, and we plan to deprecate it in future LLVM releases.

llvm.dbg.value

```
void @llvm.dbg.value(metadata, metadata, metadata)
```

This intrinsic provides information when a user source variable is set to a new value. The first argument is the new value (wrapped as metadata). The second argument is a [local variable](#) containing a description of the variable. The third argument is a [complex expression](#).

An *llvm.dbg.value* intrinsic describes the *value* of a source variable directly, not its address. Note that the value operand of this intrinsic may be indirect (i.e, a pointer to the source variable), provided that interpreting the complex expression derives the direct value.

4.19.3 Object lifetimes and scoping

In many languages, the local variables in functions can have their lifetimes or scopes limited to a subset of a function. In the C family of languages, for example, variables are only live (readable and writable) within the source block that they are defined in. In functional languages, values are only readable after they have been defined. Though this is a very obvious concept, it is non-trivial to model in LLVM, because it has no notion of scoping in this sense, and does not want to be tied to a language's scoping rules.

In order to handle this, the LLVM debug format uses the metadata attached to llvm instructions to encode line number and scoping information. Consider the following C fragment, for example:

```
1. void foo() {
2.     int X = 21;
3.     int Y = 22;
4.     {
5.         int Z = 23;
6.         Z = X;
7.     }
8.     X = Y;
9. }
```

Compiled to LLVM, this function would be represented like this:

```
; Function Attrs: nounwind ssp uwtable
define void @foo() #0 !dbg !4 {
entry:
    %X = alloca i32, align 4
    %Y = alloca i32, align 4
    %Z = alloca i32, align 4
    call void @llvm.dbg.declare(metadata i32* %X, metadata !11, metadata !13), !dbg !14
    store i32 21, i32* %X, align 4, !dbg !14
    call void @llvm.dbg.declare(metadata i32* %Y, metadata !15, metadata !13), !dbg !16
    store i32 22, i32* %Y, align 4, !dbg !16
    call void @llvm.dbg.declare(metadata i32* %Z, metadata !17, metadata !13), !dbg !19
    store i32 23, i32* %Z, align 4, !dbg !19
    %0 = load i32, i32* %X, align 4, !dbg !20
    store i32 %0, i32* %Z, align 4, !dbg !21
    %1 = load i32, i32* %Y, align 4, !dbg !22
    store i32 %1, i32* %X, align 4, !dbg !23
    ret void, !dbg !24
}

; Function Attrs: nounwind readnone
declare void @llvm.dbg.declare(metadata, metadata, metadata) #1
```

(continues on next page)

```

This example illustrates a few important details about LLVM debugging information. In particular, it shows how the `llvm.dbg.declare` intrinsic and location information, which are attached to an instruction, are applied together to allow a debugger to analyze the relationship between statements, variable definitions, and the code used to implement the function.

```

call void @llvm.dbg.declare(metadata i32* %X, metadata !11, metadata !13), !dbg !14
; [debug line = 2:7] [debug variable = X]

```

The first intrinsic `%llvm.dbg.declare` encodes debugging information for the variable `X`. The metadata `!dbg !14` attached to the intrinsic provides scope information for the variable `X`.

```

!14 = !DILocation(line: 2, column: 9, scope: !4)
!4 = distinct !DISubprogram(name: "foo", scope: !1, file: !1, line: 1, type: !5,
                           isLocal: false, isDefinition: true, scopeLine: 1,
                           isOptimized: false, variables: !2)

```

Here !14 is metadata providing location information. In this example, scope is encoded by !4, a subprogram descriptor. This way the location information attached to the intrinsics indicates that the variable X is declared at line number 2 at a function level scope in function foo.

Now lets take another example.

```
call void @llvm.dbg.declare(metadata i32* %Z, metadata !17, metadata !13), !dbg !19
; [debug line = 5:9] [debug variable = Z]
```

The third intrinsic `llvm.dbg.declare` encodes debugging information for variable Z. The metadata `!dbg !19` attached to the intrinsic provides scope information for the variable Z.

```
!18 = distinct !DILexicalBlock(scope: !4, file: !1, line: 4, column: 5)
!19 = !DILocation(line: 5, column: 11, scope: !18)
```

Here !19 indicates that Z is declared at line number 5 and column number 11 inside of lexical scope !18. The lexical scope itself resides inside of subprogram !4 described above.

The scope information attached with each instruction provides a straightforward way to find instructions covered by a scope.

4.19.4 Object lifetime in optimized code

In the example above, every variable assignment uniquely corresponds to a memory store to the variable's position on the stack. However in heavily optimized code LLVM promotes most variables into SSA values, which can eventually be placed in physical registers or memory locations. To track SSA values through compilation, when objects are promoted to SSA values an `llvm.dbg.value` intrinsic is created for each assignment, recording the variable's new location. Compared with the `llvm.dbg.declare` intrinsic:

- A `dbg.value` terminates the effect of any preceeding `dbg.values` for (any overlapping fragments of) the specified variable.
- The `dbg.value`'s position in the IR defines where in the instruction stream the variable's value changes.
- Operands can be constants, indicating the variable is assigned a constant value.

Care must be taken to update `llvm.dbg.value` intrinsics when optimization passes alter or move instructions and blocks -- the developer could observe such changes reflected in the value of variables when debugging the program. For any execution of the optimized program, the set of variable values presented to the developer by the debugger should not show a state that would never have existed in the execution of the unoptimized program, given the same input. Doing so risks misleading the developer by reporting a state that does not exist, damaging their understanding of the optimized program and undermining their trust in the debugger.

Sometimes perfectly preserving variable locations is not possible, often when a redundant calculation is optimized out. In such cases, a `llvm.dbg.value` with operand `undef` should be used, to terminate earlier variable locations and let the debugger present optimized out to the developer. Withholding these potentially stale variable values from the developer diminishes the amount of available debug information, but increases the reliability of the remaining information.

To illustrate some potential issues, consider the following example:

```
define i32 @foo(i32 %bar, i1 %cond) {
entry:
  call @llvm.dbg.value(metadata i32 0, metadata !1, metadata !2)
  br i1 %cond, label %truebr, label %falsebr
truebr:
  %tval = add i32 %bar, 1
  call @llvm.dbg.value(metadata i32 %tval, metadata !1, metadata !2)
```

(continues on next page)

(continued from previous page)

```

    %g1 = call i32 @gazonk()
    br label %exit
falsebr:
    %fval = add i32 %bar, 2
    call @llvm.dbg.value(metadata i32 %fval, metadata !1, metadata !2)
    %g2 = call i32 @gazonk()
    br label %exit
exit:
    %merge = phi [ %tval, %truebr ], [ %fval, %falsebr ]
    %g = phi [ %g1, %truebr ], [ %g2, %falsebr ]
    call @llvm.dbg.value(metadata i32 %merge, metadata !1, metadata !2)
    call @llvm.dbg.value(metadata i32 %g, metadata !3, metadata !2)
    %plusten = add i32 %merge, 10
    %toret = add i32 %plusten, %g
    call @llvm.dbg.value(metadata i32 %toret, metadata !1, metadata !2)
    ret i32 %toret
}

```

Containing two source-level variables in !1 and !3. The function could, perhaps, be optimized into the following code:

```

define i32 @foo(i32 %bar, i1 %cond) {
entry:
    %g = call i32 @gazonk()
    %addoper = select i1 %cond, i32 11, i32 12
    %plusten = add i32 %bar, %addoper
    %toret = add i32 %plusten, %g
    ret i32 %toret
}

```

What `llvm.dbg.value` intrinsics should be placed to represent the original variable locations in this code? Unfortunately the the second, third and fourth `dbg.values` for !1 in the source function have had their operands (`%tval`, `%fval`, `%merge`) optimized out. Assuming we cannot recover them, we might consider this placement of `dbg.values`:

```

define i32 @foo(i32 %bar, i1 %cond) {
entry:
    call @llvm.dbg.value(metadata i32 0, metadata !1, metadata !2)
    %g = call i32 @gazonk()
    call @llvm.dbg.value(metadata i32 %g, metadata !3, metadata !2)
    %addoper = select i1 %cond, i32 11, i32 12
    %plusten = add i32 %bar, %addoper
    %toret = add i32 %plusten, %g
    call @llvm.dbg.value(metadata i32 %toret, metadata !1, metadata !2)
    ret i32 %toret
}

```

However, this will cause !3 to have the return value of `@gazonk()` at the same time as !1 has the constant value zero -- a pair of assignments that never occurred in the unoptimized program. To avoid this, we must terminate the range that !1 has the constant value assignment by inserting an `undef` `dbg.value` before the `dbg.value` for !3:

```

define i32 @foo(i32 %bar, i1 %cond) {
entry:
    call @llvm.dbg.value(metadata i32 0, metadata !1, metadata !2)
    %g = call i32 @gazonk()
    call @llvm.dbg.value(metadata i32 undef, metadata !1, metadata !2)
    call @llvm.dbg.value(metadata i32 %g, metadata !3, metadata !2)

```

(continues on next page)

(continued from previous page)

```

%addoper = select i1 %cond, i32 11, i32 12
%plusten = add i32 %bar, %addoper
%toret = add i32 %plusten, %g
call @llvm.dbg.value(metadata i32 %toret, metadata !1, metadata !2)
ret i32 %toret
}

```

In general, if any `dbg.value` has its operand optimized out and cannot be recovered, then an `undef` `dbg.value` is necessary to terminate earlier variable locations. Additional `undef` `dbg.values` may be necessary when the debugger can observe re-ordering of assignments.

4.19.5 How variable location metadata is transformed during CodeGen

LLVM preserves debug information throughout mid-level and backend passes, ultimately producing a mapping between source-level information and instruction ranges. This is relatively straightforward for line number information, as mapping instructions to line numbers is a simple association. For variable locations however the story is more complex. As each `llvm.dbg.value` intrinsic represents a source-level assignment of a value to a source variable, the variable location intrinsics effectively embed a small imperative program within the LLVM IR. By the end of CodeGen, this becomes a mapping from each variable to their machine locations over ranges of instructions. From IR to object emission, the major transformations which affect variable location fidelity are:

1. Instruction Selection
2. Register allocation
3. Block layout

each of which are discussed below. In addition, instruction scheduling can significantly change the ordering of the program, and occurs in a number of different passes.

Some variable locations are not transformed during CodeGen. Stack locations specified by `llvm.dbg.declare` are valid and unchanging for the entire duration of the function, and are recorded in a simple `MachineFunction` table. Location changes in the prologue and epilogue of a function are also ignored: frame setup and destruction may take several instructions, require a disproportionate amount of debugging information in the output binary to describe, and should be stepped over by debuggers anyway.

Variable locations in Instruction Selection and MIR

Instruction selection creates a MIR function from an IR function, and just as it transforms `intermediate` instructions into machine instructions, so must `intermediate` variable locations become machine variable locations. Within IR, variable locations are always identified by a `Value`, but in MIR there can be different types of variable locations. In addition, some IR locations become unavailable, for example if the operation of multiple IR instructions are combined into one machine instruction (such as `multiply-and-accumulate`) then `intermediate` `Values` are lost. To track variable locations through instruction selection, they are first separated into locations that do not depend on code generation (constants, stack locations, allocated virtual registers) and those that do. For those that do, debug metadata is attached to `SDNodes` in `SelectionDAGs`. After instruction selection has occurred and a MIR function is created, if the `SDNode` associated with debug metadata is allocated a virtual register, that virtual register is used as the variable location. If the `SDNode` is folded into a machine instruction or otherwise transformed into a non-register, the variable location becomes unavailable.

Locations that are unavailable are treated as if they have been optimized out: in IR the location would be assigned `undef` by a debug intrinsic, and in MIR the equivalent location is used.

After MIR locations are assigned to each variable, machine pseudo-instructions corresponding to each `llvm.dbg.value` and `llvm.dbg.addr` intrinsic are inserted. These `DBG_VALUE` instructions appear thus:

```
DBG_VALUE %1, $noreg, !123, !DIExpression()
```

And have the following operands:

- The first operand can record the variable location as a register, a frame index, an immediate, or the base address register if the original debug intrinsic referred to memory. \$noreg indicates the variable location is undefined, equivalent to an undef dbg.value operand.
- The type of the second operand indicates whether the variable location is directly referred to by the DBG_VALUE, or whether it is indirect. The \$noreg register signifies the former, an immediate operand (0) the latter.
- Operand 3 is the Variable field of the original debug intrinsic.
- Operand 4 is the Expression field of the original debug intrinsic.

The position at which the DBG_VALUES are inserted should correspond to the positions of their matching `llvm.dbg.value` intrinsics in the IR block. As with optimization, LLVM aims to preserve the order in which variable assignments occurred in the source program. However SelectionDAG performs some instruction scheduling, which can reorder assignments (discussed below). Function parameter locations are moved to the beginning of the function if they're not already, to ensure they're immediately available on function entry.

To demonstrate variable locations during instruction selection, consider the following example:

```
define i32 @foo(i32* %addr) {
entry:
  call void @llvm.dbg.value(metadata i32 0, metadata !3, metadata !DIExpression()), !
  ↪dbg !5
  br label %bb1, !dbg !5

bb1:                                     ; preds = %bb1, %entry
  %bar.0 = phi i32 [ 0, %entry ], [ %add, %bb1 ]
  call void @llvm.dbg.value(metadata i32 %bar.0, metadata !3, metadata !
  ↪DIExpression()), !dbg !5
  %addr1 = getelementptr i32, i32 *%addr, i32 1, !dbg !5
  call void @llvm.dbg.value(metadata i32 *%addr1, metadata !3, metadata !
  ↪DIExpression()), !dbg !5
  %loaded1 = load i32, i32* %addr1, !dbg !5
  %addr2 = getelementptr i32, i32 *%addr, i32 %bar.0, !dbg !5
  call void @llvm.dbg.value(metadata i32 *%addr2, metadata !3, metadata !
  ↪DIExpression()), !dbg !5
  %loaded2 = load i32, i32* %addr2, !dbg !5
  %add = add i32 %bar.0, 1, !dbg !5
  call void @llvm.dbg.value(metadata i32 %add, metadata !3, metadata !DIExpression()),
  ↪ !dbg !5
  %added = add i32 %loaded1, %loaded2
  %cond = icmp ult i32 %added, %bar.0, !dbg !5
  br i1 %cond, label %bb1, label %bb2, !dbg !5

bb2:                                     ; preds = %bb1
  ret i32 0, !dbg !5
}
```

If one compiles this IR with `llc -o - -start-after=codegen-prepare -stop-after=expand-isel-pseudos -mtriple=x86_64--`, the following MIR is produced:

```
bb.0.entry:
  successors: %bb.1(0x80000000)
  liveins: $rdi
```

(continues on next page)

(continued from previous page)

```

%2:gr64 = COPY $rdi
%3:gr32 = MOV32r0 implicit-def dead $eflags
DBG_VALUE 0, $noreg, !3, !DIExpression(), debug-location !5

bb.1.bb1:
  successors: %bb.1(0x7c000000), %bb.2(0x04000000)

  %0:gr32 = PHI %3, %bb.0, %1, %bb.1
  DBG_VALUE %0, $noreg, !3, !DIExpression(), debug-location !5
  DBG_VALUE %2, $noreg, !3, !DIExpression(DW_OP_plus_uconst, 4, DW_OP_stack_value),
↳ debug-location !5
  %4:gr32 = MOV32rm %2, 1, $noreg, 4, $noreg, debug-location !5 :: (load 4 from %ir.
↳ addr1)
  %5:gr64_nosp = MOV64rr32 %0, debug-location !5
  DBG_VALUE $noreg, $noreg, !3, !DIExpression(), debug-location !5
  %1:gr32 = INC32r %0, implicit-def dead $eflags, debug-location !5
  DBG_VALUE %1, $noreg, !3, !DIExpression(), debug-location !5
  %6:gr32 = ADD32rm %4, %2, 4, killed %5, 0, $noreg, implicit-def dead $eflags ::
↳ (load 4 from %ir.addr2)
  %7:gr32 = SUB32rr %6, %0, implicit-def $eflags, debug-location !5
  JB_1 %bb.1, implicit $eflags, debug-location !5
  JMP_1 %bb.2, debug-location !5

bb.2.bb2:
  %8:gr32 = MOV32r0 implicit-def dead $eflags
  $eax = COPY %8, debug-location !5
  RET 0, $eax, debug-location !5

```

Observe first that there is a `DBG_VALUE` instruction for every `llvm.dbg.value` intrinsic in the source IR, ensuring no source level assignments go missing. Then consider the different ways in which variable locations have been recorded:

- For the first `dbg.value` an immediate operand is used to record a zero value.
- The `dbg.value` of the PHI instruction leads to a `DBG_VALUE` of virtual register `%0`.
- The first GEP has its effect folded into the first load instruction (as a 4-byte offset), but the variable location is salvaged by folding the GEPs effect into the `DIExpression`.
- The second GEP is also folded into the corresponding load. However, it is insufficiently simple to be salvaged, and is emitted as a `$noreg` `DBG_VALUE`, indicating that the variable takes on an undefined location.
- The final `dbg.value` has its Value placed in virtual register `%1`.

Instruction Scheduling

A number of passes can reschedule instructions, notably instruction selection and the pre-and-post RA machine schedulers. Instruction scheduling can significantly change the nature of the program -- in the (very unlikely) worst case the instruction sequence could be completely reversed. In such circumstances LLVM follows the principle applied to optimizations, that it is better for the debugger not to display any state than a misleading state. Thus, whenever instructions are advanced in order of execution, any corresponding `DBG_VALUE` is kept in its original position, and if an instruction is delayed then the variable is given an undefined location for the duration of the delay. To illustrate, consider this pseudo-MIR:

```
%1:gr32 = MOV32rr %0, 1, $noreg, 4, $noreg, debug-location !5 :: (load 4 from %ir.  
↳addr1)  
DBG_VALUE %1, $noreg, !1, !2  
%4:gr32 = ADD32rr %3, %2, implicit-def dead $eflags  
DBG_VALUE %4, $noreg, !3, !4  
%7:gr32 = SUB32rr %6, %5, implicit-def dead $eflags  
DBG_VALUE %7, $noreg, !5, !6
```

Imagine that the SUB32rr were moved forward to give us the following MIR:

```
%7:gr32 = SUB32rr %6, %5, implicit-def dead $eflags  
%1:gr32 = MOV32rr %0, 1, $noreg, 4, $noreg, debug-location !5 :: (load 4 from %ir.  
↳addr1)  
DBG_VALUE %1, $noreg, !1, !2  
%4:gr32 = ADD32rr %3, %2, implicit-def dead $eflags  
DBG_VALUE %4, $noreg, !3, !4  
DBG_VALUE %7, $noreg, !5, !6
```

In this circumstance LLVM would leave the MIR as shown above. Were we to move the DBG_VALUE of virtual register %7 upwards with the SUB32rr, we would re-order assignments and introduce a new state of the program. Whereas with the solution above, the debugger will see one fewer combination of variable values, because !3 and !5 will change value at the same time. This is preferred over misrepresenting the original program.

In comparison, if one sunk the MOV32rm, LLVM would produce the following:

```
DBG_VALUE $noreg, $noreg, !1, !2  
%4:gr32 = ADD32rr %3, %2, implicit-def dead $eflags  
DBG_VALUE %4, $noreg, !3, !4  
%7:gr32 = SUB32rr %6, %5, implicit-def dead $eflags  
DBG_VALUE %7, $noreg, !5, !6  
%1:gr32 = MOV32rm %0, 1, $noreg, 4, $noreg, debug-location !5 :: (load 4 from %ir.  
↳addr1)  
DBG_VALUE %1, $noreg, !1, !2
```

Here, to avoid presenting a state in which the first assignment to !1 disappears, the DBG_VALUE at the top of the block assigns the variable the undefined location, until its value is available at the end of the block where an additional DBG_VALUE is added. Were any other DBG_VALUE for !1 to occur in the instructions that the MOV32rm was sunk past, the DBG_VALUE for %1 would be dropped and the debugger would never observe it in the variable. This accurately reflects that the value is not available during the corresponding portion of the original program.

Variable locations during Register Allocation

To avoid debug instructions interfering with the register allocator, the LiveDebugVariables pass extracts variable locations from a MIR function and deletes the corresponding DBG_VALUE instructions. Some localized copy propagation is performed within blocks. After register allocation, the VirtRegRewriter pass re-inserts DBG_VALUE instructions in their original positions, translating virtual register references into their physical machine locations. To avoid encoding incorrect variable locations, in this pass any DBG_VALUE of a virtual register that is not live, is replaced by the undefined location.

LiveDebugValues expansion of variable locations

After all optimizations have run and shortly before emission, the LiveDebugValues pass runs to achieve two aims:

- To propagate the location of variables through copies and register spills,
- For every block, to record every valid variable location in that block.

After this pass the `DBG_VALUE` instruction changes meaning: rather than corresponding to a source-level assignment where the variable may change value, it asserts the location of a variable in a block, and loses effect outside the block. Propagating variable locations through copies and spills is straightforward: determining the variable location in every basic block requires the consideration of control flow. Consider the following IR, which presents several difficulties:

```
define dso_local i32 @foo(i1 %cond, i32 %input) !dbg !12 {
entry:
  br i1 %cond, label %truebr, label %falsebr

bb1:
  %value = phi i32 [ %value1, %truebr ], [ %value2, %falsebr ]
  br label %exit, !dbg !26

truebr:
  call void @llvm.dbg.value(metadata i32 %input, metadata !30, metadata !
↪DIEExpression()), !dbg !24
  call void @llvm.dbg.value(metadata i32 1, metadata !23, metadata !DIEExpression()), !
↪dbg !24
  %value1 = add i32 %input, 1
  br label %bb1

falsebr:
  call void @llvm.dbg.value(metadata i32 %input, metadata !30, metadata !
↪DIEExpression()), !dbg !24
  call void @llvm.dbg.value(metadata i32 2, metadata !23, metadata !DIEExpression()), !
↪dbg !24
  %value = add i32 %input, 2
  br label %bb1

exit:
  ret i32 %value, !dbg !30
}
```

Here the difficulties are:

- The control flow is roughly the opposite of basic block order
- The value of the `!23` variable merges into `%bb1`, but there is no PHI node

As mentioned above, the `llvm.dbg.value` intrinsics essentially form an imperative program embedded in the IR, with each intrinsic defining a variable location. This *could* be converted to an SSA form by `mem2reg`, in the same way that it uses use-def chains to identify control flow merges and insert phi nodes for IR Values. However, because debug variable locations are defined for every machine instruction, in effect every IR instruction uses every variable location, which would lead to a large number of debugging intrinsics being generated.

Examining the example above, variable `!30` is assigned `%input` on both conditional paths through the function, while `!23` is assigned differing constant values on either path. Where control flow merges in `%bb1` we would want `!30` to keep its location (`%input`), but `!23` to become undefined as we cannot determine at runtime what value it should have in `%bb1` without inserting a PHI node. `mem2reg` does not insert the PHI node to avoid changing codegen when debugging is enabled, and does not insert the other `dbg.values` to avoid adding very large numbers of intrinsics.

Instead, LiveDebugValues determines variable locations when control flow merges. A dataflow analysis is used to

propagate locations between blocks: when control flow merges, if a variable has the same location in all predecessors then that location is propagated into the successor. If the predecessor locations disagree, the location becomes undefined.

Once `LiveDebugValues` has run, every block should have all valid variable locations described by `DBG_VALUE` instructions within the block. Very little effort is then required by supporting classes (such as `DbgEntityHistoryCalculator`) to build a map of each instruction to every valid variable location, without the need to consider control flow. From the example above, it is otherwise difficult to determine that the location of variable `!30` should flow "up" into block `%bb1`, but that the location of variable `!23` should not flow "down" into the `%exit` block.

4.19.6 C/C++ front-end specific debug information

The C and C++ front-ends represent information about the program in a format that is effectively identical to [DWARF 3.0](#) in terms of information content. This allows code generators to trivially support native debuggers by generating standard dwarf information, and contains enough information for non-dwarf targets to translate it as needed.

This section describes the forms used to represent C and C++ programs. Other languages could pattern themselves after this (which itself is tuned to representing programs in the same way that DWARF 3 does), or they could choose to provide completely different forms if they don't fit into the DWARF model. As support for debugging information gets added to the various LLVM source-language front-ends, the information used should be documented here.

The following sections provide examples of a few C/C++ constructs and the debug information that would best describe those constructs. The canonical references are the `DIDescriptor` classes defined in `include/llvm/IR/DebugInfo.h` and the implementations of the helper functions in `lib/IR/DIBuilder.cpp`.

C/C++ source file information

`llvm::Instruction` provides easy access to metadata attached with an instruction. One can extract line number information encoded in LLVM IR using `Instruction::getDebugLoc()` and `DILocation::getLine()`.

```
if (DILocation *Loc = I->getDebugLoc()) { // Here I is an LLVM instruction
    unsigned Line = Loc->getLine();
   StringRef File = Loc->getFilename();
   StringRef Dir = Loc->getDirectory();
    bool ImplicitCode = Loc->isImplicitCode();
}
```

When the flag `ImplicitCode` is true then it means that the `Instruction` has been added by the front-end but doesn't correspond to source code written by the user. For example

```
if (MyBoolean) {
    MyObject MO;
    ...
}
```

At the end of the scope the `MyObject`'s destructor is called but it isn't written explicitly. This information is useful to avoid to have counters on brackets when making code coverage.

C/C++ global variable information

Given an integer global variable declared as follows:

```
_Alignas(8) int MyGlobal = 100;
```

a C/C++ front-end would generate the following descriptors:

```
;;
;; Define the global itself.
;;
@MyGlobal = global i32 100, align 8, !dbg !0

;;
;; List of debug info of globals
;;
!llvm.dbg.cu = !{!1}

;; Some unrelated metadata.
!llvm.module.flags = !{!6, !7}
!llvm.ident = !{!8}

;; Define the global variable itself
!0 = distinct !DIGlobalVariable(name: "MyGlobal", scope: !1, file: !2, line: 1, type:
↳!5, isLocal: false, isDefinition: true, align: 64)

;; Define the compile unit.
!1 = distinct !DICompileUnit(language: DW_LANG_C99, file: !2,
                             producer: "clang version 4.0.0",
                             isOptimized: false, runtimeVersion: 0, emissionKind:
↳FullDebug,
                             enums: !3, globals: !4)

;;
;; Define the file
;;
!2 = !DIFile(filename: "/dev/stdin",
             directory: "/Users/dexonsmith/data/llvm/debug-info")

;; An empty array.
!3 = !{}

;; The Array of Global Variables
!4 = !{!0}

;;
;; Define the type
;;
!5 = !DIBasicType(name: "int", size: 32, encoding: DW_ATE_signed)

;; Dwarf version to output.
!6 = !{i32 2, !"Dwarf Version", i32 4}

;; Debug info schema version.
!7 = !{i32 2, !"Debug Info Version", i32 3}

;; Compiler identification
!8 = !{"clang version 4.0.0"}
```

The align value in DIGlobalVariable description specifies variable alignment in case it was forced by C11 `_Alignas()`, C++11 `alignas()` keywords or compiler attribute `__attribute__((aligned ()))`. In other case (when this field is missing) alignment is considered default. This is used when producing DWARF output for `DW_AT_alignment` value.

C/C++ function information

Given a function declared as follows:

```
int main(int argc, char *argv[]) {
    return 0;
}
```

a C/C++ front-end would generate the following descriptors:

```
;;
;; Define the anchor for subprograms.
;;
!4 = !DISubprogram(name: "main", scope: !1, file: !1, line: 1, type: !5,
                  isLocal: false, isDefinition: true, scopeLine: 1,
                  flags: DIFlagPrototyped, isOptimized: false,
                  variables: !2)

;;
;; Define the subprogram itself.
;;
define i32 @main(i32 %argc, i8** %argv) !dbg !4 {
...
}
```

4.19.7 Fortran specific debug information

Fortran function information

There are a few DWARF attributes defined to support client debugging of Fortran programs. LLVM can generate (or omit) the appropriate DWARF attributes for the prefix-specs of `ELEMENTAL`, `PURE`, `IMPURE`, `RECURSIVE`, and `NON_RECURSIVE`. This is done by using the `spFlags` values: `DISPFlagElemental`, `DISPFlagPure`, and `DISPFlagRecursive`.

```
elemental function elem_func(a)
```

a Fortran front-end would generate the following descriptors:

```
!11 = distinct !DISubprogram(name: "subroutine2", scope: !1, file: !1,
                             line: 5, type: !8, scopeLine: 6,
                             spFlags: DISPFlagDefinition | DISPFlagElemental, unit: !0,
                             retainedNodes: !2)
```

and this will materialize an additional DWARF attribute as:

```
DW_TAG_subprogram [3]
  DW_AT_low_pc [DW_FORM_addr]      (0x0000000000000010 ".text")
  DW_AT_high_pc [DW_FORM_data4]    (0x00000001)
  ...
  DW_AT_elemental [DW_FORM_flag_present] (true)
```

4.19.8 Debugging information format

Debugging Information Extension for Objective C Properties

Introduction

Objective C provides a simpler way to declare and define accessor methods using declared properties. The language provides features to declare a property and to let compiler synthesize accessor methods.

The debugger lets developer inspect Objective C interfaces and their instance variables and class variables. However, the debugger does not know anything about the properties defined in Objective C interfaces. The debugger consumes information generated by compiler in DWARF format. The format does not support encoding of Objective C properties. This proposal describes DWARF extensions to encode Objective C properties, which the debugger can use to let developers inspect Objective C properties.

Proposal

Objective C properties exist separately from class members. A property can be defined only by "setter" and "getter" selectors, and be calculated anew on each access. Or a property can just be a direct access to some declared ivar. Finally it can have an ivar "automatically synthesized" for it by the compiler, in which case the property can be referred to in user code directly using the standard C dereference syntax as well as through the property "dot" syntax, but there is no entry in the `@interface` declaration corresponding to this ivar.

To facilitate debugging, these properties we will add a new DWARF TAG into the `DW_TAG_structure_type` definition for the class to hold the description of a given property, and a set of DWARF attributes that provide said description. The property tag will also contain the name and declared type of the property.

If there is a related ivar, there will also be a DWARF property attribute placed in the `DW_TAG_member` DIE for that ivar referring back to the property TAG for that property. And in the case where the compiler synthesizes the ivar directly, the compiler is expected to generate a `DW_TAG_member` for that ivar (with the `DW_AT_artificial` set to 1), whose name will be the name used to access this ivar directly in code, and with the property attribute pointing back to the property it is backing.

The following examples will serve as illustration for our discussion:

```
@interface I1 {
    int n2;
}

@property int p1;
@property int p2;
@end

@implementation I1
@synthesize p1;
@synthesize p2 = n2;
@end
```

This produces the following DWARF (this is a "pseudo dwarfdump" output):

```
0x00000100: TAG_structure_type [7] *
               AT_APPLE_runtime_class( 0x10 )
               AT_name( "I1" )
               AT_decl_file( "Objc_Property.m" )
               AT_decl_line( 3 )
```

(continues on next page)

(continued from previous page)

```

0x00000110    TAG_APPLE_property
               AT_name ( "p1" )
               AT_type ( {0x00000150} ( int ) )

0x00000120:   TAG_APPLE_property
               AT_name ( "p2" )
               AT_type ( {0x00000150} ( int ) )

0x00000130:   TAG_member [8]
               AT_name( "_p1" )
               AT_APPLE_property ( {0x00000110} "p1" )
               AT_type( {0x00000150} ( int ) )
               AT_artificial ( 0x1 )

0x00000140:   TAG_member [8]
               AT_name( "n2" )
               AT_APPLE_property ( {0x00000120} "p2" )
               AT_type( {0x00000150} ( int ) )

0x00000150:   AT_type( ( int ) )

```

Note, the current convention is that the name of the ivar for an auto-synthesized property is the name of the property from which it derives with an underscore prepended, as is shown in the example. But we actually don't need to know this convention, since we are given the name of the ivar directly.

Also, it is common practice in ObjC to have different property declarations in the @interface and @implementation - e.g. to provide a read-only property in the interface, and a read-write interface in the implementation. In that case, the compiler should emit whichever property declaration will be in force in the current translation unit.

Developers can decorate a property with attributes which are encoded using DW_AT_APPLE_property_attribute.

```
@property (readonly, nonatomic) int pr;
```

```

TAG_APPLE_property [8]
  AT_name( "pr" )
  AT_type ( {0x00000147} (int) )
  AT_APPLE_property_attribute (DW_APPLE_PROPERTY_readonly, DW_APPLE_PROPERTY_
↪nonatomic)

```

The setter and getter method names are attached to the property using DW_AT_APPLE_property_setter and DW_AT_APPLE_property_getter attributes.

```

@interface I1
@property (setter=myOwnP3Setter:) int p3;
-(void)myOwnP3Setter:(int)a;
@end

@implementation I1
@synthesize p3;
-(void)myOwnP3Setter:(int)a{ }
@end

```

The DWARF for this would be:

```

0x000003bd: TAG_structure_type [7] *
    AT_APPLE_runtime_class( 0x10 )
    AT_name( "I1" )
    AT_decl_file( "Objc_Property.m" )
    AT_decl_line( 3 )

0x000003cd: TAG_APPLE_property
    AT_name ( "p3" )
    AT_APPLE_property_setter ( "myOwnP3Setter:" )
    AT_type( {0x00000147} ( int ) )

0x000003f3: TAG_member [8]
    AT_name( "_p3" )
    AT_type ( {0x00000147} ( int ) )
    AT_APPLE_property ( {0x000003cd} )
    AT_artificial ( 0x1 )

```

Name Accelerator Tables

Introduction

The ".debug_pubnames" and ".debug_pubtypes" formats are not what a debugger needs. The "pub" in the section name indicates that the entries in the table are publicly visible names only. This means no static or hidden functions show up in the ".debug_pubnames". No static variables or private class variables are in the ".debug_pubtypes". Many compilers add different things to these tables, so we can't rely upon the contents between gcc, icc, or clang.

The typical query given by users tends not to match up with the contents of these tables. For example, the DWARF spec states that "In the case of the name of a function member or static data member of a C++ structure, class or union, the name presented in the ".debug_pubnames" section is not the simple name given by the DW_AT_name attribute of the referenced debugging information entry, but rather the fully qualified name of the data or function member." So the only names in these tables for complex C++ entries is a fully qualified name. Debugger users tend not to enter their search strings as "a::b::c(int, const Foo&) const", but rather as "c", "b::c", or "a::b::c". So the name entered in the name table must be demangled in order to chop it up appropriately and additional names must be manually entered into the table to make it effective as a name lookup table for debuggers to use.

All debuggers currently ignore the ".debug_pubnames" table as a result of its inconsistent and useless public-only name content making it a waste of space in the object file. These tables, when they are written to disk, are not sorted in any way, leaving every debugger to do its own parsing and sorting. These tables also include an inlined copy of the string values in the table itself making the tables much larger than they need to be on disk, especially for large C++ programs.

Can't we just fix the sections by adding all of the names we need to this table? No, because that is not what the tables are defined to contain and we won't know the difference between the old bad tables and the new good tables. At best we could make our own renamed sections that contain all of the data we need.

These tables are also insufficient for what a debugger like LLDB needs. LLDB uses clang for its expression parsing where LLDB acts as a PCH. LLDB is then often asked to look for type "Foo" or namespace "bar", or list items in namespace "baz". Namespaces are not included in the pubnames or pubtypes tables. Since clang asks a lot of questions when it is parsing an expression, we need to be very fast when looking up names, as it happens a lot. Having new accelerator tables that are optimized for very quick lookups will benefit this type of debugging experience greatly.

We would like to generate name lookup tables that can be mapped into memory from disk, and used as is, with little or no up-front parsing. We would also be able to control the exact content of these different tables so they contain exactly what we need. The Name Accelerator Tables were designed to fix these issues. In order to solve these issues we need to:

- Have a format that can be mapped into memory from disk and used as is
- Lookups should be very fast
- Extensible table format so these tables can be made by many producers
- Contain all of the names needed for typical lookups out of the box
- Strict rules for the contents of tables

Table size is important and the accelerator table format should allow the reuse of strings from common string tables so the strings for the names are not duplicated. We also want to make sure the table is ready to be used as-is by simply mapping the table into memory with minimal header parsing.

The name lookups need to be fast and optimized for the kinds of lookups that debuggers tend to do. Optimally we would like to touch as few parts of the mapped table as possible when doing a name lookup and be able to quickly find the name entry we are looking for, or discover there are no matches. In the case of debuggers we optimized for lookups that fail most of the time.

Each table that is defined should have strict rules on exactly what is in the accelerator tables and documented so clients can rely on the content.

Hash Tables

Standard Hash Tables

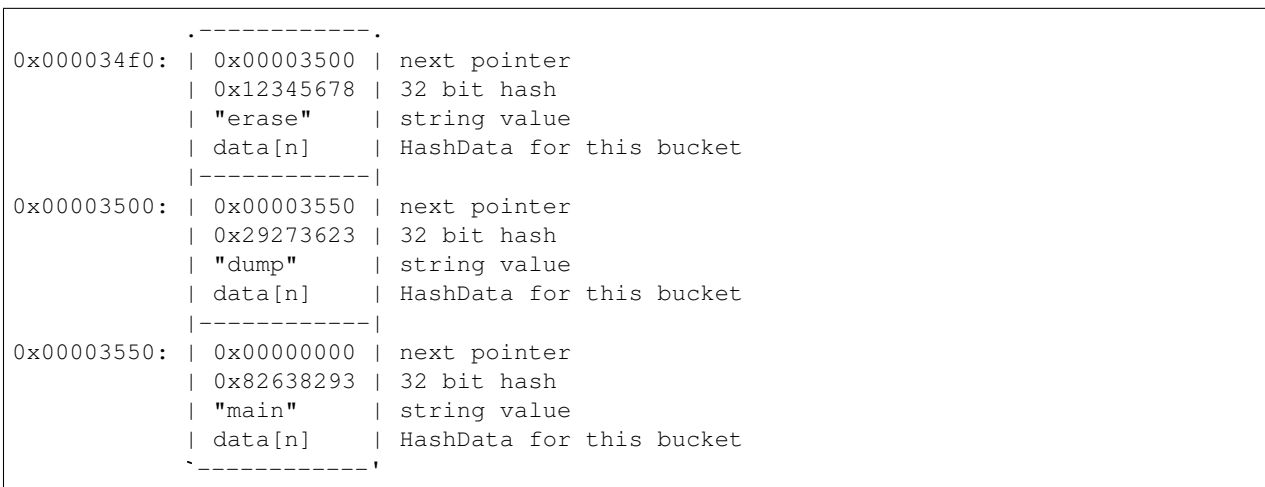

Typical hash tables have a header, buckets, and each bucket points to the bucket contents:

The BUCKETS are an array of offsets to DATA for each hash:

So for bucket[3] in the example above, we have an offset into the table 0x000034f0 which points to a chain of entries for the bucket. Each bucket must contain a next pointer, full 32 bit hash value, the string itself, and the data for the current string value.

The problem with this layout for debuggers is that we need to optimize for the negative lookup case where the symbol we're searching for is not present. So if we were to lookup "printf" in the table above, we would make a 32-bit hash for "printf", it might match bucket[3]. We would need to go to the offset 0x000034f0 and start looking to see if our 32 bit hash matches. To do so, we need to read the next pointer, then read the hash, compare it, and skip to the next bucket. Each time we are skipping many bytes in memory and touching new pages just to do the compare on the full 32 bit hash. All of these accesses then tell us that we didn't have a match.

Name Hash Tables

To solve the issues mentioned above we have structured the hash tables a bit differently: a header, buckets, an array of all unique 32 bit hash values, followed by an array of hash value data offsets, one for each hash value, then the data for all hash values:

HEADER
BUCKETS
HASHES
OFFSETS
DATA

The BUCKETS in the name tables are an index into the HASHES array. By making all of the full 32 bit hash values contiguous in memory, we allow ourselves to efficiently check for a match while touching as little memory as possible. Most often checking the 32 bit hash values is as far as the lookup goes. If it does match, it usually is a match with no collisions. So for a table with "n_buckets" buckets, and "n_hashes" unique 32 bit hash values, we can clarify the contents of the BUCKETS, HASHES and OFFSETS as:

HEADER.magic	uint32_t
HEADER.version	uint16_t
HEADER.hash_function	uint16_t
HEADER.bucket_count	uint32_t
HEADER.hashes_count	uint32_t
HEADER.header_data_len	uint32_t
HEADER_DATA	HeaderData
BUCKETS	uint32_t[n_buckets] // 32 bit hash indexes
HASHES	uint32_t[n_hashes] // 32 bit hash values
OFFSETS	uint32_t[n_hashes] // 32 bit offsets to hash value data
ALL HASH DATA	

So taking the exact same data from the standard hash example above we end up with:

HEADER
0 BUCKETS[0]
2 BUCKETS[1]
5 BUCKETS[2]
6 BUCKETS[3]
...
... BUCKETS[n_buckets]
0x..... HASHES[0]
0x..... HASHES[1]
0x..... HASHES[2]

(continues on next page)

(continued from previous page)

```

0x00003500: | 0x00001203 | String offset into .debug_str ("collision")
| 0x00000002 | A 32 bit array count - number of HashData with name
↪ "collision"
| 0x..... | HashData[0]
| 0x..... | HashData[1]
| 0x00001203 | String offset into .debug_str ("dump")
| 0x00000003 | A 32 bit array count - number of HashData with name "dump"
| 0x..... | HashData[0]
| 0x..... | HashData[1]
| 0x..... | HashData[2]
| 0x00000000 | String offset into .debug_str (terminate data for hash)
|-----|
0x00003550: | 0x00001203 | String offset into .debug_str ("main")
| 0x00000009 | A 32 bit array count - number of HashData with name "main"

```

(continues on next page)

(continued from previous page)

```

| 0x..... | HashData[0]
| 0x..... | HashData[1]
| 0x..... | HashData[2]
| 0x..... | HashData[3]
| 0x..... | HashData[4]
| 0x..... | HashData[5]
| 0x..... | HashData[6]
| 0x..... | HashData[7]
| 0x..... | HashData[8]
| 0x00000000 | String offset into .debug_str (terminate data for hash)
|-----|

```

So we still have all of the same data, we just organize it more efficiently for debugger lookup. If we repeat the same "printf" lookup from above, we would hash "printf" and find it matches BUCKETS[3] by taking the 32 bit hash value and modulo it by n_buckets. BUCKETS[3] contains "6" which is the index into the HASHES table. We would then compare any consecutive 32 bit hashes values in the HASHES array as long as the hashes would be in BUCKETS[3]. We do this by verifying that each subsequent hash value modulo n_buckets is still 3. In the case of a failed lookup we would access the memory for BUCKETS[3], and then compare a few consecutive 32 bit hashes before we know that we have no match. We don't end up marching through multiple words of memory and we really keep the number of processor data cache lines being accessed as small as possible.

The string hash that is used for these lookup tables is the Daniel J. Bernstein hash which is also used in the ELF GNU_HASH sections. It is a very good hash for all kinds of names in programs with very few hash collisions.

Empty buckets are designated by using an invalid hash index of UINT32_MAX.

Details

These name hash tables are designed to be generic where specializations of the table get to define additional data that goes into the header ("HeaderData"), how the string value is stored ("KeyType") and the content of the data for each hash value.

Header Layout

The header has a fixed part, and the specialized part. The exact format of the header is:

```

struct Header
{
    uint32_t    magic;           // 'HASH' magic value to allow endian detection
    uint16_t    version;        // Version number
    uint16_t    hash_function;   // The hash function enumeration that was used
    uint32_t    bucket_count;    // The number of buckets in this hash table
    uint32_t    hashes_count;    // The total number of unique hash values and hash data
    ↪ offsets in this table
    uint32_t    header_data_len; // The bytes to skip to get to the hash indexes
    ↪ (buckets) for correct alignment
                                // Specifically the length of the following HeaderData
    ↪ field - this does not
                                // include the size of the preceding fields
    HeaderData header_data;      // Implementation specific header data
};

```

The header starts with a 32 bit "magic" value which must be 'HASH' encoded as an ASCII integer. This allows the detection of the start of the hash table and also allows the table's byte order to be determined so the table can be

correctly extracted. The "magic" value is followed by a 16 bit version number which allows the table to be revised and modified in the future. The current version number is 1. `hash_function` is a `uint16_t` enumeration that specifies which hash function was used to produce this table. The current values for the hash function enumerations include:

```
enum HashFunctionType
{
    eHashFunctionDJB = 0u, // Daniel J Bernstein hash function
};
```

`bucket_count` is a 32 bit unsigned integer that represents how many buckets are in the `BUCKETS` array. `hashes_count` is the number of unique 32 bit hash values that are in the `HASHES` array, and is the same number of offsets are contained in the `OFFSETS` array. `header_data_len` specifies the size in bytes of the `HeaderData` that is filled in by specialized versions of this table.

Fixed Lookup

The header is followed by the buckets, hashes, offsets, and hash value data.

```
struct FixedTable
{
    uint32_t buckets[Header.bucket_count]; // An array of hash indexes into the
    ↪ "hashes[]" array below
    uint32_t hashes [Header.hashes_count]; // Every unique 32 bit hash for the entire
    ↪ table is in this table
    uint32_t offsets[Header.hashes_count]; // An offset that corresponds to each item
    ↪ in the "hashes[]" array above
};
```

`buckets` is an array of 32 bit indexes into the `hashes` array. The `hashes` array contains all of the 32 bit hash values for all names in the hash table. Each hash in the `hashes` table has an offset in the `offsets` array that points to the data for the hash value.

This table setup makes it very easy to repurpose these tables to contain different data, while keeping the lookup mechanism the same for all tables. This layout also makes it possible to save the table to disk and map it in later and do very efficient name lookups with little or no parsing.

DWARF lookup tables can be implemented in a variety of ways and can store a lot of information for each name. We want to make the DWARF tables extensible and able to store the data efficiently so we have used some of the DWARF features that enable efficient data storage to define exactly what kind of data we store for each name.

The `HeaderData` contains a definition of the contents of each `HashData` chunk. We might want to store an offset to all of the debug information entries (DIEs) for each name. To keep things extensible, we create a list of items, or Atoms, that are contained in the data for each name. First comes the type of the data in each atom:

```
enum AtomType
{
    eAtomTypeNULL      = 0u,
    eAtomTypeDIEOffset = 1u, // DIE offset, check form for encoding
    eAtomTypeCUOffset  = 2u, // DIE offset of the compiler unit header that contains
    ↪ the item in question
    eAtomTypeTag        = 3u, // DW_TAG_XXX value, should be encoded as DW_FORM_data1
    ↪ (if no tags exceed 255) or DW_FORM_data2
    eAtomTypeNameFlags  = 4u, // Flags from enum NameFlags
    eAtomTypeTypeFlags  = 5u, // Flags from enum TypeFlags
};
```

The enumeration values and their meanings are:

```
eAtomTypeNULL      - a termination atom that specifies the end of the atom list
eAtomTypeDIEOffset - an offset into the .debug_info section for the DWARF DIE for_
↳this name
eAtomTypeCUOffset  - an offset into the .debug_info section for the CU that contains_
↳the DIE
eAtomTypeDIETag    - The DW_TAG_XXX enumeration value so you don't have to parse the_
↳DWARF to see what it is
eAtomTypeNameFlags - Flags for functions and global variables (isFunction, isInlined,
↳ isExternal...)
eAtomTypeTypeFlags - Flags for types (isCXXClass, isObjCClass, ...)
```

Then we allow each atom type to define the atom type and how the data for each atom type data is encoded:

```
struct Atom
{
    uint16_t type; // AtomType enum value
    uint16_t form; // DWARF DW_FORM_XXX defines
};
```

The form type above is from the DWARF specification and defines the exact encoding of the data for the Atom type. See the DWARF specification for the DW_FORM_ definitions.

```
struct HeaderData
{
    uint32_t die_offset_base;
    uint32_t atom_count;
    Atoms    atoms[atom_count0];
};
```

HeaderData defines the base DIE offset that should be added to any atoms that are encoded using the DW_FORM_ref1, DW_FORM_ref2, DW_FORM_ref4, DW_FORM_ref8 or DW_FORM_ref_udata. It also defines what is contained in each HashData object -- Atom.form tells us how large each field will be in the HashData and the Atom.type tells us how this data should be interpreted.

For the current implementations of the ".apple_names" (all functions + globals), the ".apple_types" (names of all types that are defined), and the ".apple_namespaces" (all namespaces), we currently set the Atom array to be:

```
HeaderData.atom_count = 1;
HeaderData.atoms[0].type = eAtomTypeDIEOffset;
HeaderData.atoms[0].form = DW_FORM_data4;
```

This defines the contents to be the DIE offset (eAtomTypeDIEOffset) that is encoded as a 32 bit value (DW_FORM_data4). This allows a single name to have multiple matching DIEs in a single file, which could come up with an inlined function for instance. Future tables could include more information about the DIE such as flags indicating if the DIE is a function, method, block, or inlined.

The KeyType for the DWARF table is a 32 bit string table offset into the ".debug_str" table. The ".debug_str" is the string table for the DWARF which may already contain copies of all of the strings. This helps make sure, with help from the compiler, that we reuse the strings between all of the DWARF sections and keeps the hash table size down. Another benefit to having the compiler generate all strings as DW_FORM_strp in the debug info, is that DWARF parsing can be made much faster.

After a lookup is made, we get an offset into the hash data. The hash data needs to be able to deal with 32 bit hash collisions, so the chunk of data at the offset in the hash data consists of a triple:

```
uint32_t str_offset
uint32_t hash_data_count
HashData[hash_data_count]
```

If "str_offset" is zero, then the bucket contents are done. 99.9% of the hash data chunks contain a single item (no 32 bit hash collision):

```
-----
| 0x00001023 | uint32_t KeyType (.debug_str[0x0001023] => "main")
| 0x00000004 | uint32_t HashData count
| 0x..... | uint32_t HashData[0] DIE offset
| 0x..... | uint32_t HashData[1] DIE offset
| 0x..... | uint32_t HashData[2] DIE offset
| 0x..... | uint32_t HashData[3] DIE offset
| 0x00000000 | uint32_t KeyType (end of hash chain)
-----
```

If there are collisions, you will have multiple valid string offsets:

```
-----
| 0x00001023 | uint32_t KeyType (.debug_str[0x0001023] => "main")
| 0x00000004 | uint32_t HashData count
| 0x..... | uint32_t HashData[0] DIE offset
| 0x..... | uint32_t HashData[1] DIE offset
| 0x..... | uint32_t HashData[2] DIE offset
| 0x..... | uint32_t HashData[3] DIE offset
| 0x00002023 | uint32_t KeyType (.debug_str[0x0002023] => "print")
| 0x00000002 | uint32_t HashData count
| 0x..... | uint32_t HashData[0] DIE offset
| 0x..... | uint32_t HashData[1] DIE offset
| 0x00000000 | uint32_t KeyType (end of hash chain)
-----
```

Current testing with real world C++ binaries has shown that there is around 1 32 bit hash collision per 100,000 name entries.

Contents

As we said, we want to strictly define exactly what is included in the different tables. For DWARF, we have 3 tables: ".apple_names", ".apple_types", and ".apple_namespaces".

".apple_names" sections should contain an entry for each DWARF DIE whose DW_TAG is a DW_TAG_label, DW_TAG_inlined_subroutine, or DW_TAG_subprogram that has address attributes: DW_AT_low_pc, DW_AT_high_pc, DW_AT_ranges or DW_AT_entry_pc. It also contains DW_TAG_variable DIEs that have a DW_OP_addr in the location (global and static variables). All global and static variables should be included, including those scoped within functions and classes. For example using the following code:

```
static int var = 0;

void f ()
{
    static int var = 0;
}
```

Both of the static var variables would be included in the table. All functions should emit both their full names and their basenames. For C or C++, the full name is the mangled name (if available) which is usually in the

DW_AT_MIPS_linkage_name attribute, and the DW_AT_name contains the function basename. If global or static variables have a mangled name in a DW_AT_MIPS_linkage_name attribute, this should be emitted along with the simple name found in the DW_AT_name attribute.

".apple_types" sections should contain an entry for each DWARF DIE whose tag is one of:

- DW_TAG_array_type
- DW_TAG_class_type
- DW_TAG_enumeration_type
- DW_TAG_pointer_type
- DW_TAG_reference_type
- DW_TAG_string_type
- DW_TAG_structure_type
- DW_TAG_subroutine_type
- DW_TAG_typedef
- DW_TAG_union_type
- DW_TAG_ptr_to_member_type
- DW_TAG_set_type
- DW_TAG_subrange_type
- DW_TAG_base_type
- DW_TAG_const_type
- DW_TAG_file_type
- DW_TAG_namelist
- DW_TAG_packed_type
- DW_TAG_volatile_type
- DW_TAG_restrict_type
- DW_TAG_atomic_type
- DW_TAG_interface_type
- DW_TAG_unspecified_type
- DW_TAG_shared_type

Only entries with a DW_AT_name attribute are included, and the entry must not be a forward declaration (DW_AT_declaration attribute with a non-zero value). For example, using the following code:

```
int main ()
{
    int *b = 0;
    return *b;
}
```

We get a few type DIEs:

```

0x00000067:    TAG_base_type [5]
               AT_encoding( DW_ATE_signed )
               AT_name( "int" )
               AT_byte_size( 0x04 )

0x0000006e:    TAG_pointer_type [6]
               AT_type( {0x00000067} ( int ) )
               AT_byte_size( 0x08 )

```

The DW_TAG_pointer_type is not included because it does not have a DW_AT_name.

".apple_namespaces" section should contain all DW_TAG_namespace DIEs. If we run into a namespace that has no name this is an anonymous namespace, and the name should be output as "(anonymous namespace)" (without the quotes). Why? This matches the output of the `abi::cxa_demangle()` that is in the standard C++ library that demangles mangled names.

Language Extensions and File Format Changes

Objective-C Extensions

".apple_objc" section should contain all DW_TAG_subprogram DIEs for an Objective-C class. The name used in the hash table is the name of the Objective-C class itself. If the Objective-C class has a category, then an entry is made for both the class name without the category, and for the class name with the category. So if we have a DIE at offset 0x1234 with a name of method `-[NSString(my_additions) stringWithSpecialString:]`, we would add an entry for "NSString" that points to DIE 0x1234, and an entry for "NSString(my_additions)" that points to 0x1234. This allows us to quickly track down all Objective-C methods for an Objective-C class when doing expressions. It is needed because of the dynamic nature of Objective-C where anyone can add methods to a class. The DWARF for Objective-C methods is also emitted differently from C++ classes where the methods are not usually contained in the class definition, they are scattered about across one or more compile units. Categories can also be defined in different shared libraries. So we need to be able to quickly find all of the methods and class functions given the Objective-C class name, or quickly find all methods and class functions for a class + category name. This table does not contain any selector names, it just maps Objective-C class names (or class names + category) to all of the methods and class functions. The selectors are added as function basenames in the ".debug_names" section.

In the ".apple_names" section for Objective-C functions, the full name is the entire function name with the brackets (`-[NSString stringWithCString:]`) and the basename is the selector only (`"stringWithCString:"`).

Mach-O Changes

The sections names for the apple hash tables are for non-mach-o files. For mach-o files, the sections should be contained in the `__DWARF` segment with names as follows:

- ".apple_names" -> "__apple_names"
- ".apple_types" -> "__apple_types"
- ".apple_namespaces" -> "__apple_namespac" (16 character limit)
- ".apple_objc" -> "__apple_objc"

4.19.9 CodeView Debug Info Format

LLVM supports emitting CodeView, the Microsoft debug info format, and this section describes the design and implementation of that support.

Format Background

CodeView as a format is clearly oriented around C++ debugging, and in C++, the majority of debug information tends to be type information. Therefore, the overriding design constraint of CodeView is the separation of type information from other "symbol" information so that type information can be efficiently merged across translation units. Both type information and symbol information is generally stored as a sequence of records, where each record begins with a 16-bit record size and a 16-bit record kind.

Type information is usually stored in the `.debug$T` section of the object file. All other debug info, such as line info, string table, symbol info, and inlined info, is stored in one or more `.debug$S` sections. There may only be one `.debug$T` section per object file, since all other debug info refers to it. If a PDB (enabled by the `/Zi` MSVC option) was used during compilation, the `.debug$T` section will contain only an `LF_TYPESERVER2` record pointing to the PDB. When using PDBs, symbol information appears to remain in the object file `.debug$S` sections.

Type records are referred to by their index, which is the number of records in the stream before a given record plus `0x1000`. Many common basic types, such as the basic integral types and unqualified pointers to them, are represented using type indices less than `0x1000`. Such basic types are built in to CodeView consumers and do not require type records.

Each type record may only contain type indices that are less than its own type index. This ensures that the graph of type stream references is acyclic. While the source-level type graph may contain cycles through pointer types (consider a linked list struct), these cycles are removed from the type stream by always referring to the forward declaration record of user-defined record types. Only "symbol" records in the `.debug$S` streams may refer to complete, non-forward-declaration type records.

Working with CodeView

These are instructions for some common tasks for developers working to improve LLVM's CodeView support. Most of them revolve around using the CodeView dumper embedded in `llvm-readobj`.

- Testing MSVC's output:

```
$ cl -c -Z7 foo.cpp # Use /Z7 to keep types in the object file
$ llvm-readobj --codeview foo.obj
```

- Getting LLVM IR debug info out of Clang:

```
$ clang -g -gcodeview --target=x86_64-windows-msvc foo.cpp -S -emit-llvm
```

Use this to generate LLVM IR for LLVM test cases.

- Generate and dump CodeView from LLVM IR metadata:

```
$ llc foo.ll -filetype=obj -o foo.obj
$ llvm-readobj --codeview foo.obj > foo.txt
```

Use this pattern in lit test cases and FileCheck the output of `llvm-readobj`

Improving LLVM's CodeView support is a process of finding interesting type records, constructing a C++ test case that makes MSVC emit those records, dumping the records, understanding them, and then generating equivalent records in LLVM's backend.

4.19.10 Testing Debug Info Preservation in Optimizations

The following paragraphs are an introduction to the debugify utility and examples of how to use it in regression tests to check debug info preservation after optimizations.

The debugify utility

The debugify synthetic debug info testing utility consists of two main parts. The debugify pass and the check-debugify one. They are meant to be used with opt for development purposes.

The first applies synthetic debug information to every instruction of the module, while the latter checks that this DI is still available after an optimization has occurred, reporting any errors/warnings while doing so.

The instructions are assigned sequentially increasing line locations, and are immediately used by debug value intrinsics when possible.

For example, here is a module before:

```
define void @f(i32* %x) {
entry:
    %x.addr = alloca i32*, align 8
    store i32* %x, i32** %x.addr, align 8
    %0 = load i32*, i32** %x.addr, align 8
    store i32 10, i32* %0, align 4
    ret void
}
```

and after running opt -debugify on it we get:

```
define void @f(i32* %x) !dbg !6 {
entry:
    %x.addr = alloca i32*, align 8, !dbg !12
    call void @llvm.dbg.value(metadata i32** %x.addr, metadata !9, metadata !
    ↪DIEExpression()), !dbg !12
    store i32* %x, i32** %x.addr, align 8, !dbg !13
    %0 = load i32*, i32** %x.addr, align 8, !dbg !14
    call void @llvm.dbg.value(metadata i32* %0, metadata !11, metadata !DIEExpression()),
    ↪ !dbg !14
    store i32 10, i32* %0, align 4, !dbg !15
    ret void, !dbg !16
}

!llvm.dbg.cu = !{!0}
!llvm.debugify = !{!3, !4}
!llvm.module.flags = !{!5}

!0 = distinct !DICompileUnit(language: DW_LANG_C, file: !1, producer: "debugify",
    ↪isOptimized: true, runtimeVersion: 0, emissionKind: FullDebug, enums: !2)
!1 = !DIFile(filename: "debugify-sample.ll", directory: "/")
!2 = !{}
!3 = !{i32 5}
!4 = !{i32 2}
!5 = !{i32 2, !"Debug Info Version", i32 3}
!6 = distinct !DISubprogram(name: "f", linkageName: "f", scope: null, file: !1, line:
    ↪1, type: !7, isLocal: false, isDefinition: true, scopeLine: 1, isOptimized: true,
    ↪unit: !0, retainedNodes: !8)
!7 = !DISubroutineType(types: !2)
```

(continues on next page)

(continued from previous page)

```
!8 = !{!9, !11}
!9 = !DILocalVariable(name: "1", scope: !6, file: !1, line: 1, type: !10)
!10 = !DIBasicType(name: "ty64", size: 64, encoding: DW_ATE_unsigned)
!11 = !DILocalVariable(name: "2", scope: !6, file: !1, line: 3, type: !10)
!12 = !DILocation(line: 1, column: 1, scope: !6)
!13 = !DILocation(line: 2, column: 1, scope: !6)
!14 = !DILocation(line: 3, column: 1, scope: !6)
!15 = !DILocation(line: 4, column: 1, scope: !6)
!16 = !DILocation(line: 5, column: 1, scope: !6)
```

The following is an example of the `-check-debugify` output:

```
$ opt -enable-debugify -loop-vectorize llvm/test/Transforms/LoopVectorize/i8-
↳induction.ll -disable-output
ERROR: Instruction with empty DebugLoc in function f -- %index = phi i32 [ 0,
↳%vector.ph ], [ %index.next, %vector.body ]
```

Errors/warnings can range from instructions with empty debug location to an instruction having a type that's incompatible with the source variable it describes, all the way to missing lines and missing debug value intrinsics.

Fixing errors

Each of the errors above has a relevant API available to fix it.

- In the case of missing debug location, `Instruction::setDebugLoc` or possibly `IRBuilder::setCurrentDebugLocation` when using a `Builder` and the new location should be reused.
- When a debug value has incompatible type `llvm::replaceAllDbgUsesWith` can be used. After a RAUW call an incompatible type error can occur because RAUW does not handle widening and narrowing of variables while `llvm::replaceAllDbgUsesWith` does. It is also capable of changing the DWARF expression used by the debugger to describe the variable. It also prevents use-before-def by salvaging or deleting invalid debug values.
- When a debug value is missing `llvm::salvageDebugInfo` can be used when no replacement exists, or `llvm::replaceAllDbgUsesWith` when a replacement exists.

Using debugify

In order for `check-debugify` to work, the DI must be coming from `debugify`. Thus, modules with existing DI will be skipped.

The most straightforward way to use `debugify` is as follows:

```
$ opt -debugify -pass-to-test -check-debugify sample.ll
```

This will inject synthetic DI to `sample.ll` run the `pass-to-test` and then check for missing DI.

Some other ways to run `debugify` are available:

```
# Same as the above example.
$ opt -enable-debugify -pass-to-test sample.ll

# Suppresses verbose debugify output.
$ opt -enable-debugify -debugify-quiet -pass-to-test sample.ll
```

(continues on next page)

(continued from previous page)

```
# Prepend -debugify before and append -check-debugify -strip after
# each pass on the pipeline (similar to -verify-each).
$ opt -debugify-each -O2 sample.ll
```

debugify can also be used to test a backend, e.g:

```
$ opt -debugify < sample.ll | llc -o -
```

debugify in regression tests

The `-debugify` pass is especially helpful when it comes to testing that a given pass preserves DI while transforming the module. For this to work, the `-debugify` output must be stable enough to use in regression tests. Changes to this pass are not allowed to break existing tests.

It allows us to test for DI loss in the same tests we check that the transformation is actually doing what it should.

Here is an example from `test/Transforms/InstCombine/cast-mul-select.ll`:

```
; RUN: opt < %s -debugify -instcombine -S | FileCheck %s --check-prefix=DEBUGINFO

define i32 @mul(i32 %x, i32 %y) {
; DBGINFO-LABEL: @mul(
; DBGINFO-NEXT:      [[C:%.*]] = mul i32 {{.*}}
; DBGINFO-NEXT:      call void @llvm.dbg.value(metadata i32 [[C]])
; DBGINFO-NEXT:      [[D:%.*]] = and i32 {{.*}}
; DBGINFO-NEXT:      call void @llvm.dbg.value(metadata i32 [[D]])

    %A = trunc i32 %x to i8
    %B = trunc i32 %y to i8
    %C = mul i8 %A, %B
    %D = zext i8 %C to i32
    ret i32 %D
}
```

Here we test that the two `dbg.value` intrinsics are preserved and are correctly pointing to the `[[C]]` and `[[D]]` variables.

Note: Note, that when writing this kind of regression tests, it is important to make them as robust as possible. That's why we should try to avoid hardcoding line/variable numbers in check lines. If for example you test for a `DILocation` to have a specific line number, and someone later adds an instruction before the one we check the test will fail. In the cases this can't be avoided (say, if a test wouldn't be precise enough), moving the test to its own file is preferred.

4.20 Auto-Vectorization in LLVM

- *The Loop Vectorizer*
 - *Usage*
 - * *Command line flags*
 - * *Pragma loop hint directives*
 - *Diagnostics*
 - *Features*
 - * *Loops with unknown trip count*
 - * *Runtime Checks of Pointers*
 - * *Reductions*
 - * *Inductions*
 - * *If Conversion*
 - * *Pointer Induction Variables*
 - * *Reverse Iterators*
 - * *Scatter / Gather*
 - * *Vectorization of Mixed Types*
 - * *Global Structures Alias Analysis*
 - * *Vectorization of function calls*
 - * *Partial unrolling during vectorization*
 - *Performance*
 - *Ongoing Development Directions*
- *The SLP Vectorizer*
 - *Details*
 - *Usage*

LLVM has two vectorizers: The *Loop Vectorizer*, which operates on Loops, and the *SLP Vectorizer*. These vectorizers focus on different optimization opportunities and use different techniques. The SLP vectorizer merges multiple scalars that are found in the code into vectors while the Loop Vectorizer widens instructions in loops to operate on multiple consecutive iterations.

Both the Loop Vectorizer and the SLP Vectorizer are enabled by default.

4.20.1 The Loop Vectorizer

Usage

The Loop Vectorizer is enabled by default, but it can be disabled through clang using the command line flag:

```
$ clang ... -fno-vectorize file.c
```

Command line flags

The loop vectorizer uses a cost model to decide on the optimal vectorization factor and unroll factor. However, users of the vectorizer can force the vectorizer to use specific values. Both 'clang' and 'opt' support the flags below.

Users can control the vectorization SIMD width using the command line flag "-force-vector-width".

```
$ clang -mllvm -force-vector-width=8 ...
$ opt -loop-vectorize -force-vector-width=8 ...
```

Users can control the unroll factor using the command line flag "-force-vector-interleave"

```
$ clang -mllvm -force-vector-interleave=2 ...
$ opt -loop-vectorize -force-vector-interleave=2 ...
```

Pragma loop hint directives

The `#pragma clang loop` directive allows loop vectorization hints to be specified for the subsequent `for`, `while`, `do-while`, or `c++11` range-based `for` loop. The directive allows vectorization and interleaving to be enabled or disabled. Vector width as well as interleave count can also be manually specified. The following example explicitly enables vectorization and interleaving:

```
#pragma clang loop vectorize(enable) interleave(enable)
while(...) {
    ...
}
```

The following example implicitly enables vectorization and interleaving by specifying a vector width and interleaving count:

```
#pragma clang loop vectorize_width(2) interleave_count(2)
for(...) {
    ...
}
```

See the Clang [language extensions](#) for details.

Diagnostics

Many loops cannot be vectorized including loops with complicated control flow, unvectorizable types, and unvectorizable calls. The loop vectorizer generates optimization remarks which can be queried using command line options to identify and diagnose loops that are skipped by the loop-vectorizer.

Optimization remarks are enabled using:

`-Rpass=loop-vectorize` identifies loops that were successfully vectorized.

`-Rpass-missed=loop-vectorize` identifies loops that failed vectorization and indicates if vectorization was specified.

`-Rpass-analysis=loop-vectorize` identifies the statements that caused vectorization to fail. If in addition `-fsave-optimization-record` is provided, multiple causes of vectorization failure may be listed (this behavior might change in the future).

Consider the following loop:

```
#pragma clang loop vectorize(enable)
for (int i = 0; i < Length; i++) {
    switch(A[i]) {
        case 0: A[i] = i*2; break;
        case 1: A[i] = i;   break;
        default: A[i] = 0;
    }
}
```

The command line `-Rpass-missed=loop-vectorized` prints the remark:

```
no_switch.cpp:4:5: remark: loop not vectorized: vectorization is explicitly enabled [-
↪Rpass-missed=loop-vectorize]
```

And the command line `-Rpass-analysis=loop-vectorize` indicates that the switch statement cannot be vectorized.

```
no_switch.cpp:4:5: remark: loop not vectorized: loop contains a switch statement [-
↪Rpass-analysis=loop-vectorize]
    switch(A[i]) {
    ^
```

To ensure line and column numbers are produced include the command line options `-gline-tables-only` and `-gcolumn-info`. See the Clang [user manual](#) for details

Features

The LLVM Loop Vectorizer has a number of features that allow it to vectorize complex loops.

Loops with unknown trip count

The Loop Vectorizer supports loops with an unknown trip count. In the loop below, the iteration start and finish points are unknown, and the Loop Vectorizer has a mechanism to vectorize loops that do not start at zero. In this example, 'n' may not be a multiple of the vector width, and the vectorizer has to execute the last few iterations as scalar code. Keeping a scalar copy of the loop increases the code size.

```
void bar(float *A, float* B, float K, int start, int end) {
    for (int i = start; i < end; ++i)
        A[i] *= B[i] + K;
}
```

Runtime Checks of Pointers

In the example below, if the pointers A and B point to consecutive addresses, then it is illegal to vectorize the code because some elements of A will be written before they are read from array B.

Some programmers use the 'restrict' keyword to notify the compiler that the pointers are disjointed, but in our example, the Loop Vectorizer has no way of knowing that the pointers A and B are unique. The Loop Vectorizer handles this loop by placing code that checks, at runtime, if the arrays A and B point to disjointed memory locations. If arrays A and B overlap, then the scalar version of the loop is executed.

```
void bar(float *A, float* B, float K, int n) {
    for (int i = 0; i < n; ++i)
        A[i] *= B[i] + K;
}
```

Reductions

In this example the sum variable is used by consecutive iterations of the loop. Normally, this would prevent vectorization, but the vectorizer can detect that 'sum' is a reduction variable. The variable 'sum' becomes a vector of integers, and at the end of the loop the elements of the array are added together to create the correct result. We support a number of different reduction operations, such as addition, multiplication, XOR, AND and OR.

```
int foo(int *A, int *B, int n) {
    unsigned sum = 0;
    for (int i = 0; i < n; ++i)
        sum += A[i] + 5;
    return sum;
}
```

We support floating point reduction operations when *-ffast-math* is used.

Inductions

In this example the value of the induction variable `i` is saved into an array. The Loop Vectorizer knows to vectorize induction variables.

```
void bar(float *A, float* B, float K, int n) {  
    for (int i = 0; i < n; ++i)  
        A[i] = i;  
}
```

If Conversion

The Loop Vectorizer is able to "flatten" the IF statement in the code and generate a single stream of instructions. The Loop Vectorizer supports any control flow in the innermost loop. The innermost loop may contain complex nesting of IFs, ELSEs and even GOTOs.

```
int foo(int *A, int *B, int n) {  
    unsigned sum = 0;  
    for (int i = 0; i < n; ++i)  
        if (A[i] > B[i])  
            sum += A[i] + 5;  
    return sum;  
}
```

Pointer Induction Variables

This example uses the "accumulate" function of the standard c++ library. This loop uses C++ iterators, which are pointers, and not integer indices. The Loop Vectorizer detects pointer induction variables and can vectorize this loop. This feature is important because many C++ programs use iterators.

```
int baz(int *A, int n) {  
    return std::accumulate(A, A + n, 0);  
}
```

Reverse Iterators

The Loop Vectorizer can vectorize loops that count backwards.

```
int foo(int *A, int *B, int n) {  
    for (int i = n; i > 0; --i)  
        A[i] += 1;  
}
```

Scatter / Gather

The Loop Vectorizer can vectorize code that becomes a sequence of scalar instructions that scatter/gathers memory.

```
int foo(int * A, int * B, int n) {
    for (intptr_t i = 0; i < n; ++i)
        A[i] += B[i * 4];
}
```

In many situations the cost model will inform LLVM that this is not beneficial and LLVM will only vectorize such code if forced with "-mllvm -force-vector-width=#".

Vectorization of Mixed Types

The Loop Vectorizer can vectorize programs with mixed types. The Vectorizer cost model can estimate the cost of the type conversion and decide if vectorization is profitable.

```
int foo(int *A, char *B, int n, int k) {
    for (int i = 0; i < n; ++i)
        A[i] += 4 * B[i];
}
```

Global Structures Alias Analysis

Access to global structures can also be vectorized, with alias analysis being used to make sure accesses don't alias. Run-time checks can also be added on pointer access to structure members.

Many variations are supported, but some that rely on undefined behaviour being ignored (as other compilers do) are still being left un-vectorized.

```
struct { int A[100], K, B[100]; } Foo;

int foo() {
    for (int i = 0; i < 100; ++i)
        Foo.A[i] = Foo.B[i] + 100;
}
```

Vectorization of function calls

The Loop Vectorizer can vectorize intrinsic math functions. See the table below for a list of these functions.

pow	exp	exp2
sin	cos	sqrt
log	log2	log10
fabs	floor	ceil
fma	trunc	nearbyint
		fmuladd

Note that the optimizer may not be able to vectorize math library functions that correspond to these intrinsics if the library calls access external state such as "errno". To allow better optimization of C/C++ math library functions, use "-fno-math-errno".

The loop vectorizer knows about special instructions on the target and will vectorize a loop containing a function call that maps to the instructions. For example, the loop below will be vectorized on Intel x86 if the SSE4.1 roundps instruction is available.

```
void foo(float *f) {  
    for (int i = 0; i != 1024; ++i)  
        f[i] = floorf(f[i]);  
}
```

Partial unrolling during vectorization

Modern processors feature multiple execution units, and only programs that contain a high degree of parallelism can fully utilize the entire width of the machine. The Loop Vectorizer increases the instruction level parallelism (ILP) by performing partial-unrolling of loops.

In the example below the entire array is accumulated into the variable 'sum'. This is inefficient because only a single execution port can be used by the processor. By unrolling the code the Loop Vectorizer allows two or more execution ports to be used simultaneously.

```
int foo(int *A, int *B, int n) {  
    unsigned sum = 0;  
    for (int i = 0; i < n; ++i)  
        sum += A[i];  
    return sum;  
}
```

The Loop Vectorizer uses a cost model to decide when it is profitable to unroll loops. The decision to unroll the loop depends on the register pressure and the generated code size.

Performance

This section shows the execution time of Clang on a simple benchmark: [gcc-loops](#). This benchmark is a collection of loops from the GCC autovectorization [page](#) by Dorit Nuzman.

The chart below compares GCC-4.7, ICC-13, and Clang-SVN with and without loop vectorization at -O3, tuned for "corei7-avx", running on a Sandybridge iMac. The Y-axis shows the time in msec. Lower is better. The last column shows the geomean of all the kernels.

And Linpack-pc with the same configuration. Result is Mflops, higher is better.

Ongoing Development Directions

Vectorization Plan

 - *References*

Abstract

The vectorization transformation can be rather complicated, involving several potential alternatives, especially for outer-loops¹ but also possibly for innermost loops. These alternatives may have significant performance impact, both positive and negative. A cost model is therefore employed to identify the best alternative, including the alternative of avoiding any transformation altogether.

The Vectorization Plan is an explicit model for describing vectorization candidates. It serves for both optimizing candidates including estimating their cost reliably, and for performing their final translation into IR. This facilitates dealing with multiple vectorization candidates.

High-level Design

Vectorization Workflow

VPlan-based vectorization involves three major steps, taking a "scenario-based approach" to vectorization planning:

1. Legal Step: check if a loop can be legally vectorized; encode constraints and artifacts if so.
2. Plan Step:
 - a. Build initial VPlans following the constraints and decisions taken by Legal Step 1, and compute their cost.
 - b. Apply optimizations to the VPlans, possibly forking additional VPlans. Prune sub-optimal VPlans having relatively high cost.
3. Execute Step: materialize the best VPlan. Note that this is the only step that modifies the IR.

¹ "Outer-loop vectorization: revisited for short SIMD architectures", Dorit Nuzman and Ayal Zaks, PACT 2008.

Design Guidelines

In what follows, the term "input IR" refers to code that is fed into the vectorizer whereas the term "output IR" refers to code that is generated by the vectorizer. The output IR contains code that has been vectorized or "widened" according to a loop Vectorization Factor (VF), and/or loop unroll-and-jammed according to an Unroll Factor (UF). The design of VPlan follows several high-level guidelines:

1. Analysis-like: building and manipulating VPlans must not modify the input IR. In particular, if the best option is not to vectorize at all, the vectorization process terminates before reaching Step 3, and compilation should proceed as if VPlans had not been built.
2. Align Cost & Execute: each VPlan must support both estimating the cost and generating the output IR code, such that the cost estimation evaluates the to-be-generated code reliably.
3. Support vectorizing additional constructs:
 - a. Outer-loop vectorization. In particular, VPlan must be able to model the control-flow of the output IR which may include multiple basic-blocks and nested loops.
 - b. SLP vectorization.
 - c. Combinations of the above, including nested vectorization: vectorizing both an inner loop and an outer-loop at the same time (each with its own VF and UF), mixed vectorization: vectorizing a loop with SLP patterns inside⁴, (re)vectorizing input IR containing vector code.
 - d. Function vectorization².
4. Support multiple candidates efficiently. In particular, similar candidates related to a range of possible VF's and UF's must be represented efficiently. Potential versioning needs to be supported efficiently.
5. Support vectorizing idioms, such as interleaved groups of strided loads or stores. This is achieved by modeling a sequence of output instructions using a "Recipe", which is responsible for computing its cost and generating its code.
6. Encapsulate Single-Entry Single-Exit regions (SESE). During vectorization such regions may need to be, for example, predicated and linearized, or replicated VF*UF times to handle scalarized and predicated instructions. Innerloops are also modelled as SESE regions.
7. Support instruction-level analysis and transformation, as part of Planning Step 2.b: During vectorization instructions may need to be traversed, moved, replaced by other instructions or be created. For example, vector idiom detection and formation involves searching for and optimizing instruction patterns.

Definitions

The low-level design of VPlan comprises of the following classes.

LoopVectorizationPlanner A LoopVectorizationPlanner is designed to handle the vectorization of a loop or a loop nest. It can construct, optimize and discard one or more VPlans, each VPlan modelling a distinct way to vectorize the loop or the loop nest. Once the best VPlan is determined, including the best VF and UF, this VPlan drives the generation of output IR.

VPlan A model of a vectorized candidate for a given input IR loop or loop nest. This candidate is represented using a Hierarchical CFG. VPlan supports estimating the cost and driving the generation of the output IR code it represents.

Hierarchical CFG A control-flow graph whose nodes are basic-blocks or Hierarchical CFG's. The Hierarchical CFG data structure is similar to the Tile Tree⁵, where cross-Tile edges are lifted to connect

⁴ "Exploiting mixed SIMD parallelism by reducing data reorganization overhead", Hao Zhou and Jingling Xue, CGO 2016.

² "Proposal for function vectorization and loop vectorization with function calls", Xinmin Tian, [cfe-dev], March 2, 2016. See also [review](#).

⁵ "Register Allocation via Hierarchical Graph Coloring", David Callahan and Brian Koblenz, PLDI 1991

Tiles instead of the original basic-blocks as in Sharir⁶, promoting the Tile encapsulation. The terms Region and Block are used rather than Tile⁵ to avoid confusion with loop tiling.

VPBlockBase The building block of the Hierarchical CFG. A pure-virtual base-class of VPBasicBlock and VPRegionBlock, see below. VPBlockBase models the hierarchical control-flow relations with other VPBlocks. Note that in contrast to the IR BasicBlock, a VPBlockBase models its control-flow successors and predecessors directly, rather than through a Terminator branch or through predecessor branches that "use" the VPBlockBase.

VPBasicBlock VPBasicBlock is a subclass of VPBlockBase, and serves as the leaves of the Hierarchical CFG. It represents a sequence of output IR instructions that will appear consecutively in an output IR basic-block. The instructions of this basic-block originate from one or more VPBasicBlocks. VPBasicBlock holds a sequence of zero or more VPRecipes that model the cost and generation of the output IR instructions.

VPRegionBlock VPRegionBlock is a subclass of VPBlockBase. It models a collection of VPBasicBlocks and VPRegionBlocks which form a SESE subgraph of the output IR CFG. A VPRegionBlock may indicate that its contents are to be replicated a constant number of times when output IR is generated, effectively representing a loop with constant trip-count that will be completely unrolled. This is used to support scalarized and predicated instructions with a single model for multiple candidate VF's and UF's.

VPRecipeBase A pure-virtual base class modeling a sequence of one or more output IR instructions, possibly based on one or more input IR instructions. These input IR instructions are referred to as "Ingredients" of the Recipe. A Recipe may specify how its ingredients are to be transformed to produce the output IR instructions; e.g., cloned once, replicated multiple times or widened according to selected VF.

VPValue The base of VPlan's def-use relations class hierarchy. When instantiated, it models a constant or a live-in Value in VPlan. It has users, which are of type VPUser, but no operands.

VPUser A VPValue representing a general vertex in the def-use graph of VPlan. It has operands which are of type VPValue. When instantiated, it represents a live-out Instruction that exists outside VPlan. VPUser is similar in some aspects to LLVM's User class.

VPInstruction A VPInstruction is both a VPRecipe and a VPUser. It models a single VPlan-level instruction to be generated if the VPlan is executed, including its opcode and possibly additional characteristics. It is the basis for writing instruction-level analyses and optimizations in VPlan as creating, replacing or moving VPInstructions record both def-use and scheduling decisions. VPInstructions also extend LLVM IR's opcodes with idiomatic operations that enrich the Vectorizer's semantics.

VPTransformState Stores information used for generating output IR, passed from LoopVectorization-Planner to its selected VPlan for execution, and used to pass additional information down to VPBlocks and VPRecipes.

⁶ "Structural analysis: A new approach to flow analysis in optimizing compilers", M. Sharir, Journal of Computer Languages, Jan. 1980

The Planning Process and VPlan Roadmap

Transforming the Loop Vectorizer to use VPlan follows a staged approach. First, VPlan is used to record the final vectorization decisions, and to execute them: the Hierarchical CFG models the planned control-flow, and Recipes capture decisions taken inside basic-blocks. Next, VPlan will be used also as the basis for taking these decisions, effectively turning them into a series of VPlan-to-VPlan algorithms. Finally, VPlan will support the planning process itself including cost-based analyses for making these decisions, to fully support compositional and iterative decision making.

Some decisions are local to an instruction in the loop, such as whether to widen it into a vector instruction or replicate it, keeping the generated instructions in place. Other decisions, however, involve moving instructions, replacing them with other instructions, and/or introducing new instructions. For example, a cast may sink past a later instruction and be widened to handle first-order recurrence; an interleave group of strided gathers or scatters may effectively move to one place where they are replaced with shuffles and a common wide vector load or store; new instructions may be introduced to compute masks, shuffle the elements of vectors, and pack scalar values into vectors or vice-versa.

In order for VPlan to support making instruction-level decisions and analyses, it needs to model the relevant instructions along with their def/use relations. This too follows a staged approach: first, the new instructions that compute masks are modeled as VPIInstructions, along with their induced def/use subgraph. This effectively models masks in VPlan, facilitating VPlan-based predication. Next, the logic embedded within each Recipe for generating its instructions at VPlan execution time, will instead take part in the planning process by modeling them as VPIInstructions. Finally, only logic that applies to instructions as a group will remain in Recipes, such as interleave groups and potentially other idiom groups having synergistic cost.

Related LLVM components

1. SLP Vectorizer: one can compare the VPlan model with LLVM's existing SLP tree, where TSPLP³ adds Plan Step 2.b.
2. RegionInfo: one can compare VPlan's H-CFG with the Region Analysis as used by Polly⁷.
3. Loop Vectorizer: the Vectorization Plan aims to upgrade the infrastructure of the Loop Vectorizer and extend it to handle outer loops^{8,9}.

Vectorization Plan Modeling the process and upgrading the infrastructure of LLVM's Loop Vectorizer.

4.20.2 The SLP Vectorizer

Details

The goal of SLP vectorization (a.k.a. superword-level parallelism) is to combine similar independent instructions into vector instructions. Memory accesses, arithmetic operations, comparison operations, PHI-nodes, can all be vectorized using this technique.

For example, the following function performs very similar operations on its inputs (a1, b1) and (a2, b2). The basic-block vectorizer may combine these into vector operations.

```
void foo(int a1, int a2, int b1, int b2, int *A) {  
    A[0] = a1*(a1 + b1)/b1 + 50*b1/a1;  
    A[1] = a2*(a2 + b2)/b2 + 50*b2/a2;  
}
```

The SLP-vectorizer processes the code bottom-up, across basic blocks, in search of scalars to combine.

Usage

The SLP Vectorizer is enabled by default, but it can be disabled through clang using the command line flag:

```
$ clang -fno-slp-vectorize file.c
```

4.21.1 How To Use Instruction Mappings

- *Introduction*
- *InstrMapping Class Overview*
 - *Sample Example*

Introduction

This document contains information about adding instruction mapping support for a target. The motivation behind this feature comes from the need to switch between different instruction formats during various optimizations. One approach could be to use switch cases which list all the instructions along with formats they can transition to. However, it has large maintenance overhead because of the hardcoded instruction names. Also, whenever a new instruction is added in the .td files, all the relevant switch cases should be modified accordingly. Instead, the same functionality could be achieved with TableGen and some support from the .td files for a fraction of maintenance cost.

InstrMapping Class Overview

TableGen uses relationship models to map instructions with each other. These models are described using InstrMapping class as a base. Each model sets various fields of the InstrMapping class such that they can uniquely describe all the instructions using that model. TableGen parses all the relation models and uses the information to construct relation tables which relate instructions with each other. These tables are emitted in the XXXInstrInfo.inc file along with the functions to query them. Following is the definition of InstrMapping class defined in Target.td file:

```
class InstrMapping {
  // Used to reduce search space only to the instructions using this
  // relation model.
  string FilterClass;

  // List of fields/attributes that should be same for all the instructions in
  // a row of the relation table. Think of this as a set of properties shared
  // by all the instructions related by this relationship.
  list<string> RowFields = [];

  // List of fields/attributes that are same for all the instructions
  // in a column of the relation table.
  list<string> ColFields = [];

  // Values for the fields/attributes listed in 'ColFields' corresponding to
  // the key instruction. This is the instruction that will be transformed
  // using this relation model.
  list<string> KeyCol = [];

  // List of values for the fields/attributes listed in 'ColFields', one for
  // each column in the relation table. These are the instructions a key
  // instruction will be transformed into.
  list<list<string> > ValueCols = [];
}
```

Sample Example

Let's say that we want to have a function `int getPredOpcode(uint16_t Opcode, enum PredSense inPredSense)` which takes a non-predicated instruction and returns its predicated true or false form depending on some input flag, `inPredSense`. The first step in the process is to define a relationship model that relates predicated instructions to their non-predicated form by assigning appropriate values to the InstrMapping fields. For this relationship, non-predicated instructions are treated as key instruction since they are the one used to query the interface function.

```

def getPredOpcode : InstrMapping {
  // Choose a FilterClass that is used as a base class for all the
  // instructions modeling this relationship. This is done to reduce the
  // search space only to these set of instructions.
  let FilterClass = "PredRel";

  // Instructions with same values for all the fields in RowFields form a
  // row in the resulting relation table.
  // For example, if we want to relate 'ADD' (non-predicated) with 'Add_pt'
  // (predicated true) and 'Add_pf' (predicated false), then all 3
  // instructions need to have same value for BaseOpcode field. It can be any
  // unique value (Ex: XYZ) and should not be shared with any other
  // instruction not related to 'add'.
  let RowFields = ["BaseOpcode"];

  // List of attributes that can be used to define key and column instructions
  // for a relation. Key instruction is passed as an argument
  // to the function used for querying relation tables. Column instructions
  // are the instructions they (key) can transform into.
  //
  // Here, we choose 'PredSense' as ColFields since this is the unique
  // attribute of the key (non-predicated) and column (true/false)
  // instructions involved in this relationship model.
  let ColFields = ["PredSense"];

  // The key column contains non-predicated instructions.
  let KeyCol = ["none"];

  // Two value columns - first column contains instructions with
  // PredSense=true while second column has instructions with PredSense=false.
  let ValueCols = [{"true"}, {"false"}];
}

```

TableGen uses the above relationship model to emit relation table that maps non-predicated instructions with their predicated forms. It also outputs the interface function `int getPredOpcode(uint16_t Opcode, enum PredSense inPredSense)` to query the table. Here, Function `getPredOpcode` takes two arguments, opcode of the current instruction and `PredSense` of the desired instruction, and returns predicated form of the instruction, if found in the relation table. In order for an instruction to be added into the relation table, it needs to include relevant information in its definition. For example, consider following to be the current definitions of `ADD`, `ADD_pt` (true) and `ADD_pf` (false) instructions:

```

def ADD : ALU32_rr<(outs IntRegs:$dst), (ins IntRegs:$a, IntRegs:$b),
  "$dst = add($a, $b)",
  [(set (i32 IntRegs:$dst), (add (i32 IntRegs:$a),
                                (i32 IntRegs:$b)))>;

def ADD_Pt : ALU32_rr<(outs IntRegs:$dst),
  (ins PredRegs:$p, IntRegs:$a, IntRegs:$b),
  "if ($p) $dst = add($a, $b)",
  []>;

def ADD_Pf : ALU32_rr<(outs IntRegs:$dst),
  (ins PredRegs:$p, IntRegs:$a, IntRegs:$b),
  "if (!$p) $dst = add($a, $b)",
  []>;

```

In this step, we modify these instructions to include the information required by the relationship model,

<tt>getPredOpcode</tt>, so that they can be related.

```
def ADD : PredRel, ALU32_rr<(outs IntRegs:$dst), (ins IntRegs:$a, IntRegs:$b),
    "$dst = add($a, $b)",
    [(set (i32 IntRegs:$dst), (add (i32 IntRegs:$a),
                                   (i32 IntRegs:$b)))]> {
    let BaseOpcode = "ADD";
    let PredSense = "none";
}

def ADD_Pt : PredRel, ALU32_rr<(outs IntRegs:$dst),
    (ins PredRegs:$p, IntRegs:$a, IntRegs:$b),
    "if ($p) $dst = add($a, $b)",
    []> {
    let BaseOpcode = "ADD";
    let PredSense = "true";
}

def ADD_Pf : PredRel, ALU32_rr<(outs IntRegs:$dst),
    (ins PredRegs:$p, IntRegs:$a, IntRegs:$b),
    "if (!$p) $dst = add($a, $b)",
    []> {
    let BaseOpcode = "ADD";
    let PredSense = "false";
}
```

Please note that all the above instructions use `PredRel` as a base class. This is extremely important since `TableGen` uses it as a filter for selecting instructions for `getPredOpcode` model. Any instruction not derived from `PredRel` is excluded from the analysis. `BaseOpcode` is another important field. Since it's selected as a `RowFields` of the model, it is required to have the same value for all 3 instructions in order to be related. Next, `PredSense` is used to determine their column positions by comparing its value with `KeyCol` and `ValueCols`. If an instruction sets its `PredSense` value to something not used in the relation model, it will not be assigned a column in the relation table.

4.21.2 Introduction

This document describes techniques for writing compiler backends that convert the LLVM Intermediate Representation (IR) to code for a specified machine or other languages. Code intended for a specific machine can take the form of either assembly code or binary code (usable for a JIT compiler).

The backend of LLVM features a target-independent code generator that may create output for several types of target CPUs --- including X86, PowerPC, ARM, and SPARC. The backend may also be used to generate code targeted at SPU's of the Cell processor or GPUs to support the execution of compute kernels.

The document focuses on existing examples found in subdirectories of `llvm/lib/Target` in a downloaded LLVM release. In particular, this document focuses on the example of creating a static compiler (one that emits text assembly) for a SPARC target, because SPARC has fairly standard characteristics, such as a RISC instruction set and straightforward calling conventions.

Audience

The audience for this document is anyone who needs to write an LLVM backend to generate code for a specific hardware or software target.

Prerequisite Reading

These essential documents must be read before reading this document:

- [LLVM Language Reference Manual](#) --- a reference manual for the LLVM assembly language.
- [The LLVM Target-Independent Code Generator](#) --- a guide to the components (classes and code generation algorithms) for translating the LLVM internal representation into machine code for a specified target. Pay particular attention to the descriptions of code generation stages: Instruction Selection, Scheduling and Formation, SSA-based Optimization, Register Allocation, Prolog/Epilog Code Insertion, Late Machine Code Optimizations, and Code Emission.
- [TableGen](#) --- a document that describes the TableGen (`tblgen`) application that manages domain-specific information to support LLVM code generation. TableGen processes input from a target description file (`.td` suffix) and generates C++ code that can be used for code generation.
- [Writing an LLVM Pass](#) --- The assembly printer is a `FunctionPass`, as are several `SelectionDAG` processing steps.

To follow the SPARC examples in this document, have a copy of [The SPARC Architecture Manual, Version 8](#) for reference. For details about the ARM instruction set, refer to the [ARM Architecture Reference Manual](#). For more about the GNU Assembler format (GAS), see [Using As](#), especially for the assembly printer. "Using As" contains a list of target machine dependent features.

Basic Steps

To write a compiler backend for LLVM that converts the LLVM IR to code for a specified target (machine or other language), follow these steps:

- Create a subclass of the `TargetMachine` class that describes characteristics of your target machine. Copy existing examples of specific `TargetMachine` class and header files; for example, start with `SparcTargetMachine.cpp` and `SparcTargetMachine.h`, but change the file names for your target. Similarly, change code that references "Sparc" to reference your target.
- Describe the register set of the target. Use TableGen to generate code for register definition, register aliases, and register classes from a target-specific `RegisterInfo.td` input file. You should also write additional code for a subclass of the `TargetRegisterInfo` class that represents the class register file data used for register allocation and also describes the interactions between registers.
- Describe the instruction set of the target. Use TableGen to generate code for target-specific instructions from target-specific versions of `TargetInstrFormats.td` and `TargetInstrInfo.td`. You should write additional code for a subclass of the `TargetInstrInfo` class to represent machine instructions supported by the target machine.
- Describe the selection and conversion of the LLVM IR from a Directed Acyclic Graph (DAG) representation of instructions to native target-specific instructions. Use TableGen to generate code that matches patterns and selects instructions based on additional information in a target-specific version of `TargetInstrInfo.td`. Write code for `XXXISelDAGToDAG.cpp`, where XXX identifies the specific target, to perform pattern matching and DAG-to-DAG instruction selection. Also write code in `XXXISelLowering.cpp` to replace or remove operations and data types that are not supported natively in a `SelectionDAG`.
- Write code for an assembly printer that converts LLVM IR to a GAS format for your target machine. You should add assembly strings to the instructions defined in your target-specific version of `TargetInstrInfo.td`. You should also write code for a subclass of `AsmPrinter` that performs the LLVM-to-assembly conversion and a trivial subclass of `TargetAsmInfo`.
- Optionally, add support for subtargets (i.e., variants with different capabilities). You should also write code for a subclass of the `TargetSubtarget` class, which allows you to use the `-mcpu=` and `-mattr=` command-line options.

- Optionally, add JIT support and create a machine code emitter (subclass of `TargetJITInfo`) that is used to emit binary code directly into memory.

In the `.cpp` and `.h` files, initially stub up these methods and then implement them later. Initially, you may not know which private members that the class will need and which components will need to be subclassed.

Preliminaries

To actually create your compiler backend, you need to create and modify a few files. The absolute minimum is discussed here. But to actually use the LLVM target-independent code generator, you must perform the steps described in the *LLVM Target-Independent Code Generator* document.

First, you should create a subdirectory under `lib/Target` to hold all the files related to your target. If your target is called "Dummy", create the directory `lib/Target/Dummy`.

In this new directory, create a `CMakeLists.txt`. It is easiest to copy a `CMakeLists.txt` of another target and modify it. It should at least contain the `LLVM_TARGET_DEFINITIONS` variable. The library can be named `LLVMDummy` (for example, see the MIPS target). Alternatively, you can split the library into `LLVMDummyCodeGen` and `LLVMDummyAsmPrinter`, the latter of which should be implemented in a subdirectory below `lib/Target/Dummy` (for example, see the PowerPC target).

Note that these two naming schemes are hardcoded into `llvm-config`. Using any other naming scheme will confuse `llvm-config` and produce a lot of (seemingly unrelated) linker errors when linking `llc`.

To make your target actually do something, you need to implement a subclass of `TargetMachine`. This implementation should typically be in the file `lib/Target/DummyTargetMachine.cpp`, but any file in the `lib/Target` directory will be built and should work. To use LLVM's target independent code generator, you should do what all current machine backends do: create a subclass of `LLVMTargetMachine`. (To create a target from scratch, create a subclass of `TargetMachine`.)

To get LLVM to actually build and link your target, you need to run `cmake` with `-DLLVM_EXPERIMENTAL_TARGETS_TO_BUILD=Dummy`. This will build your target without needing to add it to the list of all the targets.

Once your target is stable, you can add it to the `LLVM_ALL_TARGETS` variable located in the main `CMakeLists.txt`.

4.21.3 Target Machine

`LLVMTargetMachine` is designed as a base class for targets implemented with the LLVM target-independent code generator. The `LLVMTargetMachine` class should be specialized by a concrete target class that implements the various virtual methods. `LLVMTargetMachine` is defined as a subclass of `TargetMachine` in `include/llvm/Target/TargetMachine.h`. The `TargetMachine` class implementation (`TargetMachine.cpp`) also processes numerous command-line options.

To create a concrete target-specific subclass of `LLVMTargetMachine`, start by copying an existing `TargetMachine` class and header. You should name the files that you create to reflect your specific target. For instance, for the SPARC target, name the files `SparcTargetMachine.h` and `SparcTargetMachine.cpp`.

For a target machine XXX, the implementation of `XXXTargetMachine` must have access methods to obtain objects that represent target components. These methods are named `get*Info`, and are intended to obtain the instruction set (`getInstrInfo`), register set (`getRegisterInfo`), stack frame layout (`getFrameInfo`), and similar information. `XXXTargetMachine` must also implement the `getDataLayout` method to access an object with target-specific data characteristics, such as data type size and alignment requirements.

For instance, for the SPARC target, the header file `SparcTargetMachine.h` declares prototypes for several `get*Info` and `getDataLayout` methods that simply return a class member.

```

namespace llvm {

class Module;

class SparcTargetMachine : public LLVMTargetMachine {
    const DataLayout &DataLayout;           // Calculates type size & alignment
    SparcSubtarget &Subtarget;
    SparcInstrInfo &InstrInfo;
    TargetFrameInfo &FrameInfo;

protected:
    virtual const TargetAsmInfo *createTargetAsmInfo() const;

public:
    SparcTargetMachine(const Module &M, const std::string &FS);

    virtual const SparcInstrInfo *getInstrInfo() const {return &InstrInfo; }
    virtual const TargetFrameInfo *getFrameInfo() const {return &FrameInfo; }
    virtual const TargetSubtarget *getSubtargetImpl() const {return &Subtarget; }
    virtual const TargetRegisterInfo *getRegisterInfo() const {
        return &InstrInfo.getRegisterInfo();
    }
    virtual const DataLayout *getDataLayout() const { return &DataLayout; }
    static unsigned getModuleMatchQuality(const Module &M);

    // Pass Pipeline Configuration
    virtual bool addInstSelector(PassManagerBase &PM, bool Fast);
    virtual bool addPreEmitPass(PassManagerBase &PM, bool Fast);
};

} // end namespace llvm

```

- `getInstrInfo()`
- `getRegisterInfo()`
- `getFrameInfo()`
- `getDataLayout()`
- `getSubtargetImpl()`

For some targets, you also need to support the following methods:

- `getTargetLowering()`
- `getJITInfo()`

Some architectures, such as GPUs, do not support jumping to an arbitrary program location and implement branching using masked execution and loop using special instructions around the loop body. In order to avoid CFG modifications that introduce irreducible control flow not handled by such hardware, a target must call *setRequiresStructuredCFG(true)* when being initialized.

In addition, the `XXXTargetMachine` constructor should specify a `TargetDescription` string that determines the data layout for the target machine, including characteristics such as pointer size, alignment, and endianness. For example, the constructor for `SparcTargetMachine` contains the following:

```

SparcTargetMachine::SparcTargetMachine(const Module &M, const std::string &FS)
    : DataLayout("E-p:32:32-f128:128:128"),
      Subtarget(M, FS), InstrInfo(Subtarget),

```

(continues on next page)

(continued from previous page)

```
FrameInfo(TargetFrameInfo::StackGrowsDown, 8, 0) {
}
```

Hyphens separate portions of the `TargetDescription` string.

- An upper-case "E" in the string indicates a big-endian target data model. A lower-case "e" indicates little-endian.
- "p:" is followed by pointer information: size, ABI alignment, and preferred alignment. If only two figures follow "p:", then the first value is pointer size, and the second value is both ABI and preferred alignment.
- Then a letter for numeric type alignment: "i", "f", "v", or "a" (corresponding to integer, floating point, vector, or aggregate). "i", "v", or "a" are followed by ABI alignment and preferred alignment. "f" is followed by three values: the first indicates the size of a long double, then ABI alignment, and then ABI preferred alignment.

4.21.4 Target Registration

You must also register your target with the `TargetRegistry`, which is what other LLVM tools use to be able to lookup and use your target at runtime. The `TargetRegistry` can be used directly, but for most targets there are helper templates which should take care of the work for you.

All targets should declare a global `Target` object which is used to represent the target during registration. Then, in the target's `TargetInfo` library, the target should define that object and use the `RegisterTarget` template to register the target. For example, the Sparc registration code looks like this:

```
Target llvm::getTheSparcTarget();

extern "C" void LLVMInitializeSparcTargetInfo() {
    RegisterTarget<Triple::sparc, /*HasJIT=*/false>
        X(getTheSparcTarget(), "sparc", "Sparc");
}
```

This allows the `TargetRegistry` to look up the target by name or by target triple. In addition, most targets will also register additional features which are available in separate libraries. These registration steps are separate, because some clients may wish to only link in some parts of the target --- the JIT code generator does not require the use of the assembler printer, for example. Here is an example of registering the Sparc assembly printer:

```
extern "C" void LLVMInitializeSparcAsmPrinter() {
    RegisterAsmPrinter<SparcAsmPrinter> X(getTheSparcTarget());
}
```

For more information, see `"llvm/Target/TargetRegistry.h"`.

4.21.5 Register Set and Register Classes

You should describe a concrete target-specific class that represents the register file of a target machine. This class is called `XXXRegisterInfo` (where XXX identifies the target) and represents the class register file data that is used for register allocation. It also describes the interactions between registers.

You also need to define register classes to categorize related registers. A register class should be added for groups of registers that are all treated the same way for some instruction. Typical examples are register classes for integer, floating-point, or vector registers. A register allocator allows an instruction to use any register in a specified register class to perform the instruction in a similar manner. Register classes allocate virtual registers to instructions from these sets, and register classes let the target-independent register allocator automatically choose the actual registers.

Much of the code for registers, including register definition, register aliases, and register classes, is generated by TableGen from XXXRegisterInfo.td input files and placed in XXXGenRegisterInfo.h.inc and XXXGenRegisterInfo.inc output files. Some of the code in the implementation of XXXRegisterInfo requires hand-coding.

Defining a Register

The XXXRegisterInfo.td file typically starts with register definitions for a target machine. The Register class (specified in Target.td) is used to define an object for each register. The specified string *n* becomes the Name of the register. The basic Register object does not have any subregisters and does not specify any aliases.

```
class Register<string n> {
  string Namespace = "";
  string AsmName = n;
  string Name = n;
  int SpillSize = 0;
  int SpillAlignment = 0;
  list<Register> Aliases = [];
  list<Register> SubRegs = [];
  list<int> DwarfNumbers = [];
}
```

For example, in the X86RegisterInfo.td file, there are register definitions that utilize the Register class, such as:

```
def AL : Register<"AL">, DwarfRegNum<[0, 0, 0]>;
```

This defines the register AL and assigns it values (with DwarfRegNum) that are used by gcc, gdb, or a debug information writer to identify a register. For register AL, DwarfRegNum takes an array of 3 values representing 3 different modes: the first element is for X86-64, the second for exception handling (EH) on X86-32, and the third is generic. -1 is a special Dwarf number that indicates the gcc number is undefined, and -2 indicates the register number is invalid for this mode.

From the previously described line in the X86RegisterInfo.td file, TableGen generates this code in the X86GenRegisterInfo.inc file:

```
static const unsigned GR8[] = { X86::AL, ... };

const unsigned AL_AliasSet[] = { X86::AX, X86::EAX, X86::RAX, 0 };

const TargetRegisterDesc RegisterDescriptors[] = {
  ...
  { "AL", "AL", AL_AliasSet, Empty_SubRegsSet, Empty_SubRegsSet, AL_SuperRegsSet }, ...
}
```

From the register info file, TableGen generates a TargetRegisterDesc object for each register. TargetRegisterDesc is defined in include/llvm/Target/TargetRegisterInfo.h with the following fields:

```
struct TargetRegisterDesc {
  const char *AsmName;           // Assembly language name for the register
  const char *Name;              // Printable name for the reg (for debugging)
  const unsigned *AliasSet;      // Register Alias Set
  const unsigned *SubRegs;       // Sub-register set
  const unsigned *ImmSubRegs;    // Immediate sub-register set
  const unsigned *SuperRegs;     // Super-register set
};
```

TableGen uses the entire target description file (.td) to determine text names for the register (in the `AsmName` and `Name` fields of `TargetRegisterDesc`) and the relationships of other registers to the defined register (in the other `TargetRegisterDesc` fields). In this example, other definitions establish the registers "AX", "EAX", and "RAX" as aliases for one another, so TableGen generates a null-terminated array (`AL_AliasSet`) for this register alias set.

The `Register` class is commonly used as a base class for more complex classes. In `Target.td`, the `Register` class is the base for the `RegisterWithSubRegs` class that is used to define registers that need to specify subregisters in the `SubRegs` list, as shown here:

```
class RegisterWithSubRegs<string n, list<Register> subregs> : Register<n> {
  let SubRegs = subregs;
}
```

In `SparcRegisterInfo.td`, additional register classes are defined for SPARC: a `Register` subclass, `SparcReg`, and further subclasses: `Ri`, `Rf`, and `Rd`. SPARC registers are identified by 5-bit ID numbers, which is a feature common to these subclasses. Note the use of "let" expressions to override values that are initially defined in a superclass (such as `SubRegs` field in the `Rd` class).

```
class SparcReg<string n> : Register<n> {
  field bits<5> Num;
  let Namespace = "SP";
}
// Ri - 32-bit integer registers
class Ri<bits<5> num, string n> :
SparcReg<n> {
  let Num = num;
}
// Rf - 32-bit floating-point registers
class Rf<bits<5> num, string n> :
SparcReg<n> {
  let Num = num;
}
// Rd - Slots in the FP register file for 64-bit floating-point values.
class Rd<bits<5> num, string n, list<Register> subregs> : SparcReg<n> {
  let Num = num;
  let SubRegs = subregs;
}
```

In the `SparcRegisterInfo.td` file, there are register definitions that utilize these subclasses of `Register`, such as:

```
def G0 : Ri< 0, "G0">, DwarfRegNum<[0]>;
def G1 : Ri< 1, "G1">, DwarfRegNum<[1]>;
...
def F0 : Rf< 0, "F0">, DwarfRegNum<[32]>;
def F1 : Rf< 1, "F1">, DwarfRegNum<[33]>;
...
def D0 : Rd< 0, "F0", [F0, F1]>, DwarfRegNum<[32]>;
def D1 : Rd< 2, "F2", [F2, F3]>, DwarfRegNum<[34]>;
```

The last two registers shown above (`D0` and `D1`) are double-precision floating-point registers that are aliases for pairs of single-precision floating-point sub-registers. In addition to aliases, the sub-register and super-register relationships of the defined register are in fields of a register's `TargetRegisterDesc`.

Defining a Register Class

The `RegisterClass` class (specified in `Target.td`) is used to define an object that represents a group of related registers and also defines the default allocation order of the registers. A target description file `XXXRegisterInfo.td` that uses `Target.td` can construct register classes using the following class:

```
class RegisterClass<string namespace,
list<ValueType> regTypes, int alignment, dag regList> {
  string Namespace = namespace;
  list<ValueType> RegTypes = regTypes;
  int Size = 0; // spill size, in bits; zero lets tblgen pick the size
  int Alignment = alignment;

  // CopyCost is the cost of copying a value between two registers
  // default value 1 means a single instruction
  // A negative value means copying is extremely expensive or impossible
  int CopyCost = 1;
  dag MemberList = regList;

  // for register classes that are subregisters of this class
  list<RegisterClass> SubRegClassList = [];

  code MethodProtos = [{}]; // to insert arbitrary code
  code MethodBodies = [{}];
}
```

To define a `RegisterClass`, use the following 4 arguments:

- The first argument of the definition is the name of the namespace.
- The second argument is a list of `ValueType` register type values that are defined in `include/llvm/CodeGen/ValueTypes.td`. Defined values include integer types (such as `i16`, `i32`, and `i1` for Boolean), floating-point types (`f32`, `f64`), and vector types (for example, `v8i16` for an 8 × `i16` vector). All registers in a `RegisterClass` must have the same `ValueType`, but some registers may store vector data in different configurations. For example a register that can process a 128-bit vector may be able to handle 16 8-bit integer elements, 8 16-bit integers, 4 32-bit integers, and so on.
- The third argument of the `RegisterClass` definition specifies the alignment required of the registers when they are stored or loaded to memory.
- The final argument, `regList`, specifies which registers are in this class. If an alternative allocation order method is not specified, then `regList` also defines the order of allocation used by the register allocator. Besides simply listing registers with `(add R0, R1, ...)`, more advanced set operators are available. See `include/llvm/Target/Target.td` for more information.

In `SparcRegisterInfo.td`, three `RegisterClass` objects are defined: `FPPRegs`, `DPPRegs`, and `IntRegs`. For all three register classes, the first argument defines the namespace with the string "SP". `FPPRegs` defines a group of 32 single-precision floating-point registers (F0 to F31); `DPPRegs` defines a group of 16 double-precision registers (D0–D15).

```
// F0, F1, F2, ..., F31
def FPPRegs : RegisterClass<"SP", [f32], 32, (sequence "F%u", 0, 31)>;

def DPPRegs : RegisterClass<"SP", [f64], 64,
    (add D0, D1, D2, D3, D4, D5, D6, D7, D8,
     D9, D10, D11, D12, D13, D14, D15)>;

def IntRegs : RegisterClass<"SP", [i32], 32,
```

(continues on next page)

(continued from previous page)

```

    (add L0, L1, L2, L3, L4, L5, L6, L7,
        I0, I1, I2, I3, I4, I5,
        O0, O1, O2, O3, O4, O5, O7,
        G1,
        // Non-allocatable regs:
        G2, G3, G4,
        O6,          // stack ptr
        I6,          // frame ptr
        I7,          // return address
        G0,          // constant zero
        G5, G6, G7 // reserved for kernel
    );

```

Using `SparcRegisterInfo.td` with `TableGen` generates several output files that are intended for inclusion in other source code that you write. `SparcRegisterInfo.td` generates `SparcGenRegisterInfo.h.inc`, which should be included in the header file for the implementation of the SPARC register implementation that you write (`SparcRegisterInfo.h`). In `SparcGenRegisterInfo.h.inc` a new structure is defined called `SparcGenRegisterInfo` that uses `TargetRegisterInfo` as its base. It also specifies types, based upon the defined register classes: `DFPRegsClass`, `FPRegsClass`, and `IntRegsClass`.

`SparcRegisterInfo.td` also generates `SparcGenRegisterInfo.inc`, which is included at the bottom of `SparcRegisterInfo.cpp`, the SPARC register implementation. The code below shows only the generated integer registers and associated register classes. The order of registers in `IntRegs` reflects the order in the definition of `IntRegs` in the target description file.

```

// IntRegs Register Class...
static const unsigned IntRegs[] = {
    SP::L0, SP::L1, SP::L2, SP::L3, SP::L4, SP::L5,
    SP::L6, SP::L7, SP::I0, SP::I1, SP::I2, SP::I3,
    SP::I4, SP::I5, SP::O0, SP::O1, SP::O2, SP::O3,
    SP::O4, SP::O5, SP::O7, SP::G1, SP::G2, SP::G3,
    SP::G4, SP::O6, SP::I6, SP::I7, SP::G0, SP::G5,
    SP::G6, SP::G7,
};

// IntRegsVTs Register Class Value Types...
static const MVT::ValueType IntRegsVTs[] = {
    MVT::i32, MVT::Other
};

namespace SP { // Register class instances
    DFPRegsClass    DFPRegsRegClass;
    FPRegsClass     FPRegsRegClass;
    IntRegsClass     IntRegsRegClass;
...
    // IntRegs Sub-register Classes...
    static const TargetRegisterClass* const IntRegsSubRegClasses [] = {
        NULL
    };
...
    // IntRegs Super-register Classes..
    static const TargetRegisterClass* const IntRegsSuperRegClasses [] = {
        NULL
    };
...
    // IntRegs Register Class sub-classes...

```

(continues on next page)

(continued from previous page)

```

static const TargetRegisterClass* const IntRegsSubclasses [] = {
    NULL
};
...
// IntRegs Register Class super-classes...
static const TargetRegisterClass* const IntRegsSuperclasses [] = {
    NULL
};

IntRegsClass::IntRegsClass() : TargetRegisterClass(IntRegsRegClassID,
    IntRegsVTs, IntRegsSubclasses, IntRegsSuperclasses, IntRegsSubRegClasses,
    IntRegsSuperRegClasses, 4, 4, 1, IntRegs, IntRegs + 32) {}
}

```

The register allocators will avoid using reserved registers, and callee saved registers are not used until all the volatile registers have been used. That is usually good enough, but in some cases it may be necessary to provide custom allocation orders.

Implement a subclass of `TargetRegisterInfo`

The final step is to hand code portions of `XXXRegisterInfo`, which implements the interface described in `TargetRegisterInfo.h` (see *The `TargetRegisterInfo` class*). These functions return 0, `NULL`, or `false`, unless overridden. Here is a list of functions that are overridden for the SPARC implementation in `SparcRegisterInfo.cpp`:

- `getCalleeSavedRegs` --- Returns a list of callee-saved registers in the order of the desired callee-save stack frame offset.
- `getReservedRegs` --- Returns a bitset indexed by physical register numbers, indicating if a particular register is unavailable.
- `hasFP` --- Return a Boolean indicating if a function should have a dedicated frame pointer register.
- `eliminateCallFramePseudoInstr` --- If call frame setup or destroy pseudo instructions are used, this can be called to eliminate them.
- `eliminateFrameIndex` --- Eliminate abstract frame indices from instructions that may use them.
- `emitPrologue` --- Insert prologue code into the function.
- `emitEpilogue` --- Insert epilogue code into the function.

4.21.6 Instruction Set

During the early stages of code generation, the LLVM IR code is converted to a `SelectionDAG` with nodes that are instances of the `SDNode` class containing target instructions. An `SDNode` has an opcode, operands, type requirements, and operation properties. For example, is an operation commutative, does an operation load from memory. The various operation node types are described in the `include/llvm/CodeGen/SelectionDAGNodes.h` file (values of the `NodeType` enum in the `ISD` namespace).

TableGen uses the following target description (`.td`) input files to generate much of the code for instruction definition:

- `Target.td` --- Where the `Instruction`, `Operand`, `InstrInfo`, and other fundamental classes are defined.

- `TargetSelectionDAG.td` --- Used by `SelectionDAG` instruction selection generators, contains `SDTC*` classes (selection DAG type constraint), definitions of `SelectionDAG` nodes (such as `imm`, `cond`, `bb`, `add`, `fadd`, `sub`), and pattern support (`Pattern`, `Pat`, `PatFrag`, `PatLeaf`, `ComplexPattern`).
- `XXXInstrFormats.td` --- Patterns for definitions of target-specific instructions.
- `XXXInstrInfo.td` --- Target-specific definitions of instruction templates, condition codes, and instructions of an instruction set. For architecture modifications, a different file name may be used. For example, for Pentium with SSE instruction, this file is `X86InstrSSE.td`, and for Pentium with MMX, this file is `X86InstrMMX.td`.

There is also a target-specific `XXX.td` file, where `XXX` is the name of the target. The `XXX.td` file includes the other `.td` input files, but its contents are only directly important for subtargets.

You should describe a concrete target-specific class `XXXInstrInfo` that represents machine instructions supported by a target machine. `XXXInstrInfo` contains an array of `XXXInstrDescriptor` objects, each of which describes one instruction. An instruction descriptor defines:

- Opcode mnemonic
- Number of operands
- List of implicit register definitions and uses
- Target-independent properties (such as memory access, is commutable)
- Target-specific flags

The `Instruction` class (defined in `Target.td`) is mostly used as a base for more complex instruction classes.

```
class Instruction {
  string Namespace = "";
  dag OutOperandList;    // A dag containing the MI def operand list.
  dag InOperandList;     // A dag containing the MI use operand list.
  string AsmString = ""; // The .s format to print the instruction with.
  list<dag> Pattern;      // Set to the DAG pattern for this instruction.
  list<Register> Uses = [];
  list<Register> Defs = [];
  list<Predicate> Predicates = []; // predicates turned into isel match code
  ... remainder not shown for space ...
}
```

A `SelectionDAG` node (`SDNode`) should contain an object representing a target-specific instruction that is defined in `XXXInstrInfo.td`. The instruction objects should represent instructions from the architecture manual of the target machine (such as the SPARC Architecture Manual for the SPARC target).

A single instruction from the architecture manual is often modeled as multiple target instructions, depending upon its operands. For example, a manual might describe an `add` instruction that takes a register or an immediate operand. An LLVM target could model this with two instructions named `ADDri` and `ADDrr`.

You should define a class for each instruction category and define each opcode as a subclass of the category with appropriate parameters such as the fixed binary encoding of opcodes and extended opcodes. You should map the register bits to the bits of the instruction in which they are encoded (for the JIT). Also you should specify how the instruction should be printed when the automatic assembly printer is used.

As is described in the SPARC Architecture Manual, Version 8, there are three major 32-bit formats for instructions. Format 1 is only for the `CALL` instruction. Format 2 is for branch on condition codes and `SETHI` (set high bits of a register) instructions. Format 3 is for other instructions.

Each of these formats has corresponding classes in `SparcInstrFormat.td`. `InstSP` is a base class for other instruction classes. Additional base classes are specified for more precise formats: for example in `SparcInstrFormat.td`, `F2_1` is for `SETHI`, and `F2_2` is for branches. There are three other base classes:

F3_1 for register/register operations, F3_2 for register/immediate operations, and F3_3 for floating-point operations. `SparcInstrInfo.td` also adds the base class `Pseudo` for synthetic SPARC instructions.

`SparcInstrInfo.td` largely consists of operand and instruction definitions for the SPARC target. In `SparcInstrInfo.td`, the following target description file entry, `LDrr`, defines the Load Integer instruction for a Word (the `LD` SPARC opcode) from a memory address to a register. The first parameter, the value 3 (11_2), is the operation value for this category of operation. The second parameter (000000_2) is the specific operation value for `LD/Load Word`. The third parameter is the output destination, which is a register operand and defined in the `Register` target description file (`IntRegs`).

```
def LDrr : F3_1 <3, 0b000000, (outs IntRegs:$dst), (ins MEMrr:$addr),
    "ld [$addr], $dst",
    [(set i32:$dst, (load ADDRrr:$addr))]>;
```

The fourth parameter is the input source, which uses the address operand `MEMrr` that is defined earlier in `SparcInstrInfo.td`:

```
def MEMrr : Operand<i32> {
  let PrintMethod = "printMemOperand";
  let MIOperandInfo = (ops IntRegs, IntRegs);
}
```

The fifth parameter is a string that is used by the assembly printer and can be left as an empty string until the assembly printer interface is implemented. The sixth and final parameter is the pattern used to match the instruction during the SelectionDAG Select Phase described in *The LLVM Target-Independent Code Generator*. This parameter is detailed in the next section, *Instruction Selector*.

Instruction class definitions are not overloaded for different operand types, so separate versions of instructions are needed for register, memory, or immediate value operands. For example, to perform a Load Integer instruction for a Word from an immediate operand to a register, the following instruction class is defined:

```
def LDri : F3_2 <3, 0b000000, (outs IntRegs:$dst), (ins MEMri:$addr),
    "ld [$addr], $dst",
    [(set i32:$dst, (load ADDRri:$addr))]>;
```

Writing these definitions for so many similar instructions can involve a lot of cut and paste. In `.td` files, the `multiclass` directive enables the creation of templates to define several instruction classes at once (using the `defm` directive). For example in `SparcInstrInfo.td`, the `multiclass` pattern `F3_12` is defined to create 2 instruction classes each time `F3_12` is invoked:

```
multiclass F3_12 <string OpcStr, bits<6> Op3Val, SDNode OpNode> {
  def rr : F3_1 <2, Op3Val,
    (outs IntRegs:$dst), (ins IntRegs:$b, IntRegs:$c),
    !strconcat(OpcStr, " $b, $c, $dst"),
    [(set i32:$dst, (OpNode i32:$b, i32:$c))]>;
  def ri : F3_2 <2, Op3Val,
    (outs IntRegs:$dst), (ins IntRegs:$b, i32imm:$c),
    !strconcat(OpcStr, " $b, $c, $dst"),
    [(set i32:$dst, (OpNode i32:$b, simm13:$c))]>;
}
```

So when the `defm` directive is used for the XOR and ADD instructions, as seen below, it creates four instruction objects: `XORrr`, `XORri`, `ADDrr`, and `ADDri`.

```
defm XOR : F3_12<"xor", 0b000011, xor>;
defm ADD : F3_12<"add", 0b000000, add>;
```

`SparcInstrInfo.td` also includes definitions for condition codes that are referenced by branch instructions. The following definitions in `SparcInstrInfo.td` indicate the bit location of the SPARC condition code. For example, the 10th bit represents the "greater than" condition for integers, and the 22nd bit represents the "greater than" condition for floats.

```
def ICC_NE : ICC_VAL< 9>; // Not Equal
def ICC_E  : ICC_VAL< 1>; // Equal
def ICC_G  : ICC_VAL<10>; // Greater
...
def FCC_U  : FCC_VAL<23>; // Unordered
def FCC_G  : FCC_VAL<22>; // Greater
def FCC_UG : FCC_VAL<21>; // Unordered or Greater
...
```

(Note that `Sparc.h` also defines enums that correspond to the same SPARC condition codes. Care must be taken to ensure the values in `Sparc.h` correspond to the values in `SparcInstrInfo.td`. I.e., `SPCC::ICC_NE = 9`, `SPCC::FCC_U = 23` and so on.)

Instruction Operand Mapping

The code generator backend maps instruction operands to fields in the instruction. Operands are assigned to unbound fields in the instruction in the order they are defined. Fields are bound when they are assigned a value. For example, the Sparc target defines the `XNORrr` instruction as a `F3_1` format instruction having three operands.

```
def XNORrr : F3_1<2, 0b000111,
                (outs IntRegs:$dst), (ins IntRegs:$b, IntRegs:$c),
                "xnor $b, $c, $dst",
                [(set i32:$dst, (not (xor i32:$b, i32:$c)))]>;
```

The instruction templates in `SparcInstrFormats.td` show the base class for `F3_1` is `InstSP`.

```
class InstSP<dag outs, dag ins, string asmstr, list<dag> pattern> : Instruction {
  field bits<32> Inst;
  let Namespace = "SP";
  bits<2> op;
  let Inst{31-30} = op;
  dag OutOperandList = outs;
  dag InOperandList = ins;
  let AsmString = asmstr;
  let Pattern = pattern;
}
```

`InstSP` leaves the `op` field unbound.

```
class F3<dag outs, dag ins, string asmstr, list<dag> pattern>
  : InstSP<outs, ins, asmstr, pattern> {
  bits<5> rd;
  bits<6> op3;
  bits<5> rs1;
  let op{1} = 1; // Op = 2 or 3
  let Inst{29-25} = rd;
  let Inst{24-19} = op3;
  let Inst{18-14} = rs1;
}
```

`F3` binds the `op` field and defines the `rd`, `op3`, and `rs1` fields. `F3` format instructions will bind the operands `rd`, `op3`, and `rs1` fields.

```

class F3_1<bits<2> opVal, bits<6> op3val, dag outs, dag ins,
        string asmstr, list<dag> pattern> : F3<outs, ins, asmstr, pattern> {
    bits<8> asi = 0; // asi not currently used
    bits<5> rs2;
    let op      = opVal;
    let op3     = op3val;
    let Inst{13} = 0;      // i field = 0
    let Inst{12-5} = asi;  // address space identifier
    let Inst{4-0} = rs2;
}

```

F3_1 binds the op3 field and defines the rs2 fields. F3_1 format instructions will bind the operands to the rd, rs1, and rs2 fields. This results in the XNORrr instruction binding \$dst, \$b, and \$c operands to the rd, rs1, and rs2 fields respectively.

Instruction Operand Name Mapping

TableGen will also generate a function called `getNamedOperandIdx()` which can be used to look up an operand's index in a `MachineInstr` based on its TableGen name. Setting the `UseNamedOperandTable` bit in an instruction's TableGen definition will add all of its operands to an enumeration in the `llvm::XXX::OpName` namespace and also add an entry for it into the `OperandMap` table, which can be queried using `getNamedOperandIdx()`

```

int DstIndex = SP::getNamedOperandIdx(SP::XNORrr, SP::OpName::dst); // => 0
int BIndex  = SP::getNamedOperandIdx(SP::XNORrr, SP::OpName::b);   // => 1
int CIndex  = SP::getNamedOperandIdx(SP::XNORrr, SP::OpName::c);   // => 2
int DIndex  = SP::getNamedOperandIdx(SP::XNORrr, SP::OpName::d);   // => -1
...

```

The entries in the `OpName` enum are taken verbatim from the TableGen definitions, so operands with lowercase names will have lower case entries in the enum.

To include the `getNamedOperandIdx()` function in your backend, you will need to define a few preprocessor macros in `XXXInstrInfo.cpp` and `XXXInstrInfo.h`. For example:

`XXXInstrInfo.cpp`:

```

#define GET_INSTRINFO_NAMED_OPS // For getNamedOperandIdx() function
#include "XXXGenInstrInfo.inc"

```

`XXXInstrInfo.h`:

```

#define GET_INSTRINFO_OPERAND_ENUM // For OpName enum
#include "XXXGenInstrInfo.inc"

namespace XXX {
    int16_t getNamedOperandIdx(uint16_t Opcode, uint16_t NamedIndex);
} // End namespace XXX

```

Instruction Operand Types

TableGen will also generate an enumeration consisting of all named Operand types defined in the backend, in the `llvm::XXX::OpTypes` namespace. Some common immediate Operand types (for instance `i8`, `i32`, `i64`, `f32`, `f64`) are defined for all targets in `include/llvm/Target/Target.td`, and are available in each Target's `OpTypes` enum. Also, only named Operand types appear in the enumeration: anonymous types are ignored. For example, the X86 backend defines `brtarget` and `brtarget8`, both instances of the TableGen Operand class, which represent branch target operands:

```
def brtarget : Operand<OtherVT>;
def brtarget8 : Operand<OtherVT>;
```

This results in:

```
namespace X86 {
namespace OpTypes {
enum OperandType {
    ...
    brtarget,
    brtarget8,
    ...
    i32imm,
    i64imm,
    ...
    OPERAND_TYPE_LIST_END
} // End namespace OpTypes
} // End namespace X86
```

In typical TableGen fashion, to use the enum, you will need to define a preprocessor macro:

```
#define GET_INSTRINFO_OPERAND_TYPES_ENUM // For OpTypes enum
#include "XXXGenInstrInfo.inc"
```

Instruction Scheduling

Instruction itineraries can be queried using `MCDesc::getSchedClass()`. The value can be named by an enumeration in `llvm::XXX::Sched` namespace generated by TableGen in `XXXGenInstrInfo.inc`. The name of the schedule classes are the same as provided in `XXXSchedule.td` plus a default `NoItinerary` class.

The schedule models are generated by TableGen by the `SubtargetEmitter`, using the `CodeGenSchedModels` class. This is distinct from the itinerary method of specifying machine resource use. The tool `utils/schedcover.py` can be used to determine which instructions have been covered by the schedule model description and which haven't. The first step is to use the instructions below to create an output file. Then run `schedcover.py` on the output file:

```
$ <src>/utils/schedcover.py <build>/lib/Target/AArch64/tblGenSubtarget.with
instruction, default, CortexA53Model, CortexA57Model, CycloneModel, ExynosM1Model,
↳FalkorModel, KryoModel, ThunderX2T99Model, ThunderXT8XModel
ABSv16i8, WriteV, , , CyWriteV3, M1WriteNMISC1, FalkorWr_2VXVY_2cyc, KryoWrite_2cyc_
↳XY_XY_150ln, ,
ABSv16i4, WriteV, , , CyWriteV3, M1WriteNMISC1, FalkorWr_1VXVY_2cyc, KryoWrite_2cyc_
↳XY_noRSV_67ln, ,
...
```

To capture the debug output from generating a schedule model, change to the appropriate target directory and use the following command: command with the `subtarget-emitter` debug option:

```
$ <build>/bin/llvm-tblgen -debug-only=subtarget-emitter -gen-subtarget \
-I <src>/lib/Target/<target> -I <src>/include \
-I <src>/lib/Target <src>/lib/Target/<target>/<target>.td \
-o <build>/lib/Target/<target>/<target>GenSubtargetInfo.inc.tmp \
> tblGenSubtarget.dbg 2>&1
```

Where `<build>` is the build directory, `src` is the source directory, and `<target>` is the name of the target. To double check that the above command is what is needed, one can capture the exact TableGen command from a build by using:

```
$ VERBOSE=1 make ...
```

and search for `llvm-tblgen` commands in the output.

Instruction Relation Mapping

This TableGen feature is used to relate instructions with each other. It is particularly useful when you have multiple instruction formats and need to switch between them after instruction selection. This entire feature is driven by relation models which can be defined in `XXXInstrInfo.td` files according to the target-specific instruction set. Relation models are defined using `InstrMapping` class as a base. TableGen parses all the models and generates instruction relation maps using the specified information. Relation maps are emitted as tables in the `XXXGenInstrInfo.inc` file along with the functions to query them. For the detailed information on how to use this feature, please refer to *How To Use Instruction Mappings*.

Implement a subclass of `TargetInstrInfo`

The final step is to hand code portions of `XXXInstrInfo`, which implements the interface described in `TargetInstrInfo.h` (see *The `TargetInstrInfo` class*). These functions return 0 or a Boolean or they assert, unless overridden. Here's a list of functions that are overridden for the SPARC implementation in `SparcInstrInfo.cpp`:

- `isLoadFromStackSlot` --- If the specified machine instruction is a direct load from a stack slot, return the register number of the destination and the `FrameIndex` of the stack slot.
- `isStoreToStackSlot` --- If the specified machine instruction is a direct store to a stack slot, return the register number of the destination and the `FrameIndex` of the stack slot.
- `copyPhysReg` --- Copy values between a pair of physical registers.
- `storeRegToStackSlot` --- Store a register value to a stack slot.
- `loadRegFromStackSlot` --- Load a register value from a stack slot.
- `storeRegToAddr` --- Store a register value to memory.
- `loadRegFromAddr` --- Load a register value from memory.
- `foldMemoryOperand` --- Attempt to combine instructions of any load or store instruction for the specified operand(s).

Branch Folding and If Conversion

Performance can be improved by combining instructions or by eliminating instructions that are never reached. The `AnalyzeBranch` method in `XXXInstrInfo` may be implemented to examine conditional instructions and remove unnecessary instructions. `AnalyzeBranch` looks at the end of a machine basic block (MBB) for opportunities for improvement, such as branch folding and if conversion. The `BranchFolder` and `IfConverter` machine function passes (see the source files `BranchFolding.cpp` and `IfConversion.cpp` in the `lib/CodeGen` directory) call `AnalyzeBranch` to improve the control flow graph that represents the instructions.

Several implementations of `AnalyzeBranch` (for ARM, Alpha, and X86) can be examined as models for your own `AnalyzeBranch` implementation. Since SPARC does not implement a useful `AnalyzeBranch`, the ARM target implementation is shown below.

`AnalyzeBranch` returns a Boolean value and takes four parameters:

- `MachineBasicBlock &MBB` --- The incoming block to be examined.
- `MachineBasicBlock *&TBB` --- A destination block that is returned. For a conditional branch that evaluates to true, TBB is the destination.
- `MachineBasicBlock *&FBB` --- For a conditional branch that evaluates to false, FBB is returned as the destination.
- `std::vector<MachineOperand> &Cond` --- List of operands to evaluate a condition for a conditional branch.

In the simplest case, if a block ends without a branch, then it falls through to the successor block. No destination blocks are specified for either TBB or FBB, so both parameters return NULL. The start of the `AnalyzeBranch` (see code below for the ARM target) shows the function parameters and the code for the simplest case.

```
bool ARMInstrInfo::AnalyzeBranch(MachineBasicBlock &MBB,
                                MachineBasicBlock *&TBB,
                                MachineBasicBlock *&FBB,
                                std::vector<MachineOperand> &Cond) const
{
    MachineBasicBlock::iterator I = MBB.end();
    if (I == MBB.begin() || !isUnpredicatedTerminator(--I))
        return false;
```

If a block ends with a single unconditional branch instruction, then `AnalyzeBranch` (shown below) should return the destination of that branch in the TBB parameter.

```
if (LastOpc == ARM::B || LastOpc == ARM::tB) {
    TBB = LastInst->getOperand(0).getMBB();
    return false;
}
```

If a block ends with two unconditional branches, then the second branch is never reached. In that situation, as shown below, remove the last branch instruction and return the penultimate branch in the TBB parameter.

```
if ((SecondLastOpc == ARM::B || SecondLastOpc == ARM::tB) &&
    (LastOpc == ARM::B || LastOpc == ARM::tB)) {
    TBB = SecondLastInst->getOperand(0).getMBB();
    I = LastInst;
    I->eraseFromParent();
    return false;
}
```

A block may end with a single conditional branch instruction that falls through to successor block if the condition evaluates to false. In that case, `AnalyzeBranch` (shown below) should return the destination of that conditional branch in the `TBB` parameter and a list of operands in the `Cond` parameter to evaluate the condition.

```
if (LastOpc == ARM::Bcc || LastOpc == ARM::tBcc) {
    // Block ends with fall-through condbranch.
    TBB = LastInst->getOperand(0).getMBB();
    Cond.push_back(LastInst->getOperand(1));
    Cond.push_back(LastInst->getOperand(2));
    return false;
}
```

If a block ends with both a conditional branch and an ensuing unconditional branch, then `AnalyzeBranch` (shown below) should return the conditional branch destination (assuming it corresponds to a conditional evaluation of "true") in the `TBB` parameter and the unconditional branch destination in the `FBB` (corresponding to a conditional evaluation of "false"). A list of operands to evaluate the condition should be returned in the `Cond` parameter.

```
unsigned SecondLastOpc = SecondLastInst->getOpcode();

if ((SecondLastOpc == ARM::Bcc && LastOpc == ARM::B) ||
    (SecondLastOpc == ARM::tBcc && LastOpc == ARM::tB)) {
    TBB = SecondLastInst->getOperand(0).getMBB();
    Cond.push_back(SecondLastInst->getOperand(1));
    Cond.push_back(SecondLastInst->getOperand(2));
    FBB = LastInst->getOperand(0).getMBB();
    return false;
}
```

For the last two cases (ending with a single conditional branch or ending with one conditional and one unconditional branch), the operands returned in the `Cond` parameter can be passed to methods of other instructions to create new branches or perform other operations. An implementation of `AnalyzeBranch` requires the helper methods `RemoveBranch` and `InsertBranch` to manage subsequent operations.

`AnalyzeBranch` should return false indicating success in most circumstances. `AnalyzeBranch` should only return true when the method is stumped about what to do, for example, if a block has three terminating branches. `AnalyzeBranch` may return true if it encounters a terminator it cannot handle, such as an indirect branch.

4.21.7 Instruction Selector

LLVM uses a `SelectionDAG` to represent LLVM IR instructions, and nodes of the `SelectionDAG` ideally represent native target instructions. During code generation, instruction selection passes are performed to convert non-native DAG instructions into native target-specific instructions. The pass described in `XXXISelDAGToDAG.cpp` is used to match patterns and perform DAG-to-DAG instruction selection. Optionally, a pass may be defined (in `XXXBranchSelector.cpp`) to perform similar DAG-to-DAG operations for branch instructions. Later, the code in `XXXISelLowering.cpp` replaces or removes operations and data types not supported natively (legalizes) in a `SelectionDAG`.

TableGen generates code for instruction selection using the following target description input files:

- `XXXInstrInfo.td` --- Contains definitions of instructions in a target-specific instruction set, generates `XXXGenDAGISel.inc`, which is included in `XXXISelDAGToDAG.cpp`.
- `XXXCallingConv.td` --- Contains the calling and return value conventions for the target architecture, and it generates `XXXGenCallingConv.inc`, which is included in `XXXISelLowering.cpp`.

The implementation of an instruction selection pass must include a header that declares the `FunctionPass` class or a subclass of `FunctionPass`. In `XXXTargetMachine.cpp`, a Pass Manager (PM) should add each instruction selection pass into the queue of passes to run.

The LLVM static compiler (`llc`) is an excellent tool for visualizing the contents of DAGs. To display the SelectionDAG before or after specific processing phases, use the command line options for `llc`, described at [SelectionDAG Instruction Selection Process](#).

To describe instruction selector behavior, you should add patterns for lowering LLVM code into a SelectionDAG as the last parameter of the instruction definitions in `XXXInstrInfo.td`. For example, in `SparcInstrInfo.td`, this entry defines a register store operation, and the last parameter describes a pattern with the store DAG operator.

```
def STrr : F3_1< 3, 0b000100, (outs), (ins MEMrr:$addr, IntRegs:$src),
        "st $src, [$addr]", [(store i32:$src, ADDRrr:$addr)]>;
```

`ADDRrr` is a memory mode that is also defined in `SparcInstrInfo.td`:

```
def ADDRrr : ComplexPattern<i32, 2, "SelectADDRrr", [], []>;
```

The definition of `ADDRrr` refers to `SelectADDRrr`, which is a function defined in an implementation of the Instruction Selector (such as `SparcISelDAGToDAG.cpp`).

In `lib/Target/TargetSelectionDAG.td`, the DAG operator for store is defined below:

```
def store : PatFrag<(ops node:$val, node:$ptr),
        (st node:$val, node:$ptr), [{
  if (StoreSDNode *ST = dyn_cast<StoreSDNode>(N))
    return !ST->isTruncatingStore() &&
           ST->getAddressingMode() == ISD::UNINDEXED;
  return false;
}]>;
```

`XXXInstrInfo.td` also generates (in `XXXGenDAGISel.inc`) the `SelectCode` method that is used to call the appropriate processing method for an instruction. In this example, `SelectCode` calls `Select_ISD_STORE` for the `ISD::STORE` opcode.

```
SDNode *SelectCode(SDValue N) {
  ...
  MVT::ValueType NVT = N.getNode()->getValueType(0);
  switch (N.getOpcode()) {
  case ISD::STORE: {
    switch (NVT) {
    default:
      return Select_ISD_STORE(N);
      break;
    }
    break;
  }
  ...
}
```

The pattern for `STrr` is matched, so elsewhere in `XXXGenDAGISel.inc`, code for `STrr` is created for `Select_ISD_STORE`. The `Emit_22` method is also generated in `XXXGenDAGISel.inc` to complete the processing of this instruction.

```
SDNode *Select_ISD_STORE(const SDValue &N) {
  SDValue Chain = N.getOperand(0);
  if (Predicate_store(N.getNode())) {
    SDValue N1 = N.getOperand(1);
    SDValue N2 = N.getOperand(2);
    SDValue CPTmp0;
    SDValue CPTmp1;
```

(continues on next page)

(continued from previous page)

```

// Pattern: (st:void i32:i32:$src,
//          ADDRrr:i32:$addr)<<P:Predicate_store>>
// Emits: (STrr:void ADDRrr:i32:$addr, IntRegs:i32:$src)
// Pattern complexity = 13  cost = 1  size = 0
if (SelectADDRrr(N, N2, CPTmp0, CPTmp1) &&
    N1.getNode()->getValueType(0) == MVT::i32 &&
    N2.getNode()->getValueType(0) == MVT::i32) {
    return Emit_22(N, SP::STrr, CPTmp0, CPTmp1);
}
...

```

The SelectionDAG Legalize Phase

The Legalize phase converts a DAG to use types and operations that are natively supported by the target. For natively unsupported types and operations, you need to add code to the target-specific `XXXTargetLowering` implementation to convert unsupported types and operations to supported ones.

In the constructor for the `XXXTargetLowering` class, first use the `addRegisterClass` method to specify which types are supported and which register classes are associated with them. The code for the register classes are generated by TableGen from `XXXRegisterInfo.td` and placed in `XXXGenRegisterInfo.h.inc`. For example, the implementation of the constructor for the `SparcTargetLowering` class (in `SparcISelLowering.cpp`) starts with the following code:

```

addRegisterClass(MVT::i32, SP::IntRegsRegisterClass);
addRegisterClass(MVT::f32, SP::FPRegsRegisterClass);
addRegisterClass(MVT::f64, SP::DFPRegsRegisterClass);

```

You should examine the node types in the ISD namespace (`include/llvm/CodeGen/SelectionDAGNodes.h`) and determine which operations the target natively supports. For operations that do **not** have native support, add a callback to the constructor for the `XXXTargetLowering` class, so the instruction selection process knows what to do. The `TargetLowering` class callback methods (declared in `llvm/Target/TargetLowering.h`) are:

- `setOperationAction` --- General operation.
- `setLoadExtAction` --- Load with extension.
- `setTruncStoreAction` --- Truncating store.
- `setIndexedLoadAction` --- Indexed load.
- `setIndexedStoreAction` --- Indexed store.
- `setConvertAction` --- Type conversion.
- `setCondCodeAction` --- Support for a given condition code.

Note: on older releases, `setLoadXAction` is used instead of `setLoadExtAction`. Also, on older releases, `setCondCodeAction` may not be supported. Examine your release to see what methods are specifically supported.

These callbacks are used to determine that an operation does or does not work with a specified type (or types). And in all cases, the third parameter is a `LegalAction` type enum value: `Promote`, `Expand`, `Custom`, or `Legal`. `SparcISelLowering.cpp` contains examples of all four `LegalAction` values.

Promote

For an operation without native support for a given type, the specified type may be promoted to a larger type that is supported. For example, SPARC does not support a sign-extending load for Boolean values (`i1` type), so in `SparcISelLowering.cpp` the third parameter below, `Promote`, changes `i1` type values to a large type before loading.

```
setLoadExtAction(ISD::SEXTLOAD, MVT::i1, Promote);
```

Expand

For a type without native support, a value may need to be broken down further, rather than promoted. For an operation without native support, a combination of other operations may be used to similar effect. In SPARC, the floating-point sine and cosine trig operations are supported by expansion to other operations, as indicated by the third parameter, `Expand`, to `setOperationAction`:

```
setOperationAction(ISD::FSIN, MVT::f32, Expand);
setOperationAction(ISD::FCOS, MVT::f32, Expand);
```

Custom

For some operations, simple type promotion or operation expansion may be insufficient. In some cases, a special intrinsic function must be implemented.

For example, a constant value may require special treatment, or an operation may require spilling and restoring registers in the stack and working with register allocators.

As seen in `SparcISelLowering.cpp` code below, to perform a type conversion from a floating point value to a signed integer, first the `setOperationAction` should be called with `Custom` as the third parameter:

```
setOperationAction(ISD::FP_TO_SINT, MVT::i32, Custom);
```

In the `LowerOperation` method, for each `Custom` operation, a case statement should be added to indicate what function to call. In the following code, an `FP_TO_SINT` opcode will call the `LowerFP_TO_SINT` method:

```
SDValue SparcTargetLowering::LowerOperation(SDValue Op, SelectionDAG &DAG) {
    switch (Op.getOpcode()) {
        case ISD::FP_TO_SINT: return LowerFP_TO_SINT(Op, DAG);
        ...
    }
}
```

Finally, the `LowerFP_TO_SINT` method is implemented, using an FP register to convert the floating-point value to an integer.

```
static SDValue LowerFP_TO_SINT(SDValue Op, SelectionDAG &DAG) {
    assert(Op.getValueType() == MVT::i32);
    Op = DAG.getNode(SPISD::FTOI, MVT::f32, Op.getOperand(0));
    return DAG.getNode(ISD::BITCAST, MVT::i32, Op);
}
```

Legal

The `Legal LegalizeAction` enum value simply indicates that an operation is natively supported. `Legal` represents the default condition, so it is rarely used. In `SparcISelLowering.cpp`, the action for `CTPOP` (an operation to count the bits set in an integer) is natively supported only for SPARC v9. The following code enables the `Expand` conversion technique for non-v9 SPARC implementations.

```
setOperationAction(ISD::CTPOP, MVT::i32, Expand);
...
if (TM.getSubtarget<SparcSubtarget>().isV9())
    setOperationAction(ISD::CTPOP, MVT::i32, Legal);
```

Calling Conventions

To support target-specific calling conventions, `XXXGenCallingConv.td` uses interfaces (such as `CCIfType` and `CCAssignToReg`) that are defined in `lib/Target/TargetCallingConv.td`. `TableGen` can take the target descriptor file `XXXGenCallingConv.td` and generate the header file `XXXGenCallingConv.inc`, which is typically included in `XXXISelLowering.cpp`. You can use the interfaces in `TargetCallingConv.td` to specify:

- The order of parameter allocation.
- Where parameters and return values are placed (that is, on the stack or in registers).
- Which registers may be used.
- Whether the caller or callee unwinds the stack.

The following example demonstrates the use of the `CCIfType` and `CCAssignToReg` interfaces. If the `CCIfType` predicate is true (that is, if the current argument is of type `f32` or `f64`), then the action is performed. In this case, the `CCAssignToReg` action assigns the argument value to the first available register: either `R0` or `R1`.

```
CCIfType<[f32, f64], CCAssignToReg<[R0, R1]>>
```

`SparcCallingConv.td` contains definitions for a target-specific return-value calling convention (`RetCC_Sparc32`) and a basic 32-bit C calling convention (`CC_Sparc32`). The definition of `RetCC_Sparc32` (shown below) indicates which registers are used for specified scalar return types. A single-precision float is returned to register `F0`, and a double-precision float goes to register `D0`. A 32-bit integer is returned in register `I0` or `I1`.

```
def RetCC_Sparc32 : CallingConv<[
  CCIfType<[i32], CCAssignToReg<[I0, I1]>>,
  CCIfType<[f32], CCAssignToReg<[F0]>>,
  CCIfType<[f64], CCAssignToReg<[D0]>>
]>;
```

The definition of `CC_Sparc32` in `SparcCallingConv.td` introduces `CCAssignToStack`, which assigns the value to a stack slot with the specified size and alignment. In the example below, the first parameter, 4, indicates the size of the slot, and the second parameter, also 4, indicates the stack alignment along 4-byte units. (Special cases: if size is zero, then the ABI size is used; if alignment is zero, then the ABI alignment is used.)

```
def CC_Sparc32 : CallingConv<[
  // All arguments get passed in integer registers if there is space.
  CCIfType<[i32, f32, f64], CCAssignToReg<[I0, I1, I2, I3, I4, I5]>>,
  CCAssignToStack<4, 4>
]>;
```

CCDelegateTo is another commonly used interface, which tries to find a specified sub-calling convention, and, if a match is found, it is invoked. In the following example (in X86CallingConv.td), the definition of RetCC_X86_32_C ends with CCDelegateTo. After the current value is assigned to the register ST0 or ST1, the RetCC_X86Common is invoked.

```
def RetCC_X86_32_C : CallingConv<[
  CCIfType<[f32], CCAssignToReg<[ST0, ST1]>>,
  CCIfType<[f64], CCAssignToReg<[ST0, ST1]>>,
  CCDelegateTo<RetCC_X86Common>
]>;
```

CCIfCC is an interface that attempts to match the given name to the current calling convention. If the name identifies the current calling convention, then a specified action is invoked. In the following example (in X86CallingConv.td), if the Fast calling convention is in use, then RetCC_X86_32_Fast is invoked. If the SSECall calling convention is in use, then RetCC_X86_32_SSE is invoked.

```
def RetCC_X86_32 : CallingConv<[
  CCIfCC<"CallingConv::Fast", CCDelegateTo<RetCC_X86_32_Fast>>,
  CCIfCC<"CallingConv::X86_SSECall", CCDelegateTo<RetCC_X86_32_SSE>>,
  CCDelegateTo<RetCC_X86_32_C>
]>;
```

Other calling convention interfaces include:

- CCIf <predicate, action> --- If the predicate matches, apply the action.
- CCIfInReg <action> --- If the argument is marked with the "inreg" attribute, then apply the action.
- CCIfNest <action> --- If the argument is marked with the "nest" attribute, then apply the action.
- CCIfNotVarArg <action> --- If the current function does not take a variable number of arguments, apply the action.
- CCAssignToRegWithShadow <registerList, shadowList> --- similar to CCAssignToReg, but with a shadow list of registers.
- CCPassByVal <size, align> --- Assign value to a stack slot with the minimum specified size and alignment.
- CCPromoteToType <type> --- Promote the current value to the specified type.
- CallingConv <[actions]> --- Define each calling convention that is supported.

4.21.8 Assembly Printer

During the code emission stage, the code generator may utilize an LLVM pass to produce assembly output. To do this, you want to implement the code for a printer that converts LLVM IR to a GAS-format assembly language for your target machine, using the following steps:

- Define all the assembly strings for your target, adding them to the instructions defined in the XXXInstrInfo.td file. (See *Instruction Set*.) TableGen will produce an output file (XXXGenAsmWriter.inc) with an implementation of the printInstruction method for the XXXAsmPrinter class.
- Write XXXTargetAsmInfo.h, which contains the bare-bones declaration of the XXXTargetAsmInfo class (a subclass of TargetAsmInfo).
- Write XXXTargetAsmInfo.cpp, which contains target-specific values for TargetAsmInfo properties and sometimes new implementations for methods.

- Write `XXXAsmPrinter.cpp`, which implements the `AsmPrinter` class that performs the LLVM-to-assembly conversion.

The code in `XXXTargetAsmInfo.h` is usually a trivial declaration of the `XXXTargetAsmInfo` class for use in `XXXTargetAsmInfo.cpp`. Similarly, `XXXTargetAsmInfo.cpp` usually has a few declarations of `XXXTargetAsmInfo` replacement values that override the default values in `TargetAsmInfo.cpp`. For example in `SparcTargetAsmInfo.cpp`:

```
SparcTargetAsmInfo::SparcTargetAsmInfo(const SparcTargetMachine &TM) {
    Data16bitsDirective = "\t.half\t";
    Data32bitsDirective = "\t.word\t";
    Data64bitsDirective = 0; // .xword is only supported by V9.
    ZeroDirective = "\t.skip\t";
    CommentString = "!";
    ConstantPoolSection = "\t.section \".rodata\",#alloc\n";
}
```

The X86 assembly printer implementation (`X86TargetAsmInfo`) is an example where the target specific `TargetAsmInfo` class uses an overridden methods: `ExpandInlineAsm`.

A target-specific implementation of `AsmPrinter` is written in `XXXAsmPrinter.cpp`, which implements the `AsmPrinter` class that converts the LLVM to printable assembly. The implementation must include the following headers that have declarations for the `AsmPrinter` and `MachineFunctionPass` classes. The `MachineFunctionPass` is a subclass of `FunctionPass`.

```
#include "llvm/CodeGen/AsmPrinter.h"
#include "llvm/CodeGen/MachineFunctionPass.h"
```

As a `FunctionPass`, `AsmPrinter` first calls `doInitialization` to set up the `AsmPrinter`. In `SparcAsmPrinter`, a `Mangler` object is instantiated to process variable names.

In `XXXAsmPrinter.cpp`, the `runOnMachineFunction` method (declared in `MachineFunctionPass`) must be implemented for `XXXAsmPrinter`. In `MachineFunctionPass`, the `runOnFunction` method invokes `runOnMachineFunction`. Target-specific implementations of `runOnMachineFunction` differ, but generally do the following to process each machine function:

- Call `SetupMachineFunction` to perform initialization.
- Call `EmitConstantPool` to print out (to the output stream) constants which have been spilled to memory.
- Call `EmitJumpTableInfo` to print out jump tables used by the current function.
- Print out the label for the current function.
- Print out the code for the function, including basic block labels and the assembly for the instruction (using `printInstruction`)

The `XXXAsmPrinter` implementation must also include the code generated by `TableGen` that is output in the `XXXGenAsmWriter.inc` file. The code in `XXXGenAsmWriter.inc` contains an implementation of the `printInstruction` method that may call these methods:

- `printOperand`
- `printMemOperand`
- `printCCOperand` (for conditional statements)
- `printDataDirective`
- `printDeclare`
- `printImplicitDef`

- `printInlineAsm`

The implementations of `printDeclare`, `printImplicitDef`, `printInlineAsm`, and `printLabel` in `AsmPrinter.cpp` are generally adequate for printing assembly and do not need to be overridden.

The `printOperand` method is implemented with a long `switch/case` statement for the type of operand: register, immediate, basic block, external symbol, global address, constant pool index, or jump table index. For an instruction with a memory address operand, the `printMemOperand` method should be implemented to generate the proper output. Similarly, `printCCTemplate` should be used to print a conditional operand.

`doFinalization` should be overridden in `XXXAsmPrinter`, and it should be called to shut down the assembly printer. During `doFinalization`, global variables and constants are printed to output.

4.21.9 Subtarget Support

Subtarget support is used to inform the code generation process of instruction set variations for a given chip set. For example, the LLVM SPARC implementation provided covers three major versions of the SPARC microprocessor architecture: Version 8 (V8, which is a 32-bit architecture), Version 9 (V9, a 64-bit architecture), and the UltraSPARC architecture. V8 has 16 double-precision floating-point registers that are also usable as either 32 single-precision or 8 quad-precision registers. V8 is also purely big-endian. V9 has 32 double-precision floating-point registers that are also usable as 16 quad-precision registers, but cannot be used as single-precision registers. The UltraSPARC architecture combines V9 with UltraSPARC Visual Instruction Set extensions.

If subtarget support is needed, you should implement a target-specific `XXXSubtarget` class for your architecture. This class should process the command-line options `-mcpu=` and `-mattr=`.

TableGen uses definitions in the `Target.td` and `Sparc.td` files to generate code in `SparcGenSubtarget.inc`. In `Target.td`, shown below, the `SubtargetFeature` interface is defined. The first 4 string parameters of the `SubtargetFeature` interface are a feature name, an attribute set by the feature, the value of the attribute, and a description of the feature. (The fifth parameter is a list of features whose presence is implied, and its default value is an empty array.)

```
class SubtargetFeature<string n, string a, string v, string d,
                      list<SubtargetFeature> i = []> {
    string Name = n;
    string Attribute = a;
    string Value = v;
    string Desc = d;
    list<SubtargetFeature> Implies = i;
}
```

In the `Sparc.td` file, the `SubtargetFeature` is used to define the following features.

```
def FeatureV9 : SubtargetFeature<"v9", "IsV9", "true",
                                "Enable SPARC-V9 instructions">;
def FeatureV8Deprecated : SubtargetFeature<"deprecated-v8",
                                            "V8DeprecatedInsts", "true",
                                            "Enable deprecated V8 instructions in V9 mode">;
def FeatureVIS : SubtargetFeature<"vis", "IsVIS", "true",
                                  "Enable UltraSPARC Visual Instruction Set extensions">;
```

Elsewhere in `Sparc.td`, the `Proc` class is defined and then is used to define particular SPARC processor subtypes that may have the previously described features.

```
class Proc<string Name, list<SubtargetFeature> Features>
    : Processor<Name, NoItineraries, Features>;
```

(continues on next page)

(continued from previous page)

```

def : Proc<"generic",          []>;
def : Proc<"v8",              []>;
def : Proc<"supersparc",      []>;
def : Proc<"sparclite",       []>;
def : Proc<"f934",            []>;
def : Proc<"hypersparc",      []>;
def : Proc<"sparclite86x",    []>;
def : Proc<"sparclet",        []>;
def : Proc<"tsc701",          []>;
def : Proc<"v9",               [FeatureV9]>;
def : Proc<"ultrasparc",      [FeatureV9, FeatureV8Deprecated]>;
def : Proc<"ultrasparc3",     [FeatureV9, FeatureV8Deprecated]>;
def : Proc<"ultrasparc3-vis", [FeatureV9, FeatureV8Deprecated, FeatureVIS]>;

```

From `Target.td` and `Sparc.td` files, the resulting `SparcGenSubtarget.inc` specifies enum values to identify the features, arrays of constants to represent the CPU features and CPU subtypes, and the `ParseSubtargetFeatures` method that parses the features string that sets specified subtarget options. The generated `SparcGenSubtarget.inc` file should be included in the `SparcSubtarget.cpp`. The target-specific implementation of the `XXXSubtarget` method should follow this pseudocode:

```

XXXSubtarget::XXXSubtarget(const Module &M, const std::string &FS) {
    // Set the default features
    // Determine default and user specified characteristics of the CPU
    // Call ParseSubtargetFeatures(FS, CPU) to parse the features string
    // Perform any additional operations
}

```

4.21.10 JIT Support

The implementation of a target machine optionally includes a Just-In-Time (JIT) code generator that emits machine code and auxiliary structures as binary output that can be written directly to memory. To do this, implement JIT code generation by performing the following steps:

- Write an `XXXCodeEmitter.cpp` file that contains a machine function pass that transforms target-machine instructions into relocatable machine code.
- Write an `XXXJITInfo.cpp` file that implements the JIT interfaces for target-specific code-generation activities, such as emitting machine code and stubs.
- Modify `XXXTargetMachine` so that it provides a `TargetJITInfo` object through its `getJITInfo` method.

There are several different approaches to writing the JIT support code. For instance, TableGen and target descriptor files may be used for creating a JIT code generator, but are not mandatory. For the Alpha and PowerPC target machines, TableGen is used to generate `XXXGenCodeEmitter.inc`, which contains the binary coding of machine instructions and the `getBinaryCodeForInstr` method to access those codes. Other JIT implementations do not.

Both `XXXJITInfo.cpp` and `XXXCodeEmitter.cpp` must include the `llvm/CodeGen/MachineCodeEmitter.h` header file that defines the `MachineCodeEmitter` class containing code for several callback functions that write data (in bytes, words, strings, etc.) to the output stream.

Machine Code Emitter

In `XXXCodeEmitter.cpp`, a target-specific of the `Emitter` class is implemented as a function pass (subclass of `MachineFunctionPass`). The target-specific implementation of `runOnMachineFunction` (invoked by `runOnFunction` in `MachineFunctionPass`) iterates through the `MachineBasicBlock` calls `emitInstruction` to process each instruction and emit binary code. `emitInstruction` is largely implemented with case statements on the instruction types defined in `XXXInstrInfo.h`. For example, in `X86CodeEmitter.cpp`, the `emitInstruction` method is built around the following switch/case statements:

```
switch (Desc->TSFlags & X86::FormMask) {
case X86II::Pseudo: // for not yet implemented instructions
    ...           // or pseudo-instructions
    break;
case X86II::RawFrm: // for instructions with a fixed opcode value
    ...
    break;
case X86II::AddRegFrm: // for instructions that have one register operand
    ...               // added to their opcode
    break;
case X86II::MRMDestReg: // for instructions that use the Mod/RM byte
    ...                 // to specify a destination (register)
    break;
case X86II::MRMDestMem: // for instructions that use the Mod/RM byte
    ...                 // to specify a destination (memory)
    break;
case X86II::MRMSrcReg: // for instructions that use the Mod/RM byte
    ...                // to specify a source (register)
    break;
case X86II::MRMSrcMem: // for instructions that use the Mod/RM byte
    ...                // to specify a source (memory)
    break;
case X86II::MRM0r: case X86II::MRM1r: // for instructions that operate on
case X86II::MRM2r: case X86II::MRM3r: // a REGISTER r/m operand and
case X86II::MRM4r: case X86II::MRM5r: // use the Mod/RM byte and a field
case X86II::MRM6r: case X86II::MRM7r: // to hold extended opcode data
    ...
    break;
case X86II::MRM0m: case X86II::MRM1m: // for instructions that operate on
case X86II::MRM2m: case X86II::MRM3m: // a MEMORY r/m operand and
case X86II::MRM4m: case X86II::MRM5m: // use the Mod/RM byte and a field
case X86II::MRM6m: case X86II::MRM7m: // to hold extended opcode data
    ...
    break;
case X86II::MRMInitReg: // for instructions whose source and
    ...                 // destination are the same register
    break;
}
```

The implementations of these case statements often first emit the opcode and then get the operand(s). Then depending upon the operand, helper methods may be called to process the operand(s). For example, in `X86CodeEmitter.cpp`, for the `X86II::AddRegFrm` case, the first data emitted (by `emitByte`) is the opcode added to the register operand. Then an object representing the machine operand, `MO1`, is extracted. The helper methods such as `isImmediate`, `isGlobalAddress`, `isExternalSymbol`, `isConstantPoolIndex`, and `isJumpTableIndex` determine the operand type. (`X86CodeEmitter.cpp` also has private methods such as `emitConstant`, `emitGlobalAddress`, `emitExternalSymbolAddress`, `emitConstPoolAddress`, and `emitJumpTableAddress` that emit the data into the output stream.)

```

case X86II::AddRegFrm:
    MCE.emitByte(BaseOpcode + getX86RegNum(MI.getOperand(CurOp++) .getReg()));

    if (CurOp != NumOps) {
        const MachineOperand &MO1 = MI.getOperand(CurOp++);
        unsigned Size = X86InstrInfo::sizeOfImm(Desc);
        if (MO1.isImmediate())
            emitConstant(MO1.getImm(), Size);
        else {
            unsigned rt = Is64BitMode ? X86::reloc_pcrel_word
                : (IsPIC ? X86::reloc_picrel_word : X86::reloc_absolute_word);
            if (Opcode == X86::MOV64ri)
                rt = X86::reloc_absolute_dword; // FIXME: add X86II flag?
            if (MO1.isGlobalAddress()) {
                bool NeedStub = isa<Function>(MO1.getGlobal());
                bool isLazy = gvNeedsLazyPtr(MO1.getGlobal());
                emitGlobalAddress(MO1.getGlobal(), rt, MO1.getOffset(), 0,
                    NeedStub, isLazy);
            } else if (MO1.isExternalSymbol())
                emitExternalSymbolAddress(MO1.getSymbolName(), rt);
            else if (MO1.isConstantPoolIndex())
                emitConstPoolAddress(MO1.getIndex(), rt);
            else if (MO1.isJumpTableIndex())
                emitJumpTableAddress(MO1.getIndex(), rt);
        }
    }
    break;

```

In the previous example, `XXXCodeEmitter.cpp` uses the variable `rt`, which is a `RelocationType` enum that may be used to relocate addresses (for example, a global address with a PIC base offset). The `RelocationType` enum for that target is defined in the short target-specific `XXXRelocations.h` file. The `RelocationType` is used by the `relocate` method defined in `XXXJITInfo.cpp` to rewrite addresses for referenced global symbols.

For example, `X86Relocations.h` specifies the following relocation types for the X86 addresses. In all four cases, the relocated value is added to the value already in memory. For `reloc_pcrel_word` and `reloc_picrel_word`, there is an additional initial adjustment.

```

enum RelocationType {
    reloc_pcrel_word = 0,    // add reloc value after adjusting for the PC loc
    reloc_picrel_word = 1,   // add reloc value after adjusting for the PIC base
    reloc_absolute_word = 2, // absolute relocation; no additional adjustment
    reloc_absolute_dword = 3 // absolute relocation; no additional adjustment
};

```

Target JIT Info

`XXXJITInfo.cpp` implements the JIT interfaces for target-specific code-generation activities, such as emitting machine code and stubs. At minimum, a target-specific version of `XXXJITInfo` implements the following:

- `getLazyResolverFunction` --- Initializes the JIT, gives the target a function that is used for compilation.
- `emitFunctionStub` --- Returns a native function with a specified address for a callback function.
- `relocate` --- Changes the addresses of referenced globals, based on relocation types.
- Callback function that are wrappers to a function stub that is used when the real target is not initially known.

`getLazyResolverFunction` is generally trivial to implement. It makes the incoming parameter as the global `JITCompilerFunction` and returns the callback function that will be used a function wrapper. For the Alpha target (in `AlphaJITInfo.cpp`), the `getLazyResolverFunction` implementation is simply:

```
TargetJITInfo::LazyResolverFn AlphaJITInfo::getLazyResolverFunction(  
    JITCompilerFn F) {  
    JITCompilerFunction = F;  
    return AlphaCompilationCallback;  
}
```

For the X86 target, the `getLazyResolverFunction` implementation is a little more complicated, because it returns a different callback function for processors with SSE instructions and XMM registers.

The callback function initially saves and later restores the callee register values, incoming arguments, and frame and return address. The callback function needs low-level access to the registers or stack, so it is typically implemented with assembler.

4.22.1 Abstract

This document covers how to integrate LLVM into a compiler for a language which supports garbage collection. **Note that LLVM itself does not provide a garbage collector.** You must provide your own.

4.22.2 Quick Start

First, you should pick a collector strategy. LLVM includes a number of built in ones, but you can also implement a loadable plugin with a custom definition. Note that the collector strategy is a description of how LLVM should generate code such that it interacts with your collector and runtime, not a description of the collector itself.

Next, mark your generated functions as using your chosen collector strategy. From c++, you can call:

```
F.setGC(<collector description name>);
```

This will produce IR like the following fragment:

```
define void @foo() gc "<collector description name>" { ... }
```

When generating LLVM IR for your functions, you will need to:

- Use `@llvm.gcload` and/or `@llvm.gcwrite` in place of standard load and store instructions. These intrinsics are used to represent load and store barriers. If your collector does not require such barriers, you can skip this step.
- Use the memory allocation routines provided by your garbage collector's runtime library.
- If your collector requires them, generate type maps according to your runtime's binary interface. LLVM is not involved in the process. In particular, the LLVM type system is not suitable for conveying such information through the compiler.
- Insert any coordination code required for interacting with your collector. Many collectors require running application code to periodically check a flag and conditionally call a runtime function. This is often referred to as a safepoint poll.

You will need to identify roots (i.e. references to heap objects your collector needs to know about) in your generated IR, so that LLVM can encode them into your final stack maps. Depending on the collector strategy chosen, this is accomplished by using either the `@llvm.gcroot` intrinsics or an `gc.statepoint` relocation sequence.

Don't forget to create a root for each intermediate value that is generated when evaluating an expression. In `h(f(), g())`, the result of `f()` could easily be collected if evaluating `g()` triggers a collection.

Finally, you need to link your runtime library with the generated program executable (for a static compiler) or ensure the appropriate symbols are available for the runtime linker (for a JIT compiler).

4.22.3 Introduction

What is Garbage Collection?

Garbage collection is a widely used technique that frees the programmer from having to know the lifetimes of heap objects, making software easier to produce and maintain. Many programming languages rely on garbage collection for automatic memory management. There are two primary forms of garbage collection: conservative and accurate.

Conservative garbage collection often does not require any special support from either the language or the compiler: it can handle non-type-safe programming languages (such as C/C++) and does not require any special information from the compiler. The *Boehm collector* is an example of a state-of-the-art conservative collector.

Accurate garbage collection requires the ability to identify all pointers in the program at run-time (which requires that the source-language be type-safe in most cases). Identifying pointers at run-time requires compiler support to locate all places that hold live pointer variables at run-time, including the *processor stack and registers*.

Conservative garbage collection is attractive because it does not require any special compiler support, but it does have problems. In particular, because the conservative garbage collector cannot *know* that a particular word in the machine is a pointer, it cannot move live objects in the heap (preventing the use of compacting and generational GC algorithms) and it can occasionally suffer from memory leaks due to integer values that happen to point to objects in the program. In addition, some aggressive compiler transformations can break conservative garbage collectors (though these seem rare in practice).

Accurate garbage collectors do not suffer from any of these problems, but they can suffer from degraded scalar optimization of the program. In particular, because the runtime must be able to identify and update all pointers active in the program, some optimizations are less effective. In practice, however, the locality and performance benefits of using aggressive garbage collection techniques dominates any low-level losses.

This document describes the mechanisms and interfaces provided by LLVM to support accurate garbage collection.

Goals and non-goals

LLVM's intermediate representation provides *garbage collection intrinsics* that offer support for a broad class of collector models. For instance, the intrinsics permit:

- semi-space collectors
- mark-sweep collectors
- generational collectors
- incremental collectors
- concurrent collectors
- cooperative collectors
- reference counting

We hope that the support built into the LLVM IR is sufficient to support a broad class of garbage collected languages including Scheme, ML, Java, C#, Perl, Python, Lua, Ruby, other scripting languages, and more.

Note that LLVM **does not itself provide a garbage collector** --- this should be part of your language's runtime library. LLVM provides a framework for describing the garbage collectors requirements to the compiler. In particular, LLVM provides support for generating stack maps at call sites, polling for a safepoint, and emitting load and store barriers. You can also extend LLVM - possibly through a loadable *code generation plugins* - to generate code and data structures which conforms to the *binary interface* specified by the *runtime library*. This is similar to the relationship between LLVM and DWARF debugging info, for example. The difference primarily lies in the lack of an established standard in the domain of garbage collection --- thus the need for a flexible extension mechanism.

The aspects of the binary interface with which LLVM's GC support is concerned are:

- Creation of GC safepoints within code where collection is allowed to execute safely.
- Computation of the stack map. For each safe point in the code, object references within the stack frame must be identified so that the collector may traverse and perhaps update them.
- Write barriers when storing object references to the heap. These are commonly used to optimize incremental scans in generational collectors.
- Emission of read barriers when loading object references. These are useful for interoperating with concurrent collectors.

There are additional areas that LLVM does not directly address:

- Registration of global roots with the runtime.
- Registration of stack map entries with the runtime.
- The functions used by the program to allocate memory, trigger a collection, etc.
- Computation or compilation of type maps, or registration of them with the runtime. These are used to crawl the heap for object references.

In general, LLVM's support for GC does not include features which can be adequately addressed with other features of the IR and does not specify a particular binary interface. On the plus side, this means that you should be able to integrate LLVM with an existing runtime. On the other hand, it can have the effect of leaving a lot of work for the developer of a novel language. We try to mitigate this by providing built in collector strategy descriptions that can work with many common collector designs and easy extension points. If you don't already have a specific binary interface you need to support, we recommend trying to use one of these built in collector strategies.

4.22.4 LLVM IR Features

This section describes the garbage collection facilities provided by the *LLVM intermediate representation*. The exact behavior of these IR features is specified by the selected *GC strategy description*.

Specifying GC code generation: `gc "..."`

```
define <returntype> @name(...) gc "name" { ... }
```

The `gc` function attribute is used to specify the desired GC strategy to the compiler. Its programmatic equivalent is the `setGC` method of `Function`.

Setting `gc "name"` on a function triggers a search for a matching subclass of `GCStrategy`. Some collector strategies are built in. You can add others using either the loadable plugin mechanism, or by patching your copy of LLVM. It is the selected GC strategy which defines the exact nature of the code generated to support GC. If none is found, the compiler will raise an error.

Specifying the GC style on a per-function basis allows LLVM to link together programs that use different garbage collection algorithms (or none at all).

Identifying GC roots on the stack

LLVM currently supports two different mechanisms for describing references in compiled code at safepoints. `llvm.gcroot` is the older mechanism; `gc.statepoint` has been added more recently. At the moment, you can choose either implementation (on a per *GC strategy* basis). Longer term, we will probably either migrate away from `llvm.gcroot` entirely, or substantially merge their implementations. Note that most new development work is focused on `gc.statepoint`.

Using `gc.statepoint`

This page contains detailed documentation for `gc.statepoint`.

Using `llvm.gcwrite`

```
void @llvm.gcroot(i8** %ptrloc, i8* %metadata)
```

The `llvm.gcroot` intrinsic is used to inform LLVM that a stack variable references an object on the heap and is to be tracked for garbage collection. The exact impact on generated code is specified by the Function's selected *GC strategy*. All calls to `llvm.gcroot` **must** reside inside the first basic block.

The first argument **must** be a value referring to an `alloca` instruction or a bitcast of an `alloca`. The second contains a pointer to metadata that should be associated with the pointer, and **must** be a constant or global value address. If your target collector uses tags, use a null pointer for metadata.

A compiler which performs manual SSA construction **must** ensure that SSA values representing GC references are stored in to the `alloca` passed to the respective `gcroot` before every call site and reloaded after every call. A compiler which uses `mem2reg` to raise imperative code using `alloca` into SSA form need only add a call to `@llvm.gcroot` for those variables which are pointers into the GC heap.

It is also important to mark intermediate values with `llvm.gcroot`. For example, consider `h(f(), g())`. Beware leaking the result of `f()` in the case that `g()` triggers a collection. Note, that stack variables must be initialized and marked with `llvm.gcroot` in function's prologue.

The `%metadata` argument can be used to avoid requiring heap objects to have 'isa' pointers or tag bits. [Appel89, Goldberg91, Tolmach94] If specified, its value will be tracked along with the location of the pointer in the stack frame.

Consider the following fragment of Java code:

```
{
  Object X;    // A null-initialized reference to an object
  ...
}
```

This block (which may be located in the middle of a function or in a loop nest), could be compiled to this LLVM code:

```
Entry:
  ;; In the entry block for the function, allocate the
  ;; stack space for X, which is an LLVM pointer.
  %X = alloca %Object*

  ;; Tell LLVM that the stack space is a stack root.
  ;; Java has type-tags on objects, so we pass null as metadata.
  %tmp = bitcast %Object** %X to i8**
  call void @llvm.gcroot(i8** %tmp, i8* null)
  ...
```

(continues on next page)

(continued from previous page)

```

    ;; "CodeBlock" is the block corresponding to the start
    ;; of the scope above.
CodeBlock:
    ;; Java null-initializes pointers.
    store %Object* null, %Object** %X

    ...

    ;; As the pointer goes out of scope, store a null value into
    ;; it, to indicate that the value is no longer live.
    store %Object* null, %Object** %X
    ...

```

Reading and writing references in the heap

Some collectors need to be informed when the mutator (the program that needs garbage collection) either reads a pointer from or writes a pointer to a field of a heap object. The code fragments inserted at these points are called *read barriers* and *write barriers*, respectively. The amount of code that needs to be executed is usually quite small and not on the critical path of any computation, so the overall performance impact of the barrier is tolerable.

Barriers often require access to the *object pointer* rather than the *derived pointer* (which is a pointer to the field within the object). Accordingly, these intrinsics take both pointers as separate arguments for completeness. In this snippet, %object is the object pointer, and %derived is the derived pointer:

```

;; An array type.
@class.Array = type { %class.Object, i32, [0 x %class.Object*] }
...

;; Load the object pointer from a gcroot.
%object = load %class.Array** %object_addr

;; Compute the derived pointer.
%derived = getelementptr %object, i32 0, i32 2, i32 %n

```

LLVM does not enforce this relationship between the object and derived pointer (although a particular *collector strategy* might). However, it would be an unusual collector that violated it.

The use of these intrinsics is naturally optional if the target GC does not require the corresponding barrier. The GC strategy used with such a collector should replace the intrinsic calls with the corresponding `load` or `store` instruction if they are used.

One known deficiency with the current design is that the barrier intrinsics do not include the size or alignment of the underlying operation performed. It is currently assumed that the operation is of pointer size and the alignment is assumed to be the target machine's default alignment.

Write barrier: `llvm.gcwrite`

```
void @llvm.gcwrite(i8* %value, i8* %object, i8** %derived)
```

For write barriers, LLVM provides the `llvm.gcwrite` intrinsic function. It has exactly the same semantics as a non-volatile `store` to the derived pointer (the third argument). The exact code generated is specified by the Function's selected *GC strategy*.

Many important algorithms require write barriers, including generational and concurrent collectors. Additionally, write barriers could be used to implement reference counting.

Read barrier: `llvm.gcread`

```
i8* @llvm.gcread(i8* %object, i8** %derived)
```

For read barriers, LLVM provides the `llvm.gcread` intrinsic function. It has exactly the same semantics as a non-volatile `load` from the derived pointer (the second argument). The exact code generated is specified by the Function's selected *GC strategy*.

Read barriers are needed by fewer algorithms than write barriers, and may have a greater performance impact since pointer reads are more frequent than writes.

4.22.5 Built In GC Strategies

LLVM includes built in support for several varieties of garbage collectors.

The Shadow Stack GC

To use this collector strategy, mark your functions with:

```
F.setGC("shadow-stack");
```

Unlike many GC algorithms which rely on a cooperative code generator to compile stack maps, this algorithm carefully maintains a linked list of stack roots [Henderson2002]. This so-called "shadow stack" mirrors the machine stack. Maintaining this data structure is slower than using a stack map compiled into the executable as constant data, but has a significant portability advantage because it requires no special support from the target code generator, and does not require tricky platform-specific code to crawl the machine stack.

The tradeoff for this simplicity and portability is:

- High overhead per function call.
- Not thread-safe.

Still, it's an easy way to get started. After your compiler and runtime are up and running, writing a *plugin* will allow you to take advantage of *more advanced GC features* of LLVM in order to improve performance.

The shadow stack doesn't imply a memory allocation algorithm. A semispace collector or building atop `malloc` are great places to start, and can be implemented with very little code.

When it comes time to collect, however, your runtime needs to traverse the stack roots, and for this it needs to integrate with the shadow stack. Luckily, doing so is very simple. (This code is heavily commented to help you understand the data structure, but there are only 20 lines of meaningful code.)

```

/// The map for a single function's stack frame. One of these is
///     compiled as constant data into the executable for each function.
///
/// Storage of metadata values is elided if the %metadata parameter to
/// @llvm.gcroot is null.
struct FrameMap {
    int32_t NumRoots;    ///< Number of roots in stack frame.
    int32_t NumMeta;     ///< Number of metadata entries. May be < NumRoots.
    const void *Meta[0]; ///< Metadata for each root.
};

/// A link in the dynamic shadow stack. One of these is embedded in
///     the stack frame of each function on the call stack.
struct StackEntry {
    StackEntry *Next;    ///< Link to next stack entry (the caller's).
    const FrameMap *Map; ///< Pointer to constant FrameMap.
    void *Roots[0];      ///< Stack roots (in-place array).
};

/// The head of the singly-linked list of StackEntries. Functions push
///     and pop onto this in their prologue and epilogue.
///
/// Since there is only a global list, this technique is not threadsafe.
StackEntry *llvm_gc_root_chain;

/// Calls Visitor(root, meta) for each GC root on the stack.
///     root and meta are exactly the values passed to
///     @llvm.gcroot.
///
/// Visitor could be a function to recursively mark live objects. Or it
/// might copy them to another heap or generation.
///
/// @param Visitor A function to invoke for every GC root on the stack.
void visitGCRoots(void (*Visitor)(void **Root, const void *Meta)) {
    for (StackEntry *R = llvm_gc_root_chain; R; R = R->Next) {
        unsigned i = 0;

        // For roots [0, NumMeta), the metadata pointer is in the FrameMap.
        for (unsigned e = R->Map->NumMeta; i != e; ++i)
            Visitor(&R->Roots[i], R->Map->Meta[i]);

        // For roots [NumMeta, NumRoots), the metadata pointer is null.
        for (unsigned e = R->Map->NumRoots; i != e; ++i)
            Visitor(&R->Roots[i], NULL);
    }
}

```

The 'Erlang' and 'Ocaml' GCs

LLVM ships with two example collectors which leverage the `gcroot` mechanisms. To our knowledge, these are not actually used by any language runtime, but they do provide a reasonable starting point for someone interested in writing an `gcroot` compatible GC plugin. In particular, these are the only in tree examples of how to produce a custom binary stack map format using a `gcroot` strategy.

As there names imply, the binary format produced is intended to model that used by the Erlang and OCaml compilers respectively.

The Statepoint Example GC

```
F.setGC("statepoint-example");
```

This GC provides an example of how one might use the infrastructure provided by `gc.statepoint`. This example GC is compatible with the [PlaceSafepoints](#) and [RewriteStatepointsForGC](#) utility passes which simplify `gc.statepoint` sequence insertion. If you need to build a custom GC strategy around the `gc.statepoints` mechanisms, it is recommended that you use this one as a starting point.

This GC strategy does not support read or write barriers. As a result, these intrinsics are lowered to normal loads and stores.

The stack map format generated by this GC strategy can be found in the [Stack Map Section](#) using a format documented [here](#). This format is intended to be the standard format supported by LLVM going forward.

The CoreCLR GC

```
F.setGC("coreclr");
```

This GC leverages the `gc.statepoint` mechanism to support the [CoreCLR](#) runtime.

Support for this GC strategy is a work in progress. This strategy will differ from [statepoint-example GC](#) strategy in certain aspects like:

- Base-pointers of interior pointers are not explicitly tracked and reported.
- A different format is used for encoding stack maps.
- Safe-point polls are only needed before loop-back edges and before tail-calls (not needed at function-entry).

4.22.6 Custom GC Strategies

If none of the built in GC strategy descriptions met your needs above, you will need to define a custom `GCStrategy` and possibly, a custom LLVM pass to perform lowering. Your best example of where to start defining a custom `GCStrategy` would be to look at one of the built in strategies.

You may be able to structure this additional code as a loadable plugin library. Loadable plugins are sufficient if all you need is to enable a different combination of built in functionality, but if you need to provide a custom lowering pass, you will need to build a patched version of LLVM. If you think you need a patched build, please ask for advice on `llvm-dev`. There may be an easy way we can extend the support to make it work for your use case without requiring a custom build.

Collector Requirements

You should be able to leverage any existing collector library that includes the following elements:

1. A memory allocator which exposes an allocation function your compiled code can call.
2. A binary format for the stack map. A stack map describes the location of references at a safepoint and is used by precise collectors to identify references within a stack frame on the machine stack. Note that collectors which conservatively scan the stack don't require such a structure.
3. A stack crawler to discover functions on the call stack, and enumerate the references listed in the stack map for each call site.
4. A mechanism for identifying references in global locations (e.g. global variables).
5. If your collector requires them, an LLVM IR implementation of your collectors load and store barriers. Note that since many collectors don't require barriers at all, LLVM defaults to lowering such barriers to normal loads and stores unless you arrange otherwise.

Implementing a collector plugin

User code specifies which GC code generation to use with the `gc` function attribute or, equivalently, with the `setGC` method of `Function`.

To implement a GC plugin, it is necessary to subclass `llvm::GCStrategy`, which can be accomplished in a few lines of boilerplate code. LLVM's infrastructure provides access to several important algorithms. For an uncontroversial collector, all that remains may be to compile LLVM's computed stack map to assembly code (using the binary representation expected by the runtime library). This can be accomplished in about 100 lines of code.

This is not the appropriate place to implement a garbage collected heap or a garbage collector itself. That code should exist in the language's runtime library. The compiler plugin is responsible for generating code which conforms to the binary interface defined by library, most essentially the *stack map*.

To subclass `llvm::GCStrategy` and register it with the compiler:

```
// lib/MyGC/MyGC.cpp - Example LLVM GC plugin

#include "llvm/CodeGen/GCStrategy.h"
#include "llvm/CodeGen/GCMetadata.h"
#include "llvm/Support/Compiler.h"

using namespace llvm;

namespace {
  class LLVM_LIBRARY_VISIBILITY MyGC : public GCStrategy {
  public:
    MyGC() {}
  };

  GCRegistry::Add<MyGC>
  X("mygc", "My bespoke garbage collector.");
}
```

This boilerplate collector does nothing. More specifically:

- `llvm.gcread` calls are replaced with the corresponding load instruction.
- `llvm.gcwrite` calls are replaced with the corresponding store instruction.
- No safe points are added to the code.

- The stack map is not compiled into the executable.

Using the LLVM makefiles, this code can be compiled as a plugin using a simple makefile:

```
# lib/MyGC/Makefile

LEVEL := ../..
LIBRARYNAME = MyGC
LOADABLE_MODULE = 1

include $(LEVEL)/Makefile.common
```

Once the plugin is compiled, code using it may be compiled using `llc -load=MyGC.so` (though `MyGC.so` may have some other platform-specific extension):

```
$ cat sample.ll
define void @f() gc "mygc" {
entry:
    ret void
}
$ llvm-as < sample.ll | llc -load=MyGC.so
```

It is also possible to statically link the collector plugin into tools, such as a language-specific compiler front-end.

Overview of available features

`GCStrategy` provides a range of features through which a plugin may do useful work. Some of these are callbacks, some are algorithms that can be enabled, disabled, or customized. This matrix summarizes the supported (and planned) features and correlates them with the collection techniques which typically require them.

Algorithm	Done	Shadow stack	ref-count	mark-sweep	copying	incremental	threaded	concurrent
stack map	✓							
initialize roots	✓							
derived pointers	NO						N*	N*
custom lowering	✓							
<i>gcroot</i>	✓							
<i>gcwrite</i>	✓							
<i>gcread</i>	✓							
safe points								
<i>in calls</i>	✓							
<i>before calls</i>	✓							
<i>for loops</i>	NO						N	N
<i>before escape</i>	✓							
emit code at safe points	NO						N	N
output								
<i>assembly</i>	✓							
<i>JIT</i>	NO			?	?	?	?	?
<i>obj</i>	NO			?	?	?	?	?
live analysis	NO			?	?	?	?	?
register map	NO			?	?	?	?	?

* Derived pointers only pose a hazard to copying collections.

? denotes a feature which could be utilized if available.

To be clear, the collection techniques above are defined as:

Shadow Stack The mutator carefully maintains a linked list of stack roots.

Reference Counting The mutator maintains a reference count for each object and frees an object when its count falls to zero.

Mark-Sweep When the heap is exhausted, the collector marks reachable objects starting from the roots, then deallocates unreachable objects in a sweep phase.

Copying As reachability analysis proceeds, the collector copies objects from one heap area to another, compacting them in the process. Copying collectors enable highly efficient "bump pointer" allocation and can improve locality of reference.

Incremental (Including generational collectors.) Incremental collectors generally have all the properties of a copying collector (regardless of whether the mature heap is compacting), but bring the added complexity of requiring write barriers.

Threaded Denotes a multithreaded mutator; the collector must still stop the mutator ("stop the world") before beginning reachability analysis. Stopping a multithreaded mutator is a complicated problem. It generally requires highly platform-specific code in the runtime, and the production of carefully designed machine code at safe points.

Concurrent In this technique, the mutator and the collector run concurrently, with the goal of eliminating pause times. In a *cooperative* collector, the mutator further aids with collection should a pause occur, allowing collection to take advantage of multiprocessor hosts. The "stop the world" problem of threaded collectors is generally still present to a limited extent. Sophisticated marking algorithms are necessary. Read barriers may be necessary.

As the matrix indicates, LLVM's garbage collection infrastructure is already suitable for a wide variety of collectors, but does not currently extend to multithreaded programs. This will be added in the future as there is interest.

Computing stack maps

LLVM automatically computes a stack map. One of the most important features of a `GCStrategy` is to compile this information into the executable in the binary representation expected by the runtime library.

The stack map consists of the location and identity of each GC root in the each function in the module. For each root:

- `RootNum`: The index of the root.
- `StackOffset`: The offset of the object relative to the frame pointer.
- `RootMetadata`: The value passed as the `%metadata` parameter to the `@llvm.gcroot` intrinsic.

Also, for the function as a whole:

- `getFrameSize()`: The overall size of the function's initial stack frame, not accounting for any dynamic allocation.
- `roots_size()`: The count of roots in the function.

To access the stack map, use `GCFunctionMetadata::roots_begin()` and `-end()` from the *GCMetadataPrinter*:

```
for (iterator I = begin(), E = end(); I != E; ++I) {
    GCFunctionInfo *FI = *I;
    unsigned FrameSize = FI->getFrameSize();
    size_t RootCount = FI->roots_size();

    for (GCFunctionInfo::roots_iterator RI = FI->roots_begin(),
         RE = FI->roots_end();
```

(continues on next page)

(continued from previous page)

```

                                RI != RE; ++RI) {
    int RootNum = RI->Num;
    int RootStackOffset = RI->StackOffset;
    Constant *RootMetadata = RI->Metadata;
}
}

```

If the `llvm.gcroot` intrinsic is eliminated before code generation by a custom lowering pass, LLVM will compute an empty stack map. This may be useful for collector plugins which implement reference counting or a shadow stack.

Initializing roots to null

It is recommended that frontends initialize roots explicitly to avoid potentially confusing the optimizer. This prevents the GC from visiting uninitialized pointers, which will almost certainly cause it to crash.

As a fallback, LLVM will automatically initialize each root to `null` upon entry to the function. Support for this mode in code generation is largely a legacy detail to keep old collector implementations working.

Custom lowering of intrinsics

For GCs which use barriers or unusual treatment of stack roots, the implementor is responsibly for providing a custom pass to lower the intrinsics with the desired semantics. If you have opted in to custom lowering of a particular intrinsic your pass **must** eliminate all instances of the corresponding intrinsic in functions which opt in to your GC. The best example of such a pass is the `ShadowStackGC` and its `ShadowStackGCLowering` pass.

There is currently no way to register such a custom lowering pass without building a custom copy of LLVM.

Generating safe points

LLVM provides support for associating stackmaps with the return address of a call. Any loop or return safe-points required by a given collector design can be modeled via calls to runtime routines, or potentially patchable call sequences. Using `gcroot`, all call instructions are inferred to be possible safe-points and will thus have an associated stackmap.

Emitting assembly code: `GCMetadataPrinter`

LLVM allows a plugin to print arbitrary assembly code before and after the rest of a module's assembly code. At the end of the module, the GC can compile the LLVM stack map into assembly code. (At the beginning, this information is not yet computed.)

Since `AsmWriter` and `CodeGen` are separate components of LLVM, a separate abstract base class and registry is provided for printing assembly code, the `GCMetadataPrinter` and `GCMetadataPrinterRegistry`. The `AsmWriter` will look for such a subclass if the `GCStrategy` sets `UsesMetadata`:

```

MyGC::MyGC() {
    UsesMetadata = true;
}

```

This separation allows JIT-only clients to be smaller.

Note that LLVM does not currently have analogous APIs to support code generation in the JIT, nor using the object writers.

```
// lib/MyGC/MyGCPrinter.cpp - Example LLVM GC printer

#include "llvm/CodeGen/GCMetadataPrinter.h"
#include "llvm/Support/Compiler.h"

using namespace llvm;

namespace {
  class LLVM_LIBRARY_VISIBILITY MyGCPrinter : public GCMetadataPrinter {
  public:
    virtual void beginAssembly(AsmPrinter &AP);

    virtual void finishAssembly(AsmPrinter &AP);
  };

  GCMetadataPrinterRegistry::Add<MyGCPrinter>
  X("mygc", "My bespoke garbage collector.");
}
```

The collector should use `AsmPrinter` to print portable assembly code. The collector itself contains the stack map for the entire module, and may access the `GCFunctionInfo` using its own `begin()` and `end()` methods. Here's a realistic example:

```
#include "llvm/CodeGen/AsmPrinter.h"
#include "llvm/IR/Function.h"
#include "llvm/IR/DataLayout.h"
#include "llvm/Target/TargetAsmInfo.h"
#include "llvm/Target/TargetMachine.h"

void MyGCPrinter::beginAssembly(AsmPrinter &AP) {
  // Nothing to do.
}

void MyGCPrinter::finishAssembly(AsmPrinter &AP) {
  MCStreamer &OS = AP.OutStreamer;
  unsigned IntPtrSize = AP.getPointerSize();

  // Put this in the data section.
  OS.SwitchSection(AP.getObjFileLowering().getDataSection());

  // For each function...
  for (iterator FI = begin(), FE = end(); FI != FE; ++FI) {
    GCFunctionInfo &MD = **FI;

    // A compact GC layout. Emit this data structure:
    //
    // struct {
    //   int32_t PointCount;
    //   void *SafePointAddress[PointCount];
    //   int32_t StackFrameSize; // in words
    //   int32_t StackArity;
    //   int32_t LiveCount;
    //   int32_t LiveOffsets[LiveCount];
    // } __gcmmap_<FUNCTIONNAME>;

    // Align to address width.
    AP.EmitAlignment(IntPtrSize == 4 ? 2 : 3);
  }
}
```

(continues on next page)

(continued from previous page)

```

// Emit PointCount.
OS.AddComment("safe point count");
AP.emitInt32(MD.size());

// And each safe point...
for (GCFunctionInfo::iterator PI = MD.begin(),
      PE = MD.end(); PI != PE; ++PI) {
    // Emit the address of the safe point.
    OS.AddComment("safe point address");
    MCSymbol *Label = PI->Label;
    AP.EmitLabelPlusOffset(Label/*Hi*/, 0/*Offset*/, 4/*Size*/);
}

// Stack information never change in safe points! Only print info from the
// first call-site.
GCFunctionInfo::iterator PI = MD.begin();

// Emit the stack frame size.
OS.AddComment("stack frame size (in words)");
AP.emitInt32(MD.getFrameSize() / IntPtrSize);

// Emit stack arity, i.e. the number of stacked arguments.
unsigned RegisteredArgs = IntPtrSize == 4 ? 5 : 6;
unsigned StackArity = MD.getFunction().arg_size() > RegisteredArgs ?
    MD.getFunction().arg_size() - RegisteredArgs : 0;
OS.AddComment("stack arity");
AP.emitInt32(StackArity);

// Emit the number of live roots in the function.
OS.AddComment("live root count");
AP.emitInt32(MD.live_size(PI));

// And for each live root...
for (GCFunctionInfo::live_iterator LI = MD.live_begin(PI),
      LE = MD.live_end(PI);
      LI != LE; ++LI) {
    // Emit live root's offset within the stack frame.
    OS.AddComment("stack index (offset / wordsize)");
    AP.emitInt32(LI->StackOffset);
}
}
}

```

4.23.1 Introduction --- What is a pass?

The LLVM Pass Framework is an important part of the LLVM system, because LLVM passes are where most of the interesting parts of the compiler exist. Passes perform the transformations and optimizations that make up the compiler, they build the analysis results that are used by these transformations, and they are, above all, a structuring technique for compiler code.

All LLVM passes are subclasses of the `Pass` class, which implement functionality by overriding virtual methods inherited from `Pass`. Depending on how your pass works, you should inherit from the `ModulePass`, `CallGraphSCCPass`, `FunctionPass`, or `LoopPass`, or `RegionPass`, or `BasicBlockPass` classes, which gives the system more information about what your pass does, and how it can be combined with other passes. One of the main features of the LLVM Pass Framework is that it schedules passes to run in an efficient way based on the constraints that your pass meets (which are indicated by which class they derive from).

We start by showing you how to construct a pass, everything from setting up the code, to compiling, loading, and executing it. After the basics are down, more advanced features are discussed.

4.23.2 Quick Start --- Writing hello world

Here we describe how to write the "hello world" of passes. The "Hello" pass is designed to simply print out the name of non-external functions that exist in the program being compiled. It does not modify the program at all, it just inspects it. The source code and files for this pass are available in the LLVM source tree in the `lib/Transforms/Hello` directory.

Setting up the build environment

First, configure and build LLVM. Next, you need to create a new directory somewhere in the LLVM source base. For this example, we'll assume that you made `lib/Transforms/Hello`. Finally, you must set up a build script that will compile the source code for the new pass. To do this, copy the following into `CMakeLists.txt`:

```
add_llvm_library( LLVMHello MODULE
  Hello.cpp

  PLUGIN_TOOL
  opt
)
```

and the following line into `lib/Transforms/CMakeLists.txt`:

```
add_subdirectory(Hello)
```

(Note that there is already a directory named `Hello` with a sample "Hello" pass; you may play with it -- in which case you don't need to modify any `CMakeLists.txt` files -- or, if you want to create everything from scratch, use another name.)

This build script specifies that `Hello.cpp` file in the current directory is to be compiled and linked into a shared object `$(LEVEL)/lib/LLVMHello.so` that can be dynamically loaded by the `opt` tool via its `-load` option. If your operating system uses a suffix other than `.so` (such as Windows or macOS), the appropriate extension will be used.

Now that we have the build scripts set up, we just need to write the code for the pass itself.

Basic code required

Now that we have a way to compile our new pass, we just have to write it. Start out with:

```
#include "llvm/Pass.h"
#include "llvm/IR/Function.h"
#include "llvm/Support/raw_ostream.h"
```

Which are needed because we are writing a `Pass`, we are operating on `Functions`, and we will be doing some printing.

Next we have:

```
using namespace llvm;
```

... which is required because the functions from the include files live in the `llvm` namespace.

Next we have:

```
namespace {
```

... which starts out an anonymous namespace. Anonymous namespaces are to C++ what the "static" keyword is to C (at global scope). It makes the things declared inside of the anonymous namespace visible only to the current file. If you're not familiar with them, consult a decent C++ book for more information.

Next, we declare our pass itself:

```
struct Hello : public FunctionPass {
```

This declares a "Hello" class that is a subclass of *FunctionPass*. The different builtin pass subclasses are described in detail *later*, but for now, know that *FunctionPass* operates on a function at a time.

```
static char ID;
Hello() : FunctionPass(ID) {}
```

This declares pass identifier used by LLVM to identify pass. This allows LLVM to avoid using expensive C++ runtime information.

```
bool runOnFunction(Function &F) override {
    errs() << "Hello: ";
    errs().write_escaped(F.getName()) << '\n';
    return false;
}
}; // end of struct Hello
} // end of anonymous namespace
```

We declare a *runOnFunction* method, which overrides an abstract virtual method inherited from *FunctionPass*. This is where we are supposed to do our thing, so we just print out our message with the name of each function.

```
char Hello::ID = 0;
```

We initialize pass ID here. LLVM uses ID's address to identify a pass, so initialization value is not important.

```
static RegisterPass<Hello> X("hello", "Hello World Pass",
                             false /* Only looks at CFG */,
                             false /* Analysis Pass */);
```

Lastly, we *register our class* Hello, giving it a command line argument "hello", and a name "Hello World Pass". The last two arguments describe its behavior: if a pass walks CFG without modifying it then the third argument is set to true; if a pass is an analysis pass, for example dominator tree pass, then true is supplied as the fourth argument.

If we want to register the pass as a step of an existing pipeline, some extension points are provided, e.g. *PassManagerBuilder::EP_EarlyAsPossible* to apply our pass before any optimization, or *PassManagerBuilder::EP_FullLinkTimeOptimizationLast* to apply it after Link Time Optimizations.

```
static llvm::RegisterStandardPasses Y(
    llvm::PassManagerBuilder::EP_EarlyAsPossible,
    [] (const llvm::PassManagerBuilder &Builder,
        llvm::legacy::PassManagerBase &PM) { PM.add(new Hello()); });
```

As a whole, the .cpp file looks like:

```
#include "llvm/Pass.h"
#include "llvm/IR/Function.h"
#include "llvm/Support/raw_ostream.h"

#include "llvm/IR/LegacyPassManager.h"
#include "llvm/Transforms/IPO/PassManagerBuilder.h"
```

(continues on next page)

(continued from previous page)

```

using namespace llvm;

namespace {
struct Hello : public FunctionPass {
    static char ID;
    Hello() : FunctionPass(ID) {}

    bool runOnFunction(Function &F) override {
        errs() << "Hello: ";
        errs().write_escaped(F.getName()) << '\n';
        return false;
    }
}; // end of struct Hello
} // end of anonymous namespace

char Hello::ID = 0;
static RegisterPass<Hello> X("hello", "Hello World Pass",
                             false /* Only looks at CFG */,
                             false /* Analysis Pass */);

static RegisterStandardPasses Y(
    PassManagerBuilder::EP_EarlyAsPossible,
    [] (const PassManagerBuilder &Builder,
        legacy::PassManagerBase &PM) { PM.add(new Hello()); });

```

Now that it's all together, compile the file with a simple "gmake" command from the top level of your build directory and you should get a new file "lib/LLVMHello.so". Note that everything in this file is contained in an anonymous namespace --- this reflects the fact that passes are self contained units that do not need external interfaces (although they can have them) to be useful.

Running a pass with `opt`

Now that you have a brand new shiny shared object file, we can use the `opt` command to run an LLVM program through your pass. Because you registered your pass with `RegisterPass`, you will be able to use the `opt` tool to access it, once loaded.

To test it, follow the example at the end of the *Getting Started with the LLVM System* to compile "Hello World" to LLVM. We can now run the bitcode file (hello.bc) for the program through our transformation like this (or course, any bitcode file will work):

```

$ opt -load lib/LLVMHello.so -hello < hello.bc > /dev/null
Hello: __main
Hello: puts
Hello: main

```

The `-load` option specifies that `opt` should load your pass as a shared object, which makes "-hello" a valid command line argument (which is one reason you need to *register your pass*). Because the Hello pass does not modify the program in any interesting way, we just throw away the result of `opt` (sending it to /dev/null).

To see what happened to the other string you registered, try running `opt` with the `-help` option:

```

$ opt -load lib/LLVMHello.so -help
OVERVIEW: llvm .bc -> .bc modular optimizer and analysis printer

```

(continues on next page)

(continued from previous page)

```

USAGE: opt [subcommand] [options] <input bitcode file>

OPTIONS:
  Optimizations available:
  ...
    -guard-widening      - Widen guards
    -gvn                  - Global Value Numbering
    -gvn-hoist            - Early GVN Hoisting of Expressions
    -hello                - Hello World Pass
    -indvars              - Induction Variable Simplification
    -inferattrs           - Infer set function attributes
  ...

```

The pass name gets added as the information string for your pass, giving some documentation to users of `opt`. Now that you have a working pass, you would go ahead and make it do the cool transformations you want. Once you get it all working and tested, it may become useful to find out how fast your pass is. The *PassManager* provides a nice command line option (`-time-passes`) that allows you to get information about the execution time of your pass along with the other passes you queue up. For example:

```

$ opt -load lib/LLVMHello.so -hello -time-passes < hello.bc > /dev/null
Hello: __main
Hello: puts
Hello: main
=====
... Pass execution timing report ...
=====
Total Execution Time: 0.0007 seconds (0.0005 wall clock)

---User Time---  --User+System--  ---Wall Time---  --- Name ---
0.0004 ( 55.3%)  0.0004 ( 55.3%)  0.0004 ( 75.7%)  Bitcode Writer
0.0003 ( 44.7%)  0.0003 ( 44.7%)  0.0001 ( 13.6%)  Hello World Pass
0.0000 (  0.0%)  0.0000 (  0.0%)  0.0001 ( 10.7%)  Module Verifier
0.0007 (100.0%)  0.0007 (100.0%)  0.0005 (100.0%)  Total

```

As you can see, our implementation above is pretty fast. The additional passes listed are automatically inserted by the `opt` tool to verify that the LLVM emitted by your pass is still valid and well formed LLVM, which hasn't been broken somehow.

Now that you have seen the basics of the mechanics behind passes, we can talk about some more details of how they work and how to use them.

4.23.3 Pass classes and requirements

One of the first things that you should do when designing a new pass is to decide what class you should subclass for your pass. The *Hello World* example uses the *FunctionPass* class for its implementation, but we did not discuss why or when this should occur. Here we talk about the classes available, from the most general to the most specific.

When choosing a superclass for your `Pass`, you should choose the **most specific** class possible, while still being able to meet the requirements listed. This gives the LLVM Pass Infrastructure information necessary to optimize how passes are run, so that the resultant compiler isn't unnecessarily slow.

The ImmutablePass class

The most plain and boring type of pass is the "ImmutablePass" class. This pass type is used for passes that do not have to be run, do not change state, and never need to be updated. This is not a normal type of transformation or analysis, but can provide information about the current compiler configuration.

Although this pass class is very infrequently used, it is important for providing information about the current target machine being compiled for, and other static information that can affect the various transformations.

ImmutablePasses never invalidate other transformations, are never invalidated, and are never "run".

The ModulePass class

The `ModulePass` class is the most general of all superclasses that you can use. Deriving from `ModulePass` indicates that your pass uses the entire program as a unit, referring to function bodies in no predictable order, or adding and removing functions. Because nothing is known about the behavior of `ModulePass` subclasses, no optimization can be done for their execution.

A module pass can use function level passes (e.g. dominators) using the `getAnalysis` interface `getAnalysis<DominatorTree>(llvm::Function *)` to provide the function to retrieve analysis result for, if the function pass does not require any module or immutable passes. Note that this can only be done for functions for which the analysis ran, e.g. in the case of dominators you should only ask for the `DominatorTree` for function definitions, not declarations.

To write a correct `ModulePass` subclass, derive from `ModulePass` and overload the `runOnModule` method with the following signature:

The runOnModule method

```
virtual bool runOnModule(Module &M) = 0;
```

The `runOnModule` method performs the interesting work of the pass. It should return `true` if the module was modified by the transformation and `false` otherwise.

The CallGraphSCCPass class

The `CallGraphSCCPass` is used by passes that need to traverse the program bottom-up on the call graph (callees before callers). Deriving from `CallGraphSCCPass` provides some mechanics for building and traversing the `CallGraph`, but also allows the system to optimize execution of `CallGraphSCCPasses`. If your pass meets the requirements outlined below, and doesn't meet the requirements of a *FunctionPass* or *BasicBlockPass*, you should derive from `CallGraphSCCPass`.

TODO: explain briefly what SCC, Tarjan's algo, and B-U mean.

To be explicit, `CallGraphSCCPass` subclasses are:

1. ... *not allowed* to inspect or modify any `Functions` other than those in the current SCC and the direct callers and direct callees of the SCC.
2. ... *required* to preserve the current `CallGraph` object, updating it to reflect any changes made to the program.
3. ... *not allowed* to add or remove SCC's from the current `Module`, though they may change the contents of an SCC.
4. ... *allowed* to add or remove global variables from the current `Module`.
5. ... *allowed* to maintain state across invocations of *runOnSCC* (including global data).

Implementing a `CallGraphSCCPass` is slightly tricky in some cases because it has to handle SCCs with more than one node in it. All of the virtual methods described below should return `true` if they modified the program, or `false` if they didn't.

The `doInitialization(CallGraph &) method`

```
virtual bool doInitialization(CallGraph &CG);
```

The `doInitialization` method is allowed to do most of the things that `CallGraphSCCPasses` are not allowed to do. They can add and remove functions, get pointers to functions, etc. The `doInitialization` method is designed to do simple initialization type of stuff that does not depend on the SCCs being processed. The `doInitialization` method call is not scheduled to overlap with any other pass executions (thus it should be very fast).

The `runOnSCC` method

```
virtual bool runOnSCC(CallGraphSCC &SCC) = 0;
```

The `runOnSCC` method performs the interesting work of the pass, and should return `true` if the module was modified by the transformation, `false` otherwise.

The `doFinalization(CallGraph &) method`

```
virtual bool doFinalization(CallGraph &CG);
```

The `doFinalization` method is an infrequently used method that is called when the pass framework has finished calling `runOnSCC` for every SCC in the program being compiled.

The `FunctionPass` class

In contrast to `ModulePass` subclasses, `FunctionPass` subclasses do have a predictable, local behavior that can be expected by the system. All `FunctionPass` execute on each function in the program independent of all of the other functions in the program. `FunctionPasses` do not require that they are executed in a particular order, and `FunctionPasses` do not modify external functions.

To be explicit, `FunctionPass` subclasses are not allowed to:

1. Inspect or modify a `Function` other than the one currently being processed.
2. Add or remove `Functions` from the current `Module`.
3. Add or remove global variables from the current `Module`.
4. Maintain state across invocations of `runOnFunction` (including global data).

Implementing a `FunctionPass` is usually straightforward (See the *Hello World* pass for example). `FunctionPasses` may overload three virtual methods to do their work. All of these methods should return `true` if they modified the program, or `false` if they didn't.

The `doInitialization(Module &) method`

```
virtual bool doInitialization(Module &M);
```

The `doInitialization` method is allowed to do most of the things that `FunctionPasses` are not allowed to do. They can add and remove functions, get pointers to functions, etc. The `doInitialization` method is designed to do simple initialization type of stuff that does not depend on the functions being processed. The `doInitialization` method call is not scheduled to overlap with any other pass executions (thus it should be very fast).

A good example of how this method should be used is the `LowerAllocations` pass. This pass converts `malloc` and `free` instructions into platform dependent `malloc()` and `free()` function calls. It uses the `doInitialization` method to get a reference to the `malloc` and `free` functions that it needs, adding proto-types to the module if necessary.

The `runOnFunction` method

```
virtual bool runOnFunction(Function &F) = 0;
```

The `runOnFunction` method must be implemented by your subclass to do the transformation or analysis work of your pass. As usual, a `true` value should be returned if the function is modified.

The `doFinalization(Module &) method`

```
virtual bool doFinalization(Module &M);
```

The `doFinalization` method is an infrequently used method that is called when the pass framework has finished calling `runOnFunction` for every function in the program being compiled.

The `LoopPass` class

All `LoopPass` execute on each loop in the function independent of all of the other loops in the function. `LoopPass` processes loops in loop nest order such that outer most loop is processed last.

`LoopPass` subclasses are allowed to update loop nest using `LPPassManager` interface. Implementing a loop pass is usually straightforward. `LoopPasses` may overload three virtual methods to do their work. All these methods should return `true` if they modified the program, or `false` if they didn't.

A `LoopPass` subclass which is intended to run as part of the main loop pass pipeline needs to preserve all of the same *function* analyses that the other loop passes in its pipeline require. To make that easier, a `getLoopAnalysisUsage` function is provided by `LoopUtils.h`. It can be called within the subclass's `getAnalysisUsage` override to get consistent and correct behavior. Analogously, `INITIALIZE_PASS_DEPENDENCY(LoopPass)` will initialize this set of function analyses.

The `doInitialization(Loop *, LPPassManager &)` method

```
virtual bool doInitialization(Loop *, LPPassManager &LPM);
```

The `doInitialization` method is designed to do simple initialization type of stuff that does not depend on the functions being processed. The `doInitialization` method call is not scheduled to overlap with any other pass executions (thus it should be very fast). `LPPassManager` interface should be used to access `Function` or `Module` level analysis information.

The `runOnLoop` method

```
virtual bool runOnLoop(Loop *, LPPassManager &LPM) = 0;
```

The `runOnLoop` method must be implemented by your subclass to do the transformation or analysis work of your pass. As usual, a `true` value should be returned if the function is modified. `LPPassManager` interface should be used to update loop nest.

The `doFinalization()` method

```
virtual bool doFinalization();
```

The `doFinalization` method is an infrequently used method that is called when the pass framework has finished calling *runOnLoop* for every loop in the program being compiled.

The `RegionPass` class

`RegionPass` is similar to *LoopPass*, but executes on each single entry single exit region in the function. `RegionPass` processes regions in nested order such that the outer most region is processed last.

`RegionPass` subclasses are allowed to update the region tree by using the `RGPassManager` interface. You may overload three virtual methods of `RegionPass` to implement your own region pass. All these methods should return `true` if they modified the program, or `false` if they did not.

The `doInitialization(Region *, RGPassManager &)` method

```
virtual bool doInitialization(Region *, RGPassManager &RGM);
```

The `doInitialization` method is designed to do simple initialization type of stuff that does not depend on the functions being processed. The `doInitialization` method call is not scheduled to overlap with any other pass executions (thus it should be very fast). `RGPassManager` interface should be used to access `Function` or `Module` level analysis information.

The `runOnRegion` method

```
virtual bool runOnRegion(Region *, RGPassManager &RGM) = 0;
```

The `runOnRegion` method must be implemented by your subclass to do the transformation or analysis work of your pass. As usual, a true value should be returned if the region is modified. `RGPassManager` interface should be used to update region tree.

The `doFinalization()` method

```
virtual bool doFinalization();
```

The `doFinalization` method is an infrequently used method that is called when the pass framework has finished calling *runOnRegion* for every region in the program being compiled.

The `BasicBlockPass` class

`BasicBlockPasses` are just like *FunctionPass's*, except that they must limit their scope of inspection and modification to a single basic block at a time. As such, they are **not** allowed to do any of the following:

1. Modify or inspect any basic blocks outside of the current one.
2. Maintain state across invocations of *runOnBasicBlock*.
3. Modify the control flow graph (by altering terminator instructions)
4. Any of the things forbidden for *FunctionPasses*.

`BasicBlockPasses` are useful for traditional local and "peephole" optimizations. They may override the same *doInitialization(Module &)* and *doFinalization(Module &)* methods that *FunctionPass's* have, but also have the following virtual methods that may also be implemented:

The `doInitialization(Function &)` method

```
virtual bool doInitialization(Function &F);
```

The `doInitialization` method is allowed to do most of the things that `BasicBlockPasses` are not allowed to do, but that `FunctionPasses` can. The `doInitialization` method is designed to do simple initialization that does not depend on the `BasicBlocks` being processed. The `doInitialization` method call is not scheduled to overlap with any other pass executions (thus it should be very fast).

The `runOnBasicBlock` method

```
virtual bool runOnBasicBlock(BasicBlock &BB) = 0;
```

Override this function to do the work of the `BasicBlockPass`. This function is not allowed to inspect or modify basic blocks other than the parameter, and are not allowed to modify the CFG. A true value must be returned if the basic block is modified.

The `doFinalization(Function &)` method

```
virtual bool doFinalization(Function &F);
```

The `doFinalization` method is an infrequently used method that is called when the pass framework has finished calling `runOnBasicBlock` for every `BasicBlock` in the program being compiled. This can be used to perform per-function finalization.

The `MachineFunctionPass` class

A `MachineFunctionPass` is a part of the LLVM code generator that executes on the machine-dependent representation of each LLVM function in the program.

Code generator passes are registered and initialized specially by `TargetMachine::addPassesToEmitFile` and similar routines, so they cannot generally be run from the `opt` or `bugpoint` commands.

A `MachineFunctionPass` is also a `FunctionPass`, so all the restrictions that apply to a `FunctionPass` also apply to it. `MachineFunctionPasses` also have additional restrictions. In particular, `MachineFunctionPasses` are not allowed to do any of the following:

1. Modify or create any LLVM IR Instructions, BasicBlocks, Arguments, Functions, GlobalVariables, GlobalAliases, or Modules.
2. Modify a `MachineFunction` other than the one currently being processed.
3. Maintain state across invocations of `runOnMachineFunction` (including global data).

The `runOnMachineFunction(MachineFunction &MF)` method

```
virtual bool runOnMachineFunction(MachineFunction &MF) = 0;
```

`runOnMachineFunction` can be considered the main entry point of a `MachineFunctionPass`; that is, you should override this method to do the work of your `MachineFunctionPass`.

The `runOnMachineFunction` method is called on every `MachineFunction` in a `Module`, so that the `MachineFunctionPass` may perform optimizations on the machine-dependent representation of the function. If you want to get at the LLVM `Function` for the `MachineFunction` you're working on, use `MachineFunction's` `getFunction()` accessor method --- but remember, you may not modify the LLVM `Function` or its contents from a `MachineFunctionPass`.

Pass registration

In the *Hello World* example pass we illustrated how pass registration works, and discussed some of the reasons that it is used and what it does. Here we discuss how and why passes are registered.

As we saw above, passes are registered with the `RegisterPass` template. The template parameter is the name of the pass that is to be used on the command line to specify that the pass should be added to a program (for example, with `opt` or `bugpoint`). The first argument is the name of the pass, which is to be used for the `-help` output of programs, as well as for debug output generated by the `--debug-pass` option.

If you want your pass to be easily dumpable, you should implement the virtual `print` method:

The print method

```
virtual void print (llvm::raw_ostream &O, const Module *M) const;
```

The `print` method must be implemented by "analyses" in order to print a human readable version of the analysis results. This is useful for debugging an analysis itself, as well as for other people to figure out how an analysis works. Use the `opt -analyze` argument to invoke this method.

The `llvm::raw_ostream` parameter specifies the stream to write the results on, and the `Module` parameter gives a pointer to the top level module of the program that has been analyzed. Note however that this pointer may be `NULL` in certain circumstances (such as calling the `Pass::dump()` from a debugger), so it should only be used to enhance debug output, it should not be depended on.

Specifying interactions between passes

One of the main responsibilities of the `PassManager` is to make sure that passes interact with each other correctly. Because `PassManager` tries to *optimize the execution of passes* it must know how the passes interact with each other and what dependencies exist between the various passes. To track this, each pass can declare the set of passes that are required to be executed before the current pass, and the passes which are invalidated by the current pass.

Typically this functionality is used to require that analysis results are computed before your pass is run. Running arbitrary transformation passes can invalidate the computed analysis results, which is what the invalidation set specifies. If a pass does not implement the *`getAnalysisUsage`* method, it defaults to not having any prerequisite passes, and invalidating **all** other passes.

The getAnalysisUsage method

```
virtual void getAnalysisUsage (AnalysisUsage &Info) const;
```

By implementing the `getAnalysisUsage` method, the required and invalidated sets may be specified for your transformation. The implementation should fill in the *`AnalysisUsage`* object with information about which passes are required and not invalidated. To do this, a pass may call any of the following methods on the *`AnalysisUsage`* object:

The `AnalysisUsage::addRequired<>` and `AnalysisUsage::addRequiredTransitive<>` methods

If your pass requires a previous pass to be executed (an analysis for example), it can use one of these methods to arrange for it to be run before your pass. LLVM has many different types of analyses and passes that can be required, spanning the range from `DominatorSet` to `BreakCriticalEdges`. Requiring `BreakCriticalEdges`, for example, guarantees that there will be no critical edges in the CFG when your pass has been run.

Some analyses chain to other analyses to do their job. For example, an *`AliasAnalysis`* <*`AliasAnalysis`*> implementation is required to *chain* to other alias analysis passes. In cases where analyses chain, the `addRequiredTransitive` method should be used instead of the `addRequired` method. This informs the `PassManager` that the transitively required pass should be alive as long as the requiring pass is.

The `AnalysisUsage::addPreserved<>` method

One of the jobs of the `PassManager` is to optimize how and when analyses are run. In particular, it attempts to avoid recomputing data unless it needs to. For this reason, passes are allowed to declare that they preserve (i.e., they don't invalidate) an existing analysis if it's available. For example, a simple constant folding pass would not modify the CFG, so it can't possibly affect the results of dominator analysis. By default, all passes are assumed to invalidate all others.

The `AnalysisUsage` class provides several methods which are useful in certain circumstances that are related to `addPreserved`. In particular, the `setPreservesAll` method can be called to indicate that the pass does not modify the LLVM program at all (which is true for analyses), and the `setPreservesCFG` method can be used by transformations that change instructions in the program but do not modify the CFG or terminator instructions (note that this property is implicitly set for *BasicBlockPasses*).

`addPreserved` is particularly useful for transformations like `BreakCriticalEdges`. This pass knows how to update a small set of loop and dominator related analyses if they exist, so it can preserve them, despite the fact that it hacks on the CFG.

Example implementations of `getAnalysisUsage`

```
// This example modifies the program, but does not modify the CFG
void LICM::getAnalysisUsage(AnalysisUsage &AU) const {
    AU.setPreservesCFG();
    AU.addRequired<LoopInfoWrapperPass>();
}
```

The `getAnalysis<>` and `getAnalysisIfAvailable<>` methods

The `Pass::getAnalysis<>` method is automatically inherited by your class, providing you with access to the passes that you declared that you required with the *getAnalysisUsage* method. It takes a single template argument that specifies which pass class you want, and returns a reference to that pass. For example:

```
bool LICM::runOnFunction(Function &F) {
    LoopInfo &LI = getAnalysis<LoopInfoWrapperPass>().getLoopInfo();
    //...
}
```

This method call returns a reference to the pass desired. You may get a runtime assertion failure if you attempt to get an analysis that you did not declare as required in your *getAnalysisUsage* implementation. This method can be called by your `run*` method implementation, or by any other local method invoked by your `run*` method.

A module level pass can use function level analysis info using this interface. For example:

```
bool ModuleLevelPass::runOnModule(Module &M) {
    //...
    DominatorTree &DT = getAnalysis<DominatorTree>(Func);
    //...
}
```

In above example, `runOnFunction` for `DominatorTree` is called by pass manager before returning a reference to the desired pass.

If your pass is capable of updating analyses if they exist (e.g., `BreakCriticalEdges`, as described above), you can use the `getAnalysisIfAvailable` method, which returns a pointer to the analysis if it is active. For example:

```

if (DominatorSet *DS = getAnalysisIfAvailable<DominatorSet>()) {
    // A DominatorSet is active. This code will update it.
}

```

Implementing Analysis Groups

Now that we understand the basics of how passes are defined, how they are used, and how they are required from other passes, it's time to get a little bit fancier. All of the pass relationships that we have seen so far are very simple: one pass depends on one other specific pass to be run before it can run. For many applications, this is great, for others, more flexibility is required.

In particular, some analyses are defined such that there is a single simple interface to the analysis results, but multiple ways of calculating them. Consider alias analysis for example. The most trivial alias analysis returns "may alias" for any alias query. The most sophisticated analysis is a flow-sensitive, context-sensitive interprocedural analysis that can take a significant amount of time to execute (and obviously, there is a lot of room between these two extremes for other implementations). To cleanly support situations like this, the LLVM Pass Infrastructure supports the notion of Analysis Groups.

Analysis Group Concepts

An Analysis Group is a single simple interface that may be implemented by multiple different passes. Analysis Groups can be given human readable names just like passes, but unlike passes, they need not derive from the `Pass` class. An analysis group may have one or more implementations, one of which is the "default" implementation.

Analysis groups are used by client passes just like other passes are: the `AnalysisUsage::addRequired()` and `Pass::getAnalysis()` methods. In order to resolve this requirement, the *PassManager* scans the available passes to see if any implementations of the analysis group are available. If none is available, the default implementation is created for the pass to use. All standard rules for *interaction between passes* still apply.

Although *Pass Registration* is optional for normal passes, all analysis group implementations must be registered, and must use the `INITIALIZE_AG_PASS` template to join the implementation pool. Also, a default implementation of the interface **must** be registered with *RegisterAnalysisGroup*.

As a concrete example of an Analysis Group in action, consider the *AliasAnalysis* analysis group. The default implementation of the alias analysis interface (the *basicaa* pass) just does a few simple checks that don't require significant analysis to compute (such as: two different globals can never alias each other, etc). Passes that use the *AliasAnalysis* interface (for example the *gvn* pass), do not care which implementation of alias analysis is actually provided, they just use the designated interface.

From the user's perspective, commands work just like normal. Issuing the command `opt -gvn ...` will cause the *basicaa* class to be instantiated and added to the pass sequence. Issuing the command `opt -somefancyaa -gvn ...` will cause the *gvn* pass to use the *somefancyaa* alias analysis (which doesn't actually exist, it's just a hypothetical example) instead.

Using RegisterAnalysisGroup

The `RegisterAnalysisGroup` template is used to register the analysis group itself, while the `INITIALIZE_AG_PASS` is used to add pass implementations to the analysis group. First, an analysis group should be registered, with a human readable name provided for it. Unlike registration of passes, there is no command line argument to be specified for the Analysis Group Interface itself, because it is "abstract":

```
static RegisterAnalysisGroup<AliasAnalysis> A("Alias Analysis");
```

Once the analysis is registered, passes can declare that they are valid implementations of the interface by using the following code:

```
namespace {  
  // Declare that we implement the AliasAnalysis interface  
  INITIALIZE_AG_PASS(FancyAA, AliasAnalysis, "somefancyaa",  
    "A more complex alias analysis implementation",  
    false, // Is CFG Only?  
    true,  // Is Analysis?  
    false); // Is default Analysis Group implementation?  
}
```

This just shows a class `FancyAA` that uses the `INITIALIZE_AG_PASS` macro both to register and to "join" the `AliasAnalysis` analysis group. Every implementation of an analysis group should join using this macro.

```
namespace {  
  // Declare that we implement the AliasAnalysis interface  
  INITIALIZE_AG_PASS(BasicAA, AliasAnalysis, "basicaa",  
    "Basic Alias Analysis (default AA impl)",  
    false, // Is CFG Only?  
    true,  // Is Analysis?  
    true); // Is default Analysis Group implementation?  
}
```

Here we show how the default implementation is specified (using the final argument to the `INITIALIZE_AG_PASS` template). There must be exactly one default implementation available at all times for an Analysis Group to be used. Only default implementation can derive from `ImmutablePass`. Here we declare that the `BasicAliasAnalysis` pass is the default implementation for the interface.

4.23.4 Pass Statistics

The `Statistic` class is designed to be an easy way to expose various success metrics from passes. These statistics are printed at the end of a run, when the `-stats` command line option is enabled on the command line. See the [Statistics section](#) in the Programmer's Manual for details.

What PassManager does

The `PassManager` class takes a list of passes, ensures their *prerequisites* are set up correctly, and then schedules passes to run efficiently. All of the LLVM tools that run passes use the `PassManager` for execution of these passes.

The `PassManager` does two main things to try to reduce the execution time of a series of passes:

1. **Share analysis results.** The `PassManager` attempts to avoid recomputing analysis results as much as possible. This means keeping track of which analyses are available already, which analyses get invalidated, and which analyses are needed to be run for a pass. An important part of work is that the `PassManager` tracks the

exact lifetime of all analysis results, allowing it to *free memory* allocated to holding analysis results as soon as they are no longer needed.

2. **Pipeline the execution of passes on the program.** The `PassManager` attempts to get better cache and memory usage behavior out of a series of passes by pipelining the passes together. This means that, given a series of consecutive *FunctionPass*, it will execute all of the *FunctionPass* on the first function, then all of the *FunctionPasses* on the second function, etc... until the entire program has been run through the passes.

This improves the cache behavior of the compiler, because it is only touching the LLVM program representation for a single function at a time, instead of traversing the entire program. It reduces the memory consumption of compiler, because, for example, only one *DominatorSet* needs to be calculated at a time. This also makes it possible to implement some *interesting enhancements* in the future.

The effectiveness of the `PassManager` is influenced directly by how much information it has about the behaviors of the passes it is scheduling. For example, the "preserved" set is intentionally conservative in the face of an unimplemented *getAnalysisUsage* method. Not implementing when it should be implemented will have the effect of not allowing any analysis results to live across the execution of your pass.

The `PassManager` class exposes a `--debug-pass` command line options that is useful for debugging pass execution, seeing how things work, and diagnosing when you should be preserving more analyses than you currently are. (To get information about all of the variants of the `--debug-pass` option, just type `"opt -help-hidden"`).

By using the `--debug-pass=Structure` option, for example, we can see how our *Hello World* pass interacts with other passes. Lets try it out with the `gvn` and `licm` passes:

```
$ opt -load lib/LLVMHello.so -gvn -licm --debug-pass=Structure < hello.bc > /dev/null
ModulePass Manager
  FunctionPass Manager
    Dominator Tree Construction
    Basic Alias Analysis (stateless AA impl)
    Function Alias Analysis Results
    Memory Dependence Analysis
    Global Value Numbering
    Natural Loop Information
    Canonicalize natural loops
    Loop-Closed SSA Form Pass
    Basic Alias Analysis (stateless AA impl)
    Function Alias Analysis Results
    Scalar Evolution Analysis
    Loop Pass Manager
      Loop Invariant Code Motion
    Module Verifier
  Bitcode Writer
```

This output shows us when passes are constructed. Here we see that GVN uses dominator tree information to do its job. The LICM pass uses natural loop information, which uses dominator tree as well.

After the LICM pass, the module verifier runs (which is automatically added by the `opt` tool), which uses the dominator tree to check that the resultant LLVM code is well formed. Note that the dominator tree is computed once, and shared by three passes.

Lets see how this changes when we run the *Hello World* pass in between the two passes:

```
$ opt -load lib/LLVMHello.so -gvn -hello -licm --debug-pass=Structure < hello.bc > /
->dev/null
ModulePass Manager
  FunctionPass Manager
    Dominator Tree Construction
    Basic Alias Analysis (stateless AA impl)
```

(continues on next page)

(continued from previous page)

```

Function Alias Analysis Results
Memory Dependence Analysis
Global Value Numbering
Hello World Pass
Dominator Tree Construction
Natural Loop Information
Canonicalize natural loops
Loop-Closed SSA Form Pass
Basic Alias Analysis (stateless AA impl)
Function Alias Analysis Results
Scalar Evolution Analysis
Loop Pass Manager
    Loop Invariant Code Motion
Module Verifier
Bitcode Writer
Hello: __main
Hello: puts
Hello: main

```

Here we see that the *Hello World* pass has killed the Dominator Tree pass, even though it doesn't modify the code at all! To fix this, we need to add the following *getAnalysisUsage* method to our pass:

```

// We don't modify the program, so we preserve all analyses
void getAnalysisUsage(AnalysisUsage &AU) const override {
    AU.setPreservesAll();
}

```

Now when we run our pass, we get this output:

```

$ opt -load lib/LLVMHello.so -gvn -hello -licm --debug-pass=Structure < hello.bc > /
↳ dev/null
Pass Arguments: -gvn -hello -licm
ModulePass Manager
  FunctionPass Manager
    Dominator Tree Construction
    Basic Alias Analysis (stateless AA impl)
    Function Alias Analysis Results
    Memory Dependence Analysis
    Global Value Numbering
    Hello World Pass
    Natural Loop Information
    Canonicalize natural loops
    Loop-Closed SSA Form Pass
    Basic Alias Analysis (stateless AA impl)
    Function Alias Analysis Results
    Scalar Evolution Analysis
    Loop Pass Manager
      Loop Invariant Code Motion
    Module Verifier
  Bitcode Writer
Hello: __main
Hello: puts
Hello: main

```

Which shows that we don't accidentally invalidate dominator information anymore, and therefore do not have to compute it twice.

The `releaseMemory` method

```
virtual void releaseMemory();
```

The `PassManager` automatically determines when to compute analysis results, and how long to keep them around for. Because the lifetime of the pass object itself is effectively the entire duration of the compilation process, we need some way to free analysis results when they are no longer useful. The `releaseMemory` virtual method is the way to do this.

If you are writing an analysis or any other pass that retains a significant amount of state (for use by another pass which "requires" your pass and uses the `getAnalysis` method) you should implement `releaseMemory` to, well, release the memory allocated to maintain this internal state. This method is called after the `run*` method for the class, before the next call of `run*` in your pass.

4.23.5 Registering dynamically loaded passes

Size matters when constructing production quality tools using LLVM, both for the purposes of distribution, and for regulating the resident code size when running on the target system. Therefore, it becomes desirable to selectively use some passes, while omitting others and maintain the flexibility to change configurations later on. You want to be able to do all this, and, provide feedback to the user. This is where pass registration comes into play.

The fundamental mechanisms for pass registration are the `MachinePassRegistry` class and subclasses of `MachinePassRegistryNode`.

An instance of `MachinePassRegistry` is used to maintain a list of `MachinePassRegistryNode` objects. This instance maintains the list and communicates additions and deletions to the command line interface.

An instance of `MachinePassRegistryNode` subclass is used to maintain information provided about a particular pass. This information includes the command line name, the command help string and the address of the function used to create an instance of the pass. A global static constructor of one of these instances *registers* with a corresponding `MachinePassRegistry`, the static destructor *unregisters*. Thus a pass that is statically linked in the tool will be registered at start up. A dynamically loaded pass will register on load and unregister at unload.

Using existing registries

There are predefined registries to track instruction scheduling (`RegisterScheduler`) and register allocation (`RegisterRegAlloc`) machine passes. Here we will describe how to *register* a register allocator machine pass.

Implement your register allocator machine pass. In your register allocator `.cpp` file add the following include:

```
#include "llvm/CodeGen/RegAllocRegistry.h"
```

Also in your register allocator `.cpp` file, define a creator function in the form:

```
FunctionPass *createMyRegisterAllocator() {
    return new MyRegisterAllocator();
}
```

Note that the signature of this function should match the type of `RegisterRegAlloc::FunctionPassCtor`. In the same file add the "installing" declaration, in the form:

```
static RegisterRegAlloc myRegAlloc("myregalloc",
                                   "my register allocator help string",
                                   createMyRegisterAllocator);
```

Note the two spaces prior to the help string produces a tidy result on the `-help` query.

```
$ llc -help
...
-regalloc                - Register allocator to use (default=linearscan)
  =linearscan            - linear scan register allocator
  =local                 - local register allocator
  =simple                 - simple register allocator
  =myregalloc            - my register allocator help string
...
```

And that's it. The user is now free to use `-regalloc=myregalloc` as an option. Registering instruction schedulers is similar except use the `RegisterScheduler` class. Note that the `RegisterScheduler::FunctionPassCtor` is significantly different from `RegisterRegAlloc::FunctionPassCtor`.

To force the load/linking of your register allocator into the **llc/lli** tools, add your creator function's global declaration to `Passes.h` and add a "pseudo" call line to `llvm/CodeGen/LinkAllCodegenComponents.h`.

Creating new registries

The easiest way to get started is to clone one of the existing registries; we recommend `llvm/CodeGen/RegAllocRegistry.h`. The key things to modify are the class name and the `FunctionPassCtor` type.

Then you need to declare the registry. Example: if your pass registry is `RegisterMyPasses` then define:

```
MachinePassRegistry RegisterMyPasses::Registry;
```

And finally, declare the command line option for your passes. Example:

```
cl::opt<RegisterMyPasses::FunctionPassCtor, false,
      RegisterPassParser<RegisterMyPasses> >
MyPassOpt("mypass",
          cl::init(&createDefaultMyPass),
          cl::desc("my pass option help"));
```

Here the command option is "mypass", with `createDefaultMyPass` as the default creator.

Using GDB with dynamically loaded passes

Unfortunately, using GDB with dynamically loaded passes is not as easy as it should be. First of all, you can't set a breakpoint in a shared object that has not been loaded yet, and second of all there are problems with inlined functions in shared objects. Here are some suggestions to debugging your pass with GDB.

For sake of discussion, I'm going to assume that you are debugging a transformation invoked by **opt**, although nothing described here depends on that.

Setting a breakpoint in your pass

First thing you do is start gdb on the `opt` process:

```
$ gdb opt
GNU gdb 5.0
Copyright 2000 Free Software Foundation, Inc.
GDB is free software, covered by the GNU General Public License, and you are
welcome to change it and/or distribute copies of it under certain conditions.
Type "show copying" to see the conditions.
There is absolutely no warranty for GDB.  Type "show warranty" for details.
This GDB was configured as "sparc-sun-solaris2.6"...
(gdb)
```

Note that `opt` has a lot of debugging information in it, so it takes time to load. Be patient. Since we cannot set a breakpoint in our pass yet (the shared object isn't loaded until runtime), we must execute the process, and have it stop before it invokes our pass, but after it has loaded the shared object. The most foolproof way of doing this is to set a breakpoint in `PassManager::run` and then run the process with the arguments you want:

```
$ (gdb) break llvm::PassManager::run
Breakpoint 1 at 0x2413bc: file Pass.cpp, line 70.
(gdb) run test.bc -load $(LLVMTOP)/llvm/Debug+Asserts/lib/[libname].so -[passoption]
Starting program: opt test.bc -load $(LLVMTOP)/llvm/Debug+Asserts/lib/[libname].so -
↳[passoption]
Breakpoint 1, PassManager::run (this=0xffbef174, M=@0x70b298) at Pass.cpp:70
70      bool PassManager::run(Module &M) { return PM->run(M); }
(gdb)
```

Once the `opt` stops in the `PassManager::run` method you are now free to set breakpoints in your pass so that you can trace through execution or do other standard debugging stuff.

Miscellaneous Problems

Once you have the basics down, there are a couple of problems that GDB has, some with solutions, some without.

- Inline functions have bogus stack information. In general, GDB does a pretty good job getting stack traces and stepping through inline functions. When a pass is dynamically loaded however, it somehow completely loses this capability. The only solution I know of is to de-inline a function (move it from the body of a class to a `.cpp` file).
- Restarting the program breaks breakpoints. After following the information above, you have succeeded in getting some breakpoints planted in your pass. Next thing you know, you restart the program (i.e., you type "run" again), and you start getting errors about breakpoints being unsettable. The only way I have found to "fix" this problem is to delete the breakpoints that are already set in your pass, run the program, and re-set the breakpoints once execution stops in `PassManager::run`.

Hopefully these tips will help with common case debugging situations. If you'd like to contribute some tips of your own, just contact [Chris](#).

Future extensions planned

Although the LLVM Pass Infrastructure is very capable as it stands, and does some nifty stuff, there are things we'd like to add in the future. Here is where we are going:

Multithreaded LLVM

Multiple CPU machines are becoming more common and compilation can never be fast enough: obviously we should allow for a multithreaded compiler. Because of the semantics defined for passes above (specifically they cannot maintain state across invocations of their `run*` methods), a nice clean way to implement a multithreaded compiler would be for the `PassManager` class to create multiple instances of each pass object, and allow the separate instances to be hacking on different parts of the program at the same time.

This implementation would prevent each of the passes from having to implement multithreaded constructs, requiring only the LLVM core to have locking in a few places (for global resources). Although this is a simple extension, we simply haven't had time (or multiprocessor machines, thus a reason) to implement this. Despite that, we have kept the LLVM passes SMP ready, and you should too.

4.24 How To Use Attributes

- *Introduction*
- *Attribute*
- *AttributeList*
- *AttrBuilder*

4.24.1 Introduction

Attributes in LLVM have changed in some fundamental ways. It was necessary to do this to support expanding the attributes to encompass more than a handful of attributes --- e.g. command line options. The old way of handling attributes consisted of representing them as a bit mask of values. This bit mask was stored in a "list" structure that was reference counted. The advantage of this was that attributes could be manipulated with 'or's and 'and's. The disadvantage of this was that there was limited room for expansion, and virtually no support for attribute-value pairs other than alignment.

In the new scheme, an `Attribute` object represents a single attribute that's unique. You use the `Attribute::get` methods to create a new `Attribute` object. An attribute can be a single "enum" value (the enum being the `Attribute::AttrKind` enum), a string representing a target-dependent attribute, or an attribute-value pair. Some examples:

- Target-independent: `noinline`, `zext`
- Target-dependent: `"no-sse"`, `"thumb2"`
- Attribute-value pair: `"cpu" = "cortex-a8", align = 4`

Note: for an attribute value pair, we expect a target-dependent attribute to have a string for the value.

4.24.2 Attribute

An `Attribute` object is designed to be passed around by value.

Because attributes are no longer represented as a bit mask, you will need to convert any code which does treat them as a bit mask to use the new query methods on the `Attribute` class.

4.24.3 AttributeList

The `AttributeList` stores a collection of `Attribute` objects for each kind of object that may have an attribute associated with it: the function as a whole, the return type, or the function's parameters. A function's attributes are at index `AttributeList::FunctionIndex`; the return type's attributes are at index `AttributeList::ReturnIndex`; and the function's parameters' attributes are at indices 1, ..., n (where 'n' is the number of parameters). Most methods on the `AttributeList` class take an index parameter.

An `AttributeList` is also a unique and immutable object. You create an `AttributeList` through the `AttributeList::get` methods. You can add and remove attributes, which result in the creation of a new `AttributeList`.

An `AttributeList` object is designed to be passed around by value.

Note: It is advised that you do *not* use the `AttributeList` "introspection" methods (e.g. `Raw`, `getRawPointer`, etc.). These methods break encapsulation, and may be removed in a future release (i.e. LLVM 4.0).

4.24.4 AttrBuilder

Lastly, we have a "builder" class to help create the `AttributeList` object without having to create several different intermediate unique `AttributeList` objects. The `AttrBuilder` class allows you to add and remove attributes at will. The attributes won't be unique until you call the appropriate `AttributeList::get` method.

An `AttrBuilder` object is *not* designed to be passed around by value. It should be passed by reference.

Note: It is advised that you do *not* use the `AttrBuilder::addRawValue()` method or the `AttrBuilder(uint64_t Val)` constructor. These are for backwards compatibility and may be removed in a future release (i.e. LLVM 4.0).

And that's basically it! A lot of functionality is hidden behind these classes, but the interfaces are pretty straight forward.

4.25.1 Introduction

To support GPU programming, the NVPTX back-end supports a subset of LLVM IR along with a defined set of conventions used to represent GPU programming concepts. This document provides an overview of the general usage of the back-end, including a description of the conventions used and the set of accepted LLVM IR.

Note: This document assumes a basic familiarity with CUDA and the PTX assembly language. Information about the CUDA Driver API and the PTX assembly language can be found in the [CUDA documentation](#).

4.25.2 Conventions

Marking Functions as Kernels

In PTX, there are two types of functions: *device functions*, which are only callable by device code, and *kernel functions*, which are callable by host code. By default, the back-end will emit device functions. Metadata is used to declare a function as a kernel function. This metadata is attached to the `nvvm.annotations` named metadata object, and has the following format:

```
!0 = !{<function-ref>, metadata !"kernel", i32 1}
```

The first parameter is a reference to the kernel function. The following example shows a kernel function calling a device function in LLVM IR. The function `@my_kernel` is callable from host code, but `@my_fmadd` is not.

```
define float @my_fmadd(float %x, float %y, float %z) {
  %mul = fmul float %x, %y
  %add = fadd float %mul, %z
  ret float %add
}

define void @my_kernel(float* %ptr) {
  %val = load float, float* %ptr
  %ret = call float @my_fmadd(float %val, float %val, float %val)
  store float %ret, float* %ptr
  ret void
}

!nvvm.annotations = !{!1}
!1 = !{void (float*)* @my_kernel, !"kernel", i32 1}
```

When compiled, the PTX kernel functions are callable by host-side code.

Address Spaces

The NVPTX back-end uses the following address space mapping:

Address Space	Memory Space
0	Generic
1	Global
2	Internal Use
3	Shared
4	Constant
5	Local

Every global variable and pointer type is assigned to one of these address spaces, with 0 being the default address space. Intrinsic are provided which can be used to convert pointers between the generic and non-generic address spaces.

As an example, the following IR will define an array `@g` that resides in global device memory.

```
@g = internal addrspace(1) global [4 x i32] [ i32 0, i32 1, i32 2, i32 3 ]
```

LLVM IR functions can read and write to this array, and host-side code can copy data to it by name with the CUDA Driver API.

Note that since address space 0 is the generic space, it is illegal to have global variables in address space 0. Address space 0 is the default address space in LLVM, so the `addrspace (N)` annotation is *required* for global variables.

Triples

The NVPTX target uses the module triple to select between 32/64-bit code generation and the driver-compiler interface to use. The triple architecture can be one of `nvptx` (32-bit PTX) or `nvptx64` (64-bit PTX). The operating system should be one of `cuda` or `nvcl`, which determines the interface used by the generated code to communicate with the driver. Most users will want to use `cuda` as the operating system, which makes the generated PTX compatible with the CUDA Driver API.

Example: 32-bit PTX for CUDA Driver API: `nvptx-nvidia-cuda`

Example: 64-bit PTX for CUDA Driver API: `nvptx64-nvidia-cuda`

4.25.3 NVPTX Intrinsics

Address Space Conversion

'`llvm.nvvm.ptr.*.to.gen`' Intrinsics

Syntax:

These are overloaded intrinsics. You can use these on any pointer types.

```
declare i8* @llvm.nvvm.ptr.global.to.gen.p0i8.p1i8(i8 addrspace(1) *)
declare i8* @llvm.nvvm.ptr.shared.to.gen.p0i8.p3i8(i8 addrspace(3) *)
declare i8* @llvm.nvvm.ptr.constant.to.gen.p0i8.p4i8(i8 addrspace(4) *)
declare i8* @llvm.nvvm.ptr.local.to.gen.p0i8.p5i8(i8 addrspace(5) *)
```

Overview:

The '`llvm.nvvm.ptr.*.to.gen`' intrinsics convert a pointer in a non-generic address space to a generic address space pointer.

Semantics:

These intrinsics modify the pointer value to be a valid generic address space pointer.

'`llvm.nvvm.ptr.gen.to.*`' Intrinsics

Syntax:

These are overloaded intrinsics. You can use these on any pointer types.

```
declare i8 addrspace(1) * @llvm.nvvm.ptr.gen.to.global.p1i8.p0i8(i8*)
declare i8 addrspace(3) * @llvm.nvvm.ptr.gen.to.shared.p3i8.p0i8(i8*)
declare i8 addrspace(4) * @llvm.nvvm.ptr.gen.to.constant.p4i8.p0i8(i8*)
declare i8 addrspace(5) * @llvm.nvvm.ptr.gen.to.local.p5i8.p0i8(i8*)
```

Overview:

The `'llvm.nvvm.ptr.gen.to.*'` intrinsics convert a pointer in the generic address space to a pointer in the target address space. Note that these intrinsics are only useful if the address space of the target address space of the pointer is known. It is not legal to use address space conversion intrinsics to convert a pointer from one non-generic address space to another non-generic address space.

Semantics:

These intrinsics modify the pointer value to be a valid pointer in the target non-generic address space.

Reading PTX Special Registers

`'llvm.nvvm.read.ptx.sreg.*'`

Syntax:

```
declare i32 @llvm.nvvm.read.ptx.sreg.tid.x()
declare i32 @llvm.nvvm.read.ptx.sreg.tid.y()
declare i32 @llvm.nvvm.read.ptx.sreg.tid.z()
declare i32 @llvm.nvvm.read.ptx.sreg.ntid.x()
declare i32 @llvm.nvvm.read.ptx.sreg.ntid.y()
declare i32 @llvm.nvvm.read.ptx.sreg.ntid.z()
declare i32 @llvm.nvvm.read.ptx.sreg.ctaid.x()
declare i32 @llvm.nvvm.read.ptx.sreg.ctaid.y()
declare i32 @llvm.nvvm.read.ptx.sreg.ctaid.z()
declare i32 @llvm.nvvm.read.ptx.sreg.nctaid.x()
declare i32 @llvm.nvvm.read.ptx.sreg.nctaid.y()
declare i32 @llvm.nvvm.read.ptx.sreg.nctaid.z()
declare i32 @llvm.nvvm.read.ptx.sreg.warpSize()
```

Overview:

The `'@llvm.nvvm.read.ptx.sreg.*'` intrinsics provide access to the PTX special registers, in particular the kernel launch bounds. These registers map in the following way to CUDA builtins:

CUDA Builtin	PTX Special Register Intrinsic
<code>threadId</code>	<code>@llvm.nvvm.read.ptx.sreg.tid.*</code>
<code>blockIdx</code>	<code>@llvm.nvvm.read.ptx.sreg.ctaid.*</code>
<code>blockDim</code>	<code>@llvm.nvvm.read.ptx.sreg.ntid.*</code>
<code>gridDim</code>	<code>@llvm.nvvm.read.ptx.sreg.nctaid.*</code>

Barriers

`'llvm.nvvm.barrier0'`

Syntax:

```
declare void @llvm.nvvm.barrier0()
```

Overview:

The `'@llvm.nvvm.barrier0()'` intrinsic emits a PTX `bar.sync 0` instruction, equivalent to the `__syncthreads()` call in CUDA.

Other Intrinsics

For the full set of NVPTX intrinsics, please see the `include/llvm/IR/IntrinsicsNVVM.td` file in the LLVM source tree.

4.25.4 Linking with Libdevice

The CUDA Toolkit comes with an LLVM bitcode library called `libdevice` that implements many common mathematical functions. This library can be used as a high-performance math library for any compilers using the LLVM NVPTX target. The library can be found under `nvvm/libdevice/` in the CUDA Toolkit and there is a separate version for each compute architecture.

For a list of all math functions implemented in `libdevice`, see [libdevice Users Guide](#).

To accommodate various math-related compiler flags that can affect code generation of `libdevice` code, the library code depends on a special LLVM IR pass (`NVVMReflect`) to handle conditional compilation within LLVM IR. This pass looks for calls to the `@__nvvm_reflect` function and replaces them with constants based on the defined reflection parameters. Such conditional code often follows a pattern:

```
float my_function(float a) {
    if (__nvvm_reflect("FASTMATH"))
        return my_function_fast(a);
    else
        return my_function_precise(a);
}
```

The default value for all unspecified reflection parameters is zero.

The `NVVMReflect` pass should be executed early in the optimization pipeline, immediately after the link stage. The `internalize` pass is also recommended to remove unused math functions from the resulting PTX. For an input IR module `module.bc`, the following compilation flow is recommended:

1. Save list of external functions in `module.bc`
2. Link `module.bc` with `libdevice.compute_XX.YY.bc`
3. Internalize all functions not in list from (1)
4. Eliminate all unused internal functions
5. Run `NVVMReflect` pass

6. Run standard optimization pipeline

Note: `linkonce` and `linkonce_odr` linkage types are not suitable for the `libdevice` functions. It is possible to link two IR modules that have been linked against `libdevice` using different reflection variables.

Since the `NVVMReflect` pass replaces conditionals with constants, it will often leave behind dead code of the form:

```
entry:
  ..
  br i1 true, label %foo, label %bar
foo:
  ..
bar:
  ; Dead code
  ..
```

Therefore, it is recommended that `NVVMReflect` is executed early in the optimization pipeline before dead-code elimination.

The `NVPTX` `TargetMachine` knows how to schedule `NVVMReflect` at the beginning of your pass manager; just use the following code when setting up your pass manager:

```
std::unique_ptr<TargetMachine> TM = ...;
PassManagerBuilder PMBuilder(...);
if (TM)
  TM->adjustPassManager(PMBuilder);
```

Reflection Parameters

The `libdevice` library currently uses the following reflection parameters to control code generation:

Flag	Description
<code>__CUDA_FTZ=[0,1]</code>	Use optimized code paths that flush subnormals to zero

The value of this flag is determined by the "nvvm-reflect-ftz" module flag. The following sets the ftz flag to 1.

```
!llvm.module.flag = !{!0}
!0 = !{i32 4, !"nvvm-reflect-ftz", i32 1}
```

(`i32 4` indicates that the value set here overrides the value in another module we link with. See the *LangRef* <[LangRef.html#module-flags-metadata](#)> for details.)

4.25.5 Executing PTX

The most common way to execute PTX assembly on a GPU device is to use the CUDA Driver API. This API is a low-level interface to the GPU driver and allows for JIT compilation of PTX code to native GPU machine code.

Initializing the Driver API:

```
CUdevice device;
CUcontext context;

// Initialize the driver API
```

(continues on next page)

(continued from previous page)

```

cuInit(0);
// Get a handle to the first compute device
cuDeviceGet(&device, 0);
// Create a compute device context
cuCtxCreate(&context, 0, device);

```

JIT compiling a PTX string to a device binary:

```

CUmodule module;
CUfunction function;

// JIT compile a null-terminated PTX string
cuModuleLoadData(&module, (void*)PTXString);

// Get a handle to the "myfunction" kernel function
cuModuleGetFunction(&function, module, "myfunction");

```

For full examples of executing PTX assembly, please see the [CUDA Samples](#) distribution.

4.25.6 Common Issues

ptxas complains of undefined function: __nvvm_reflect

When linking with libdevice, the NVVMReflect pass must be used. See [Linking with Libdevice](#) for more information.

4.25.7 Tutorial: A Simple Compute Kernel

To start, let us take a look at a simple compute kernel written directly in LLVM IR. The kernel implements vector addition, where each thread computes one element of the output vector C from the input vectors A and B. To make this easier, we also assume that only a single CTA (thread block) will be launched, and that it will be one dimensional.

The Kernel

```

target datalayout = "e-p:64:64:64-i1:8:8-i8:8:8-i16:16:16-i32:32:32-i64:64:64-
↪f32:32:32-f64:64:64-v16:16:16-v32:32:32-v64:64:64-v128:128:128-n16:32:64"
target triple = "nvptx64-nvidia-cuda"

; Intrinsic to read X component of thread ID
declare i32 @llvm.nvvm.read.ptx.sreg.tid.x() readonly nounwind

define void @kernel(float addrspace(1)* %A,
                    float addrspace(1)* %B,
                    float addrspace(1)* %C) {
entry:
    ; What is my ID?
    %id = tail call i32 @llvm.nvvm.read.ptx.sreg.tid.x() readonly nounwind

    ; Compute pointers into A, B, and C
    %ptrA = getelementptr float, float addrspace(1)* %A, i32 %id
    %ptrB = getelementptr float, float addrspace(1)* %B, i32 %id
    %ptrC = getelementptr float, float addrspace(1)* %C, i32 %id

```

(continues on next page)

(continued from previous page)

```

; Read A, B
%valA = load float, float addrspace(1)* %ptrA, align 4
%valB = load float, float addrspace(1)* %ptrB, align 4

; Compute C = A + B
%valC = fadd float %valA, %valB

; Store back to C
store float %valC, float addrspace(1)* %ptrC, align 4

ret void
}

!nvvm.annotations = !{!0}
!0 = !{void (float addrspace(1)*,
            float addrspace(1)*,
            float addrspace(1)*)* @kernel, !"kernel", i32 1}

```

We can use the LLVM `llc` tool to directly run the NVPTX code generator:

```
# llc -mcpu=sm_20 kernel.ll -o kernel.ptx
```

Note: If you want to generate 32-bit code, change `p:64:64:64` to `p:32:32:32` in the module data layout string and use `nvptx-nvidia-cuda` as the target triple.

The output we get from `llc` (as of LLVM 3.4):

```

//
// Generated by LLVM NVPTX Back-End
//

.version 3.1
.target sm_20
.address_size 64

// .globl kernel
// @kernel

.visible .entry kernel(
  .param .u64 kernel_param_0,
  .param .u64 kernel_param_1,
  .param .u64 kernel_param_2
)
{
  .reg .f32    %f<4>;
  .reg .s32    %r<2>;
  .reg .s64    %r1<8>;

// %bb.0:
// %entry
  ld.param.u64    %r11, [kernel_param_0];
  mov.u32         %r1, %tid.x;
  mul.wide.s32    %r12, %r1, 4;
  add.s64         %r13, %r11, %r12;
  ld.param.u64    %r14, [kernel_param_1];
  add.s64         %r15, %r14, %r12;
  ld.param.u64    %r16, [kernel_param_2];

```

(continues on next page)

(continued from previous page)

```

add.s64      %r17, %r16, %r12;
ld.global.f32 %f1, [%r13];
ld.global.f32 %f2, [%r15];
add.f32      %f3, %f1, %f2;
st.global.f32 [%r17], %f3;
ret;
}

```

Dissecting the Kernel

Now let us dissect the LLVM IR that makes up this kernel.

Data Layout

The data layout string determines the size in bits of common data types, their ABI alignment, and their storage size. For NVPTX, you should use one of the following:

32-bit PTX:

```
target datalayout = "e-p:32:32:32-i1:8:8-i8:8:8-i16:16:16-i32:32:32-i64:64:64-
↪f32:32:32-f64:64:64-v16:16:16-v32:32:32-v64:64:64-v128:128:128-n16:32:64"
```

64-bit PTX:

```
target datalayout = "e-p:64:64:64-i1:8:8-i8:8:8-i16:16:16-i32:32:32-i64:64:64-
↪f32:32:32-f64:64:64-v16:16:16-v32:32:32-v64:64:64-v128:128:128-n16:32:64"
```

Target Intrinsic

In this example, we use the `@llvm.nvvm.read.ptx.sreg.tid.x` intrinsic to read the X component of the current thread's ID, which corresponds to a read of register `%tid.x` in PTX. The NVPTX back-end supports a large set of intrinsics. A short list is shown below; please see `include/llvm/IR/IntrinsicsNVVM.td` for the full list.

Intrinsic	CUDA Equivalent
<code>i32 @llvm.nvvm.read.ptx.sreg.tid.{x,y,z}</code>	<code>threadIdx.{x,y,z}</code>
<code>i32 @llvm.nvvm.read.ptx.sreg.ctaid.{x,y,z}</code>	<code>blockIdx.{x,y,z}</code>
<code>i32 @llvm.nvvm.read.ptx.sreg.ntid.{x,y,z}</code>	<code>blockDim.{x,y,z}</code>
<code>i32 @llvm.nvvm.read.ptx.sreg.nctaid.{x,y,z}</code>	<code>gridDim.{x,y,z}</code>
<code>void @llvm.nvvm.barrier0()</code>	<code>__syncthreads()</code>

Address Spaces

You may have noticed that all of the pointer types in the LLVM IR example had an explicit address space specifier. What is address space 1? NVIDIA GPU devices (generally) have four types of memory:

- Global: Large, off-chip memory
- Shared: Small, on-chip memory shared among all threads in a CTA
- Local: Per-thread, private memory
- Constant: Read-only memory shared across all threads

These different types of memory are represented in LLVM IR as address spaces. There is also a fifth address space used by the NVPTX code generator that corresponds to the "generic" address space. This address space can represent addresses in any other address space (with a few exceptions). This allows users to write IR functions that can load/store memory using the same instructions. Intrinsic are provided to convert pointers between the generic and non-generic address spaces.

See [Address Spaces](#) and [NVPTX Intrinsics](#) for more information.

Kernel Metadata

In PTX, a function can be either a *kernel* function (callable from the host program), or a *device* function (callable only from GPU code). You can think of *kernel* functions as entry-points in the GPU program. To mark an LLVM IR function as a *kernel* function, we make use of special LLVM metadata. The NVPTX back-end will look for a named metadata node called `nvvm.annotations`. This named metadata must contain a list of metadata that describe the IR. For our purposes, we need to declare a metadata node that assigns the "kernel" attribute to the LLVM IR function that should be emitted as a PTX *kernel* function. These metadata nodes take the form:

```
!{<function ref>, metadata !"kernel", i32 1}
```

For the previous example, we have:

```
!nvvm.annotations = !{!0}
!0 = !{void (float @addrspace(1) *,
           float @addrspace(1) *,
           float @addrspace(1) *) * @kernel, !"kernel", i32 1}
```

Here, we have a single metadata declaration in `nvvm.annotations`. This metadata annotates our `@kernel` function with the `kernel` attribute.

Running the Kernel

Generating PTX from LLVM IR is all well and good, but how do we execute it on a real GPU device? The CUDA Driver API provides a convenient mechanism for loading and JIT compiling PTX to a native GPU device, and launching a kernel. The API is similar to OpenCL. A simple example showing how to load and execute our vector addition code is shown below. Note that for brevity this code does not perform much error checking!

Note: You can also use the `ptxas` tool provided by the CUDA Toolkit to offline compile PTX to machine code (SASS) for a specific GPU architecture. Such binaries can be loaded by the CUDA Driver API in the same way as PTX. This can be useful for reducing startup time by precompiling the PTX kernels.

```
#include <iostream>
#include <fstream>
#include <cassert>
#include "cuda.h"

void checkCudaErrors(CUresult err) {
    assert(err == CUDA_SUCCESS);
}

/// main - Program entry point
int main(int argc, char **argv) {
    CUdevice    device;
    CUmodule    cudaModule;
    CUcontext    context;
    CUfunction    function;
    CULinkState linker;
    int          devCount;

    // CUDA initialization
    checkCudaErrors(cuInit(0));
    checkCudaErrors(cuDeviceGetCount(&devCount));
    checkCudaErrors(cuDeviceGet(&device, 0));

    char name[128];
    checkCudaErrors(cuDeviceGetName(name, 128, device));
    std::cout << "Using CUDA Device [0]: " << name << "\n";

    int devMajor, devMinor;
    checkCudaErrors(cuDeviceComputeCapability(&devMajor, &devMinor, device));
    std::cout << "Device Compute Capability: "
                << devMajor << "." << devMinor << "\n";
    if (devMajor < 2) {
        std::cerr << "ERROR: Device 0 is not SM 2.0 or greater\n";
        return 1;
    }

    std::ifstream t("kernel.ptx");
    if (!t.is_open()) {
        std::cerr << "kernel.ptx not found\n";
        return 1;
    }
    std::string str((std::istreambuf_iterator<char>(t),
                std::istreambuf_iterator<char>()));

    // Create driver context
    checkCudaErrors(cuCtxCreate(&context, 0, device));

    // Create module for object
    checkCudaErrors(cuModuleLoadDataEx(&cudaModule, str.c_str(), 0, 0, 0));

    // Get kernel function
    checkCudaErrors(cuModuleGetFunction(&function, cudaModule, "kernel"));

    // Device data
    CUdeviceptr devBufferA;
    CUdeviceptr devBufferB;
```

(continues on next page)

(continued from previous page)

```

CUdeviceptr devBufferC;

checkCudaErrors(cuMemAlloc(&devBufferA, sizeof(float)*16));
checkCudaErrors(cuMemAlloc(&devBufferB, sizeof(float)*16));
checkCudaErrors(cuMemAlloc(&devBufferC, sizeof(float)*16));

float* hostA = new float[16];
float* hostB = new float[16];
float* hostC = new float[16];

// Populate input
for (unsigned i = 0; i != 16; ++i) {
    hostA[i] = (float)i;
    hostB[i] = (float)(2*i);
    hostC[i] = 0.0f;
}

checkCudaErrors(cuMemcpyHtoD(devBufferA, &hostA[0], sizeof(float)*16));
checkCudaErrors(cuMemcpyHtoD(devBufferB, &hostB[0], sizeof(float)*16));

unsigned blockSizeX = 16;
unsigned blockSizeY = 1;
unsigned blockSizeZ = 1;
unsigned gridSizeX = 1;
unsigned gridSizeY = 1;
unsigned gridSizeZ = 1;

// Kernel parameters
void *KernelParams[] = { &devBufferA, &devBufferB, &devBufferC };

std::cout << "Launching kernel\n";

// Kernel launch
checkCudaErrors(cuLaunchKernel(function, gridSizeX, gridSizeY, gridSizeZ,
                                blockSizeX, blockSizeY, blockSizeZ,
                                0, NULL, KernelParams, NULL));

// Retrieve device data
checkCudaErrors(cuMemcpyDtoH(&hostC[0], devBufferC, sizeof(float)*16));

std::cout << "Results:\n";
for (unsigned i = 0; i != 16; ++i) {
    std::cout << hostA[i] << " + " << hostB[i] << " = " << hostC[i] << "\n";
}

// Clean up after ourselves
delete [] hostA;
delete [] hostB;
delete [] hostC;

// Clean-up
checkCudaErrors(cuMemFree(devBufferA));
checkCudaErrors(cuMemFree(devBufferB));
checkCudaErrors(cuMemFree(devBufferC));

```

(continues on next page)

(continued from previous page)

```

checkCudaErrors (cuModuleUnload (cudaModule));
checkCudaErrors (cuCtxDestroy (context));

return 0;
}

```

You will need to link with the CUDA driver and specify the path to `cuda.h`.

```
# clang++ sample.cpp -o sample -O2 -g -I/usr/local/cuda-5.5/include -lcuda
```

We don't need to specify a path to `libcuda.so` since this is installed in a system location by the driver, not the CUDA toolkit.

If everything goes as planned, you should see the following output when running the compiled program:

```

Using CUDA Device [0]: GeForce GTX 680
Device Compute Capability: 3.0
Launching kernel
Results:
0 + 0 = 0
1 + 2 = 3
2 + 4 = 6
3 + 6 = 9
4 + 8 = 12
5 + 10 = 15
6 + 12 = 18
7 + 14 = 21
8 + 16 = 24
9 + 18 = 27
10 + 20 = 30
11 + 22 = 33
12 + 24 = 36
13 + 26 = 39
14 + 28 = 42
15 + 30 = 45

```

Note: You will likely see a different device identifier based on your hardware

4.25.8 Tutorial: Linking with Libdevice

In this tutorial, we show a simple example of linking LLVM IR with the `libdevice` library. We will use the same kernel as the previous tutorial, except that we will compute $C = \text{pow}(A, B)$ instead of $C = A + B$. `Libdevice` provides an `__nv_powf` function that we will use.

```

target datalayout = "e-p:64:64:64-i1:8:8-i8:8:8-i16:16:16-i32:32:32-i64:64:64-
↪f32:32:32-f64:64:64-v16:16:16-v32:32:32-v64:64:64-v128:128:128-n16:32:64"
target triple = "nvptx64-nvidia-cuda"

; Intrinsic to read X component of thread ID
declare i32 @llvm.nvvm.read.ptx.sreg.tid.x() readonly nounwind
; libdevice function
declare float @__nv_powf(float, float)

```

(continues on next page)

(continued from previous page)

```

define void @kernel(float addrspace(1)* %A,
                    float addrspace(1)* %B,
                    float addrspace(1)* %C) {
entry:
  ; What is my ID?
  %id = tail call i32 @llvm.nvvm.read.ptx.sreg.tid.x() readnone nounwind

  ; Compute pointers into A, B, and C
  %ptrA = getelementptr float, float addrspace(1)* %A, i32 %id
  %ptrB = getelementptr float, float addrspace(1)* %B, i32 %id
  %ptrC = getelementptr float, float addrspace(1)* %C, i32 %id

  ; Read A, B
  %valA = load float, float addrspace(1)* %ptrA, align 4
  %valB = load float, float addrspace(1)* %ptrB, align 4

  ; Compute C = pow(A, B)
  %valC = call float @__nv_powf(float %valA, float %valB)

  ; Store back to C
  store float %valC, float addrspace(1)* %ptrC, align 4

  ret void
}

!nvvm.annotations = !{!0}
!0 = !{void (float addrspace(1)*,
             float addrspace(1)*,
             float addrspace(1)*)* @kernel, !"kernel", i32 1}

```

To compile this kernel, we perform the following steps:

1. Link with libdevice
2. Internalize all but the public kernel function
3. Run NVVMReflect and set `__CUDA_FTZ` to 0
4. Optimize the linked module
5. Codegen the module

These steps can be performed by the LLVM `llvm-link`, `opt`, and `llc` tools. In a complete compiler, these steps can also be performed entirely programmatically by setting up an appropriate pass configuration (see [Linking with Libdevice](#)).

```

# llvm-link t2.bc libdevice.compute_20.10.bc -o t2.linked.bc
# opt -internalize -internalize-public-api-list=kernel -nvvm-reflect-list=__CUDA_
↪FTZ=0 -nvvm-reflect -O3 t2.linked.bc -o t2.opt.bc
# llc -mcpu=sm_20 t2.opt.bc -o t2.ptx

```

Note: The `-nvvm-reflect-list=__CUDA_FTZ=0` is not strictly required, as any undefined variables will default to zero. It is shown here for evaluation purposes.

This gives us the following PTX (excerpt):

```

//
// Generated by LLVM NVPTX Back-End
//

4.26.1 Introduction

The AMDGPU backend provides ISA code generation for AMD GPUs, starting with the R600 family up until the current GCN families. It lives in the `lib/Target/AMDGPU` directory.

4.26.2 LLVM

Target Triples

Use the `clang -target <Architecture>-<Vendor>-<OS>-<Environment>` option to specify the target triple:

Table 31: AMDGPU Architectures

Architecture	Description
<code>r600</code>	AMD GPUs HD2XXX-HD6XXX for graphics and compute shaders.
<code>amdgcn</code>	AMD GPUs GCN GFX6 onwards for graphics and compute shaders.

Table 32: AMDGPU Vendors

Vendor	Description
<code>amd</code>	Can be used for all AMD GPU usage.
<code>mesa3d</code>	Can be used if the OS is <code>mesa3d</code> .

Table 33: AMDGPU Operating Systems

OS	Description
<code><empty></code>	Defaults to the <i>unknown</i> OS.
<code>amdhsa</code>	Compute kernels executed on HSA [HSA] compatible runtimes such as AMD's ROCm [AMD-ROCm].
<code>amdpal</code>	Graphic shaders and compute kernels executed on AMD PAL runtime.
<code>mesa3d</code>	Graphic shaders and compute kernels executed on Mesa 3D runtime.

Table 34: AMDGPU Environments

Environment	Description
<code><empty></code>	Default.

Processors

Use the `clang -mcpu <Processor>` option to specify the AMD GPU processor. The names from both the *Processor* and *Alternative Processor* can be used.

Table 35: AMDGPU Processors

Processor	Alternative Processor	Target Triple Architecture	dGPU/APU	Target Features Supported [Default]	ROCm Support	Example Products

Target Features

Target features control how code is generated to support certain processor specific features. Not all target features are supported by all processors. The runtime must ensure that the features supported by the device used to execute the code match the features enabled when generating the code. A mismatch of features may result in incorrect execution, or a reduction in performance.

The target features supported by each processor, and the default value used if not specified explicitly, is listed in [AMDGPU Processors](#).

Use the `clang -m[no-]<TargetFeature>` option to specify the AMD GPU target features.

For example:

-mxnack Enable the `xnack` feature.

-mno-xnack Disable the `xnack` feature.

Table 36: AMDGPU Target Features

Target Feature	Description
-m[no-]xnack	Enable/disable generating code that has memory clauses that are compatible with having XNACK replay enabled. This is used for demand paging and page migration. If XNACK replay is enabled in the device, then if a page fault occurs the code may execute incorrectly if the <code>xnack</code> feature is not enabled. Executing code that has the feature enabled on a device that does not have XNACK replay enabled will execute correctly, but may be less performant than code with the feature disabled.
-m[no-]sram-ecc	Enable/disable generating code that assumes SRAM ECC is enabled/disabled.
-m[no-]wavefrontsize64	Control the default wavefront size used when generating code for kernels. When disabled native wavefront size 32 is used, when enabled wavefront size 64 is used.
-m[no-]cumode	Control the default wavefront execution mode used when generating code for kernels. When disabled native WGP wavefront execution mode is used, when enabled CU wavefront execution mode is used (see Memory Model).

Address Spaces

The AMDGPU backend uses the following address space mappings.

The memory space names used in the table, aside from the region memory space, is from the OpenCL standard.

LLVM Address Space number is used throughout LLVM (for example, in LLVM IR).

Table 37: Address Space Mapping

LLVM Address Space	Memory Space
0	Generic (Flat)
1	Global
2	Region (GDS)
3	Local (group/LDS)
4	Constant
5	Private (Scratch)
6	Constant 32-bit
7	Buffer Fat Pointer (experimental)

The buffer fat pointer is an experimental address space that is currently unsupported in the backend. It exposes a non-integral pointer that is in future intended to support the modelling of 128-bit buffer descriptors + a 32-bit offset into the buffer descriptor (in total encapsulating a 160-bit 'pointer'), allowing us to use normal LLVM load/store/atomic operations to model the buffer descriptors used heavily in graphics workloads targeting the backend.

Memory Scopes

This section provides LLVM memory synchronization scopes supported by the AMDGPU backend memory model when the target triple OS is `amdhsa` (see [Memory Model](#) and [Target Triples](#)).

The memory model supported is based on the HSA memory model [HSA] which is based in turn on HRF-indirect with scope inclusion [HRF]. The happens-before relation is transitive over the synchronizes-with relation independent of scope, and synchronizes-with allows the memory scope instances to be inclusive (see table [AMDHSA LLVM Sync Scopes](#)).

This is different to the OpenCL [OpenCL] memory model which does not have scope inclusion and requires the memory scopes to exactly match. However, this is conservatively correct for OpenCL.

Table 38: AMDHSA LLVM Sync Scopes

LLVM Sync Scope	Description
<i>none</i>	<p>The default: <code>system</code>.</p> <p>Synchronizes with, and participates in modification and <code>seq_cst</code> total orderings with, other operations (except image operations) for all address spaces (except <code>private</code>, or <code>generic</code> that accesses <code>private</code>) provided the other operation's sync scope is:</p> <ul style="list-style-type: none"> • <code>system</code>. • <code>agent</code> and executed by a thread on the same agent. • <code>workgroup</code> and executed by a thread in the same workgroup. • <code>wavefront</code> and executed by a thread in the same wavefront.
<code>agent</code>	<p>Synchronizes with, and participates in modification and <code>seq_cst</code> total orderings with, other operations (except image operations) for all address spaces (except <code>private</code>, or <code>generic</code> that accesses <code>private</code>) provided the other operation's sync scope is:</p> <ul style="list-style-type: none"> • <code>system</code> or <code>agent</code> and executed by a thread on the same agent. • <code>workgroup</code> and executed by a thread in the same workgroup. • <code>wavefront</code> and executed by a thread in the same wavefront.
<code>workgroup</code>	<p>Synchronizes with, and participates in modification and <code>seq_cst</code> total orderings with, other operations (except image operations) for all address spaces (except <code>private</code>, or <code>generic</code> that accesses <code>private</code>) provided the other operation's sync scope is:</p> <ul style="list-style-type: none"> • <code>system</code>, <code>agent</code> or <code>workgroup</code> and executed by a thread in the same workgroup. • <code>wavefront</code> and executed by a thread in the same wavefront.
<code>wavefront</code>	<p>Synchronizes with, and participates in modification and <code>seq_cst</code> total orderings with, other operations (except image operations) for all address spaces (except <code>private</code>, or <code>generic</code> that accesses <code>private</code>) provided the other operation's sync scope is:</p> <ul style="list-style-type: none"> • <code>system</code>, <code>agent</code>, <code>workgroup</code> or <code>wavefront</code> and executed by a thread in the same wavefront.
<code>singlethread</code>	<p>Only synchronizes with, and participates in modification and <code>seq_cst</code> total orderings with, other operations (except image operations) running in the same thread for all address spaces (for example, in signal handlers).</p>
<code>one-as</code>	<p>Same as <code>system</code> but only synchronizes with other operations within the same address space.</p>
<code>agent-one-as</code>	<p>Same as <code>agent</code> but only synchronizes with other</p>

AMDGPU Intrinsics

The AMDGPU backend implements the following LLVM IR intrinsics.

This section is WIP.

AMDGPU Attributes

The AMDGPU backend supports the following LLVM IR attributes.

Table 39: AMDGPU LLVM IR Attributes

LLVM Attribute	Description
"amdgpu-flat-work-group-size"="min,max"	Specify the minimum and maximum flat work group sizes that will be specified when the kernel is dispatched. Generated by the <code>amdgpu_flat_work_group_size</code> CLANG attribute [CLANG-ATTR] .
"amdgpu-implicitarg-num-bytes"="n"	Number of kernel argument bytes to add to the kernel argument block size for the implicit arguments. This varies by OS and language (for OpenCL see <i>OpenCL kernel implicit arguments appended for AMDHSA OS</i>).
"amdgpu-num-sgpr"="n"	Specifies the number of SGPRs to use. Generated by the <code>amdgpu_num_sgpr</code> CLANG attribute [CLANG-ATTR] .
"amdgpu-num-vgpr"="n"	Specifies the number of VGPRs to use. Generated by the <code>amdgpu_num_vgpr</code> CLANG attribute [CLANG-ATTR] .
"amdgpu-waves-per-eu"="m,n"	Specify the minimum and maximum number of waves per execution unit. Generated by the <code>amdgpu_waves_per_eu</code> CLANG attribute [CLANG-ATTR] .
"amdgpu-ieee" true/false.	Specify whether the function expects the IEEE field of the mode register to be set on entry. Overrides the default for the calling convention.
"amdgpu-dx10-clamp" true/false.	Specify whether the function expects the DX10_CLAMP field of the mode register to be set on entry. Overrides the default for the calling convention.

4.26.3 Code Object

The AMDGPU backend generates a standard ELF [\[ELF\]](#) relocatable code object that can be linked by `lld` to produce a standard ELF shared code object which can be loaded and executed on an AMDGPU target.

Header

The AMDGPU backend uses the following ELF header:

Table 40: AMDGPU ELF Header

Field	Value
<code>e_ident[EI_CLASS]</code>	ELFCLASS64
<code>e_ident[EI_DATA]</code>	ELFDATA2LSB
<code>e_ident[EI_OSABI]</code>	<ul style="list-style-type: none"> • <code>ELFOSABI_NONE</code> • <code>ELFOSABI_AMDGPU_HSA</code> • <code>ELFOSABI_AMDGPU_PAL</code> • <code>ELFOSABI_AMDGPU_MESA3D</code>
<code>e_ident[EI_ABIVERSION]</code>	<ul style="list-style-type: none"> • <code>ELFABIVERSION_AMDGPU_HSA</code> • <code>ELFABIVERSION_AMDGPU_PAL</code> • <code>ELFABIVERSION_AMDGPU_MESA3D</code>
<code>e_type</code>	<ul style="list-style-type: none"> • <code>ET_REL</code> • <code>ET_DYN</code>
<code>e_machine</code>	EM_AMDGPU
<code>e_entry</code>	0
<code>e_flags</code>	See AMDGPU ELF Header <code>e_flags</code>

Table 41: AMDGPU ELF Header Enumeration Values

Name	Value
EM_AMDGPU	224
ELFOSABI_NONE	0
ELFOSABI_AMDGPU_HSA	64
ELFOSABI_AMDGPU_PAL	65
ELFOSABI_AMDGPU_MESA3D	66
ELFABIVERSION_AMDGPU_HSA	1
ELFABIVERSION_AMDGPU_PAL	0
ELFABIVERSION_AMDGPU_MESA3D	0

`e_ident[EI_CLASS]` The ELF class is:

- `ELFCLASS32` for r600 architecture.
- `ELFCLASS64` for amdgc architecture which only supports 64 bit applications.

`e_ident[EI_DATA]` All AMDGPU targets use `ELFDATA2LSB` for little-endian byte ordering.

`e_ident[EI_OSABI]` One of the following AMD GPU architecture specific OS ABIs (see [AMDGPU Operating Systems](#)):

- `ELFOSABI_NONE` for *unknown* OS.
- `ELFOSABI_AMDGPU_HSA` for amdhsa OS.
- `ELFOSABI_AMDGPU_PAL` for amdpal OS.
- `ELFOSABI_AMDGPU_MESA3D` for mesa3D OS.

`e_ident[EI_ABIVERSION]` The ABI version of the AMD GPU architecture specific OS ABI to which the code object conforms:

- `ELFABI_VERSION_AMDGPU_HSA` is used to specify the version of AMD HSA runtime ABI.
- `ELFABI_VERSION_AMDGPU_PAL` is used to specify the version of AMD PAL runtime ABI.
- `ELFABI_VERSION_AMDGPU_MESA3D` is used to specify the version of AMD MESA 3D runtime ABI.

e_type Can be one of the following values:

ET_REL The type produced by the AMD GPU backend compiler as it is relocatable code object.

ET_DYN The type produced by the linker as it is a shared code object.

The AMD HSA runtime loader requires a `ET_DYN` code object.

e_machine The value `EM_AMDGPU` is used for the machine for all processors supported by the `r600` and `amdgc`n architectures (see [AMDGPU Processors](#)). The specific processor is specified in the `EF_AMDGPU_MACH` bit field of the `e_flags` (see [AMDGPU ELF Header e_flags](#)).

e_entry The entry point is 0 as the entry points for individual kernels must be selected in order to invoke them through AQL packets.

e_flags The AMDGPU backend uses the following ELF header flags:

Table 42: AMDGPU ELF Header `e_flags`

Name	Value	Description
AMDGPU Processor Flag		See AMDGPU Processors .
<code>EF_AMDGPU_MACH_MASK</code>	<code>0x000000ff</code>	AMDGPU processor selection mask for <code>EF_AMDGPU_MACH_XXX</code> values defined in AMDGPU EF_AMDGPU_MACH Values .
<code>EF_AMDGPU_MACH_XNACK</code>	<code>0x00000100</code>	Indicates if the <code>xnack</code> target feature is enabled for all code contained in the code object. If the processor does not support the <code>xnack</code> target feature then must be 0. See Target Features .
<code>EF_AMDGPU_MACH_SRAM_ECC</code>	<code>0x00000200</code>	Indicates if the <code>sram-ecc</code> target feature is enabled for all code contained in the code object. If the processor does not support the <code>sram-ecc</code> target feature then must be 0. See Target Features .

Sections

An AMDGPU target ELF code object has the standard ELF sections which include:

Table 44: AMDGPU ELF Sections

Name	Type	Attributes
.bss	SHT_NOBITS	SHF_ALLOC + SHF_WRITE
.data	SHT_PROGBITS	SHF_ALLOC + SHF_WRITE
.debug_*	SHT_PROGBITS	<i>none</i>
.dynamic	SHT_DYNAMIC	SHF_ALLOC
.dynstr	SHT_PROGBITS	SHF_ALLOC
.dynsym	SHT_PROGBITS	SHF_ALLOC
.got	SHT_PROGBITS	SHF_ALLOC + SHF_WRITE
.hash	SHT_HASH	SHF_ALLOC
.note	SHT_NOTE	<i>none</i>
.relaname	SHT_RELA	<i>none</i>
.rela.dyn	SHT_RELA	<i>none</i>
.rodata	SHT_PROGBITS	SHF_ALLOC
.shstrtab	SHT_STRTAB	<i>none</i>
.strtab	SHT_STRTAB	<i>none</i>
.symtab	SHT_SYMTAB	<i>none</i>
.text	SHT_PROGBITS	SHF_ALLOC + SHF_EXECINSTR

These sections have their standard meanings (see [ELF]) and are only generated if needed.

- .debug*** The standard DWARF sections. See [DWARF](#) for information on the DWARF produced by the AMDGPU backend.
- .dynamic, .dynstr, .dynsym, .hash** The standard sections used by a dynamic loader.
- .note** See [Note Records](#) for the note records supported by the AMDGPU backend.
- .relaname, .rela.dyn** For relocatable code objects, *name* is the name of the section that the relocation records apply. For example, `.rela.text` is the section name for relocation records associated with the `.text` section.
- For linked shared code objects, `.rela.dyn` contains all the relocation records from each of the relocatable code object's `.relaname` sections.
- See [Relocation Records](#) for the relocation records supported by the AMDGPU backend.
- .text** The executable machine code for the kernels and functions they call. Generated as position independent code. See [Code Conventions](#) for information on conventions used in the isa generation.

Note Records

The AMDGPU backend code object contains ELF note records in the `.note` section. The set of generated notes and their semantics depend on the code object version; see [Code Object V2 Note Records \(-mattr=-code-object-v3\)](#) and [Code Object V3 Note Records \(-mattr=+code-object-v3\)](#).

As required by ELFCLASS32 and ELFCLASS64, minimal zero byte padding must be generated after the `name` field to ensure the `desc` field is 4 byte aligned. In addition, minimal zero byte padding must be generated to ensure the `desc` field size is a multiple of 4 bytes. The `sh_addralign` field of the `.note` section must be at least 4 to indicate at least 8 byte alignment.

Code Object V2 Note Records (-mattr=-code-object-v3)

Warning: Code Object V2 is not the default code object version emitted by this version of LLVM. For a description of the notes generated with the default configuration (Code Object V3) see [Code Object V3 Note Records \(-mattr=+code-object-v3\)](#).

The AMDGPU backend code object uses the following ELF note record in the `.note` section when compiling for Code Object V2 (-mattr=-code-object-v3).

Additional note records may be present, but any which are not documented here are deprecated and should not be used.

Table 45: AMDGPU Code Object V2 ELF Note Records

Name	Type	Description
"AMD"	NT_AMD_AMDGPU_HSA_METADATA	<metadata null terminated string>

Table 46: AMDGPU Code Object V2 ELF Note Record Enumeration Values

Name	Value
<i>reserved</i>	0-9
NT_AMD_AMDGPU_HSA_METADATA	10
<i>reserved</i>	11

NT_AMD_AMDGPU_HSA_METADATA Specifies extensible metadata associated with the code objects executed on HSA [HSA] compatible runtimes such as AMD's ROCm [AMD-ROCm]. It is required when the target triple OS is amdhsa (see *Target Triples*). See *Code Object V2 Metadata (-mattr=-code-object-v3)* for the syntax of the code object metadata string.

Code Object V3 Note Records (-mattr+=code-object-v3)

The AMDGPU backend code object uses the following ELF note record in the `.note` section when compiling for Code Object V3 (-mattr+=code-object-v3).

Additional note records may be present, but any which are not documented here are deprecated and should not be used.

Table 47: AMDGPU Code Object V3 ELF Note Records

Name	Type	Description
"AMDGPU"	NT_AMDGPU_METADATA	Metadata in Message Pack [MsgPack] binary format.

Table 48: AMDGPU Code Object V3 ELF Note Record Enumeration Values

Name	Value
<i>reserved</i>	0-31
NT_AMDGPU_METADATA	32

NT_AMDGPU_METADATA Specifies extensible metadata associated with an AMDGPU code object. It is encoded as a map in the Message Pack [MsgPack] binary data format. See *Code Object V3 Metadata (-mattr+=code-object-v3)* for the map keys defined for the amdhsa OS.

Symbols

Symbols include the following:

Table 49: AMDGPU ELF Symbols

Name	Type	Section	Description
<i>link-name</i>	STT_OBJECT	<ul style="list-style-type: none"> <code>.data</code> <code>.rodata</code> <code>.bss</code> 	Global variable
<i>link-name</i> .kd	STT_OBJECT	<ul style="list-style-type: none"> <code>.rodata</code> 	Kernel descriptor
<i>link-name</i>	STT_FUNC	<ul style="list-style-type: none"> <code>.text</code> 	Kernel entry point
<i>link-name</i>	STT_OBJECT	<ul style="list-style-type: none"> SHN_AMDGPU_LDS 	Global variable in LDS

Global variable Global variables both used and defined by the compilation unit.

If the symbol is defined in the compilation unit then it is allocated in the appropriate section according to if it has initialized data or is readonly.

If the symbol is external then its section is `STN_UNDEF` and the loader will resolve relocations using the definition provided by another code object or explicitly defined by the runtime.

If the symbol resides in local/group memory (LDS) then its section is the special processor-specific section name `SHN_AMDGPU_LDS`, and the `st_value` field describes alignment requirements as it does for common symbols.

Kernel descriptor Every HSA kernel has an associated kernel descriptor. It is the address of the kernel descriptor that is used in the AQL dispatch packet used to invoke the kernel, not the kernel entry point. The layout of the HSA kernel descriptor is defined in *Kernel Descriptor*.

Kernel entry point Every HSA kernel also has a symbol for its machine code entry point.

Relocation Records

AMDGPU backend generates `Elf64_Rela` relocation records. Supported relocatable fields are:

word32 This specifies a 32-bit field occupying 4 bytes with arbitrary byte alignment. These values use the same byte order as other word values in the AMD GPU architecture.

word64 This specifies a 64-bit field occupying 8 bytes with arbitrary byte alignment. These values use the same byte order as other word values in the AMD GPU architecture.

Following notations are used for specifying relocation calculations:

A Represents the addend used to compute the value of the relocatable field.

G Represents the offset into the global offset table at which the relocation entry's symbol will reside during execution.

GOT Represents the address of the global offset table.

P Represents the place (section offset for `et_rel` or address for `et_dyn`) of the storage unit being relocated (computed using `r_offset`).

S Represents the value of the symbol whose index resides in the relocation entry. Relocations not using this must specify a symbol index of `STN_UNDEF`.

B Represents the base address of a loaded executable or shared object which is the difference between the ELF address and the actual load address. Relocations using this are only valid in executable or shared objects.

The following relocation types are supported:

Table 50: AMDGPU ELF Relocation Records

Relocation Type	Kind	Value	Field	Calculation
R_AMDGPU_NONE		0	<i>none</i>	<i>none</i>
R_AMDGPU_ABS32_LO	Static, Dy- namic	1	word32	$(S + A) \& 0xFFFFFFFF$
R_AMDGPU_ABS32_HI	Static, Dy- namic	2	word32	$(S + A) \gg 32$
R_AMDGPU_ABS64	Static, Dy- namic	3	word64	$S + A$
R_AMDGPU_REL32	Static	4	word32	$S + A - P$
R_AMDGPU_REL64	Static	5	word64	$S + A - P$
R_AMDGPU_ABS32	Static, Dy- namic	6	word32	$S + A$
R_AMDGPU_GOTPCREL	Static	7	word32	$G + GOT + A - P$
R_AMDGPU_GOTPCREL32_LO	Static	8	word32	$(G + GOT + A - P) \& 0xFFFFFFFF$
R_AMDGPU_GOTPCREL32_HI	Static	9	word32	$(G + GOT + A - P) \gg 32$
R_AMDGPU_REL32_LO	Static	10	word32	$(S + A - P) \& 0xFFFFFFFF$
R_AMDGPU_REL32_HI	Static	11	word32	$(S + A - P) \gg 32$
<i>reserved</i>		12		
R_AMDGPU_RELATIVE64	Dynamic	13	word64	$B + A$

R_AMDGPU_ABS32_LO and R_AMDGPU_ABS32_HI are only supported by the mesa3d OS, which does not support R_AMDGPU_ABS64.

There is no current OS loader support for 32 bit programs and so R_AMDGPU_ABS32 is not used.

DWARF

Standard DWARF [DWARF] Version 5 sections can be generated. These contain information that maps the code object executable code and data to the source language constructs. It can be used by tools such as debuggers and profilers.

Address Space Mapping

The following address space mapping is used:

Table 51: AMDGPU DWARF Address Space Mapping

DWARF Address Space	Memory Space
1	Private (Scratch)
2	Local (group/LDS)
<i>omitted</i>	Global
<i>omitted</i>	Constant
<i>omitted</i>	Generic (Flat)
<i>not supported</i>	Region (GDS)

See [Address Spaces](#) for information on the memory space terminology used in the table.

An `address_class` attribute is generated on pointer type DIEs to specify the DWARF address space of the value of the pointer when it is in the *private* or *local* address space. Otherwise the attribute is omitted.

An `XDEREF` operation is generated in location list expressions for variables that are allocated in the *private* and *local* address space. Otherwise no `XDEREF` is omitted.

Register Mapping

This section is WIP.

Source Text

Source text for online-compiled programs (e.g. those compiled by the OpenCL runtime) may be embedded into the DWARF v5 line table using the `clang -gembed-source` option, described in table [AMDGPU Debug Options](#).

For example:

-gembed-source Enable the embedded source DWARF v5 extension.

-gno-embed-source Disable the embedded source DWARF v5 extension.

Table 52: AMDGPU Debug Options

Debug Flag	Description
-g[no-embed-source]	Enable/disable embedding source text in DWARF debug sections. Useful for environments where source cannot be written to disk, such as when performing online compilation.

This option enables one extended content types in the DWARF v5 Line Number Program Header, which is used to encode embedded source.

Table 53: AMDGPU DWARF Line Number Program Header Extended Content Types

Content Type	Form
DW_LNCT_LLVM_source	DW_FORM_line_strp

The source field will contain the UTF-8 encoded, null-terminated source text with '\n' line endings. When the source field is present, consumers can use the embedded source instead of attempting to discover the source on disk. When the source field is absent, consumers can access the file to get the source text.

The above content type appears in the `file_name_entry_format` field of the line table prologue, and its corresponding value appear in the `file_names` field. The current encoding of the content type is documented in table [AMDGPU DWARF Line Number Program Header Extended Content Types Encoding](#)

Table 54: AMDGPU DWARF Line Number Program Header Extended Content Types Encoding

Content Type	Value
DW_LNCT_LLVM_source	0x2001

4.26.4 Code Conventions

This section provides code conventions used for each supported target triple OS (see [Target Triples](#)).

AMDHSA

This section provides code conventions used when the target triple OS is amdhisa (see [Target Triples](#)).

Code Object Target Identification

The AMDHSA OS uses the following syntax to specify the code object target as a single string:

```
<Architecture>-<Vendor>-<OS>-<Environment>-<Processor><Target  
Features>
```

Where:

- <Architecture>, <Vendor>, <OS> and <Environment> are the same as the *Target Triple* (see [Target Triples](#)).
- <Processor> is the same as the *Processor* (see [Processors](#)).
- <Target Features> is a list of the enabled *Target Features* (see [Target Features](#)), each prefixed by a plus, that apply to *Processor*. The list must be in the same order as listed in the table [AMDGPU Target Features](#). Note that *Target Features* must be included in the list if they are enabled even if that is the default for *Processor*.

For example:

```
"amdgcnc-amd-amdhisa--gfx902+xnack"
```

Code Object Metadata

The code object metadata specifies extensible metadata associated with the code objects executed on HSA [[HSA](#)] compatible runtimes such as AMD's ROCm [[AMD-ROCm](#)]. The encoding and semantics of this metadata depends on the code object version; see [Code Object V2 Metadata \(-mattr=-code-object-v3\)](#) and [Code Object V3 Metadata \(-mattr=+code-object-v3\)](#).

Code object metadata is specified in a note record (see [Note Records](#)) and is required when the target triple OS is amdhisa (see [Target Triples](#)). It must contain the minimum information necessary to support the ROCm kernel queries. For example, the segment sizes needed in a dispatch packet. In addition, a high level language runtime may require other information to be included. For example, the AMD OpenCL runtime records kernel argument information.

Code Object V2 Metadata (-mattr=-code-object-v3)

Warning: Code Object V2 is not the default code object version emitted by this version of LLVM. For a description of the metadata generated with the default configuration (Code Object V3) see [Code Object V3 Metadata \(-mattr=+code-object-v3\)](#).

Code object V2 metadata is specified by the NT_AMD_AMDGPU_METADATA note record (see [Code Object V2 Note Records \(-mattr=-code-object-v3\)](#)).

The metadata is specified as a YAML formatted string (see [[YAML](#)] and [YAML I/O](#)).

The metadata is represented as a single YAML document comprised of the mapping defined in table [AMDHSA Code Object V2 Metadata Map](#) and referenced tables.

For boolean values, the string values of `false` and `true` are used for false and true respectively.

Additional information can be added to the mappings. To avoid conflicts, any non-AMD key names should be prefixed by `"vendor-name."`.

Table 55: AMDHSA Code Object V2 Metadata Map

String Key	Value Type	Required?	Description
"Version"	sequence of 2 integers	Required	<ul style="list-style-type: none"> The first integer is the major version. Currently 1. The second integer is the minor version. Currently 0.
"Printf"	sequence of strings		<p>Each string is encoded information about a printf function call. The encoded information is organized as fields separated by colon (':'):</p> <pre>ID:N:S[0]:S[1]:. .. :S[N-1]:FormatString</pre> <p>where:</p> <p>ID A 32 bit integer as a unique id for each printf function call</p> <p>N A 32 bit integer equal to the number of arguments of printf function call minus 1</p> <p>S[i] (where i = 0, 1, ..., N-1) 32 bit integers for the size in bytes of the i-th FormatString argument of the printf function call</p> <p>FormatString The format string passed to the printf function call.</p>
"Kernels"	sequence of mapping	Required	Sequence of the mappings for each kernel in the code object. See AMDHSA Code Object V2 Kernel Metadata Map for the definition of the mapping.

Table 56: AMDHSA Code Object V2 Kernel Metadata Map

String Key	Value Type	Required?	Description
"Name"	string	Required	Source name of the kernel.
"SymbolName"	string	Required	Name of the kernel descriptor ELF symbol.
"Language"	string		Source language of the kernel. Values include: <ul style="list-style-type: none"> • "OpenCL C" • "OpenCL C++" • "HCC" • "OpenMP"
"LanguageVersion"	sequence of 2 integers		<ul style="list-style-type: none"> • The first integer is the major version. • The second integer is the minor version.
"Attrs"	mapping		Mapping of kernel attributes. See <i>AMDHSA Code Object V2 Kernel Attribute Metadata Map</i> for the mapping definition.
"Args"	sequence of mapping		Sequence of mappings of the kernel arguments. See <i>AMDHSA Code Object V2 Kernel Argument Metadata Map</i> for the definition of the mapping.
"CodeProps"	mapping		Mapping of properties related to the kernel code. See <i>AMDHSA Code Object V2 Kernel Code Properties Metadata Map</i> for the mapping definition.

Table 57: AMDHSA Code Object V2 Kernel Attribute Metadata Map

String Key	Value Type	Required?	Description
"Reqd-Work-Group-Size"	sequence of 3 integers		If not 0, 0, 0 then all values must be ≥ 1 and the dispatch work-group size X, Y, Z must correspond to the specified values. Defaults to 0, 0, 0. Corresponds to the OpenCL <code>reqd_work_group_size</code> attribute.
"Work-Group-Size-Hint"	sequence of 3 integers		The dispatch work-group size X, Y, Z is likely to be the specified values. Corresponds to the OpenCL <code>work_group_size_hint</code> attribute.
"Vec-Type-Hint"	string		The name of a scalar or vector type. Corresponds to the OpenCL <code>vec_type_hint</code> attribute.
"Run-time-Handle"	string		The external symbol name associated with a kernel. OpenCL runtime allocates a global buffer for the symbol and saves the kernel's address to it, which is used for device side enqueueing. Only available for device side enqueued kernels.

Table 58: AMDHSA Code Object V2 Kernel Argument Metadata Map

String Key	Value Type	Required?	Description
"Name"	string		Kernel argument name.
"TypeName"	string		Kernel argument type name.
"Size"	integer	Required	Kernel argument size in bytes.
"Align"	integer	Required	Kernel argument alignment in bytes. Must be a power of two.
"ValueKind"	string	Required	<p>Kernel argument kind that specifies how to set up the corresponding argument. Values include:</p> <p>"ByValue" The argument is copied directly into the kernarg.</p> <p>"GlobalBuffer" A global address space pointer to the buffer data is passed in the kernarg.</p> <p>"DynamicSharedPointer" A group address space pointer to dynamically allocated LDS is passed in the kernarg.</p> <p>"Sampler" A global address space pointer to a S# is passed in the kernarg.</p> <p>"Image" A global address space pointer to a T# is passed in the kernarg.</p> <p>"Pipe" A global address space pointer to an OpenCL pipe is passed in the kernarg.</p> <p>"Queue" A global address space pointer to an OpenCL device enqueue queue is passed in the kernarg.</p> <p>"HiddenGlobalOffsetX" The OpenCL grid dispatch global</p>

Table 59: AMDHSA Code Object V2 Kernel Code Properties Metadata Map

String Key	Value Type	Required?	Description
"KernargSegment-Size"	Integer	Required	The size in bytes of the kernarg segment that holds the values of the arguments to the kernel.
"GroupSegment-Fixed-Size"	Integer	Required	The amount of group segment memory required by a work-group in bytes. This does not include any dynamically allocated group segment memory that may be added when the kernel is dispatched.
"Private-Segment-Fixed-Size"	Integer	Required	The amount of fixed private address space memory required for a work-item in bytes. If the kernel uses a dynamic call stack then additional space must be added to this value for the call stack.
"KernargSegment-Align"	Integer	Required	The maximum byte alignment of arguments in the kernarg segment. Must be a power of 2.
"Wavefront-Size"	Integer	Required	Wavefront size. Must be a power of 2.
"NumSGPRs"	Integer	Required	Number of scalar registers used by a wavefront for GFX6-GFX10. This includes the special SGPRs for VCC, Flat Scratch (GFX7-GFX10) and XNACK (for GFX8-GFX10). It does not include the 16 SGPR added if a trap handler is enabled. It is not rounded up to the allocation granularity.
"NumVGPRs"	Integer	Required	Number of vector registers used by each work-item for GFX6-GFX10
"MaxFlat-Work-Group-Size"	Integer	Required	Maximum flat work-group size supported by the kernel in work-items. Must be ≥ 1 and consistent with ReqWorkGroupSize if not 0, 0, 0.
"NumSpilledSGPRs"	Integer		Number of stores from a scalar register to a register allocator created spill location.
"NumSpilled-VGPRs"	Integer		Number of stores from a vector register to a register allocator created spill location.

Code Object V3 Metadata (-mattr=+code-object-v3)

Code object V3 metadata is specified by the `NT_AMDGPU_METADATA` note record (see *Code Object V3 Note Records (-mattr=+code-object-v3)*).

The metadata is represented as Message Pack formatted binary data (see [MsgPack]). The top level is a Message Pack map that includes the keys defined in table *AMDHSA Code Object V3 Metadata Map* and referenced tables.

Additional information can be added to the maps. To avoid conflicts, any key names should be prefixed by "*vendor-name*." where *vendor-name* can be the name of the vendor and specific vendor tool that generates the information. The prefix is abbreviated to simply "." when it appears within a map that has been added by the same *vendor-name*.

Table 60: AMDHSA Code Object V3 Metadata Map

String Key	Value Type	Required?	Description
"amdhsa.version"	sequence of 2 integers	Required	<ul style="list-style-type: none"> The first integer is the major version. Currently 1. The second integer is the minor version. Currently 0.
"amdhsa.printf"	sequence of strings		<p>Each string is encoded information about a printf function call. The encoded information is organized as fields separated by colon (':'):</p> <pre>ID:N:S[0]:S[1]:. .. :S[N-1]:FormatString</pre> <p>where:</p> <p>ID A 32 bit integer as a unique id for each printf function call</p> <p>N A 32 bit integer equal to the number of arguments of printf function call minus 1</p> <p>S[i] (where i = 0, 1, ..., N-1) 32 bit integers for the size in bytes of the i-th FormatString argument of the printf function call</p> <p>FormatString The format string passed to the printf function call.</p>
"amdhsa.kernels"	sequence of map	Required	Sequence of the maps for each kernel in the code object. See AMDHSA Code Object V3 Kernel Metadata Map for the definition of the keys included in that map.

Table 61: AMDHSA Code Object V3 Kernel Metadata Map

String Key	Value Type	Required?	Description
".name"	string	Required	Source name of the kernel.
".symbol"	string	Required	Name of the kernel descriptor ELF symbol.
".language"	string		Source language of the kernel. Values include: <ul style="list-style-type: none">"OpenCL C""OpenCL C++""HCC""HIP""OpenMP""Assembler"
".language_version"	sequence of 2 integers		<ul style="list-style-type: none">The first integer is the major version.The second integer is the minor version.
".args"	sequence of map		Sequence of maps of the kernel arguments. See <i>AMDHSA Code Object V3 Kernel Argument Metadata Map</i> for the definition of the keys included in that map.
".reqd_workgroup_size"	sequence of 3 integers		If not 0, 0, 0 then all values must be >=1 and the dispatch workgroup size X, Y, Z must correspond to the specified values. Defaults to 0, 0, 0. Corresponds to the OpenCL reqd_work_group_size attribute.
".workgroup_size_hint"	sequence of 3 integers		The dispatch workgroup size X, Y, Z is likely to be the specified values. Corresponds to the OpenCL work_group_size_hint attribute.
".vec_type_hint"	string		The name of a scalar or vector type. Corresponds to the OpenCL vec_type_hint attribute.
4.26. User Guide for AMDGPU Backend			
".device_enqueue_symbol"	string		The external symbol name associated with a kernel. OpenCL run-time calls to enqueue kernel

Table 62: AMDHSA Code Object V3 Kernel Argument Metadata Map

String Key	Value Type	Required?	Description
".name"	string		Kernel argument name.
".type_name"	string		Kernel argument type name.
".size"	integer	Required	Kernel argument size in bytes.
".offset"	integer	Required	Kernel argument offset in bytes. The offset must be a multiple of the alignment required by the argument.
".value_kind"	string	Required	<p>Kernel argument kind that specifies how to set up the corresponding argument. Values include:</p> <p>"by_value" The argument is copied directly into the kernarg.</p> <p>"global_buffer" A global address space pointer to the buffer data is passed in the kernarg.</p> <p>"dynamic_shared_pointer" A group address space pointer to dynamically allocated LDS is passed in the kernarg.</p> <p>"sampler" A global address space pointer to a S# is passed in the kernarg.</p> <p>"image" A global address space pointer to a T# is passed in the kernarg.</p> <p>"pipe" A global address space pointer to an OpenCL pipe is passed in the kernarg.</p> <p>"queue" A global address space pointer to an OpenCL device queue is passed in the kernarg.</p> <p>"hidden_global_offset_x"</p>

Kernel Dispatch

The HSA architected queuing language (AQL) defines a user space memory interface that can be used to control the dispatch of kernels, in an agent independent way. An agent can have zero or more AQL queues created for it using the ROCm runtime, in which AQL packets (all of which are 64 bytes) can be placed. See the *HSA Platform System Architecture Specification* [HSA] for the AQL queue mechanics and packet layouts.

The packet processor of a kernel agent is responsible for detecting and dispatching HSA kernels from the AQL queues associated with it. For AMD GPUs the packet processor is implemented by the hardware command processor (CP), asynchronous dispatch controller (ADC) and shader processor input controller (SPI).

The ROCm runtime can be used to allocate an AQL queue object. It uses the kernel mode driver to initialize and register the AQL queue with CP.

To dispatch a kernel the following actions are performed. This can occur in the CPU host program, or from an HSA kernel executing on a GPU.

1. A pointer to an AQL queue for the kernel agent on which the kernel is to be executed is obtained.
2. A pointer to the kernel descriptor (see *Kernel Descriptor*) of the kernel to execute is obtained. It must be for a kernel that is contained in a code object that that was loaded by the ROCm runtime on the kernel agent with which the AQL queue is associated.
3. Space is allocated for the kernel arguments using the ROCm runtime allocator for a memory region with the kernarg property for the kernel agent that will execute the kernel. It must be at least 16 byte aligned.
4. Kernel argument values are assigned to the kernel argument memory allocation. The layout is defined in the *HSA Programmer's Language Reference* [HSA]. For AMDGPU the kernel execution directly accesses the kernel argument memory in the same way constant memory is accessed. (Note that the HSA specification allows an implementation to copy the kernel argument contents to another location that is accessed by the kernel.)
5. An AQL kernel dispatch packet is created on the AQL queue. The ROCm runtime api uses 64 bit atomic operations to reserve space in the AQL queue for the packet. The packet must be set up, and the final write must use an atomic store release to set the packet kind to ensure the packet contents are visible to the kernel agent. AQL defines a doorbell signal mechanism to notify the kernel agent that the AQL queue has been updated. These rules, and the layout of the AQL queue and kernel dispatch packet is defined in the *HSA System Architecture Specification* [HSA].
6. A kernel dispatch packet includes information about the actual dispatch, such as grid and work-group size, together with information from the code object about the kernel, such as segment sizes. The ROCm runtime queries on the kernel symbol can be used to obtain the code object values which are recorded in the *Code Object Metadata*.
7. CP executes micro-code and is responsible for detecting and setting up the GPU to execute the wavefronts of a kernel dispatch.
8. CP ensures that when the a wavefront starts executing the kernel machine code, the scalar general purpose registers (SGPR) and vector general purpose registers (VGPR) are set up as required by the machine code. The required setup is defined in the *Kernel Descriptor*. The initial register state is defined in *Initial Kernel Execution State*.
9. The prolog of the kernel machine code (see *Kernel Prolog*) sets up the machine state as necessary before continuing executing the machine code that corresponds to the kernel.
10. When the kernel dispatch has completed execution, CP signals the completion signal specified in the kernel dispatch packet if not 0.

Memory Spaces

The memory space properties are:

Table 63: AMDHSA Memory Spaces

Memory Space Name	HSA Segment Name	Hardware Name	Address Size	NULL Value
Private	private	scratch	32	0x00000000
Local	group	LDS	32	0xFFFFFFFF
Global	global	global	64	0x0000000000000000
Constant	constant	<i>same as global</i>	64	0x0000000000000000
Generic	flat	flat	64	0x0000000000000000
Region	N/A	GDS	32	<i>not implemented for AMDHSA</i>

The global and constant memory spaces both use global virtual addresses, which are the same virtual address space used by the CPU. However, some virtual addresses may only be accessible to the CPU, some only accessible by the GPU, and some by both.

Using the constant memory space indicates that the data will not change during the execution of the kernel. This allows scalar read instructions to be used. The vector and scalar L1 caches are invalidated of volatile data before each kernel dispatch execution to allow constant memory to change values between kernel dispatches.

The local memory space uses the hardware Local Data Store (LDS) which is automatically allocated when the hardware creates work-groups of wavefronts, and freed when all the wavefronts of a work-group have terminated. The data store (DS) instructions can be used to access it.

The private memory space uses the hardware scratch memory support. If the kernel uses scratch, then the hardware allocates memory that is accessed using wavefront lane dword (4 byte) interleaving. The mapping used from private address to physical address is:

$$\text{wavefront-scratch-base} + (\text{private-address} * \text{wavefront-size} * 4) + (\text{wavefront-lane-id} * 4)$$

There are different ways that the wavefront scratch base address is determined by a wavefront (see [Initial Kernel Execution State](#)). This memory can be accessed in an interleaved manner using buffer instruction with the scratch buffer descriptor and per wavefront scratch offset, by the scratch instructions, or by flat instructions. If each lane of a wavefront accesses the same private address, the interleaving results in adjacent dwords being accessed and hence requires fewer cache lines to be fetched. Multi-dword access is not supported except by flat and scratch instructions in GFX9-GFX10.

The generic address space uses the hardware flat address support available in GFX7-GFX10. This uses two fixed ranges of virtual addresses (the private and local apertures), that are outside the range of addressable global memory, to map from a flat address to a private or local address.

FLAT instructions can take a flat address and access global, private (scratch) and group (LDS) memory depending in if the address is within one of the aperture ranges. Flat access to scratch requires hardware aperture setup and setup in the kernel prologue (see [Flat Scratch](#)). Flat access to LDS requires hardware aperture setup and M0 (GFX7-GFX8) register setup (see [M0](#)).

To convert between a segment address and a flat address the base address of the apertures address can be used. For GFX7-GFX8 these are available in the [HSA AQL Queue](#) the address of which can be obtained with Queue Ptr SGPR (see [Initial Kernel Execution State](#)). For GFX9-GFX10 the aperture base addresses are directly available as inline constant registers SRC_SHARED_BASE/LIMIT and SRC_PRIVATE_BASE/LIMIT. In 64 bit address mode the aperture sizes are 2^{32} bytes and the base is aligned to 2^{32} which makes it easier to convert from flat to segment or segment to flat.

Image and Samplers

Image and sample handles created by the ROCm runtime are 64 bit addresses of a hardware 32 byte V# and 48 byte S# object respectively. In order to support the HSA `query_sampler` operations two extra dwords are used to store the HSA BRIG enumeration values for the queries that are not trivially deducible from the S# representation.

HSA Signals

HSA signal handles created by the ROCm runtime are 64 bit addresses of a structure allocated in memory accessible from both the CPU and GPU. The structure is defined by the ROCm runtime and subject to change between releases (see [\[AMD-ROCm-github\]](#)).

HSA AQL Queue

The HSA AQL queue structure is defined by the ROCm runtime and subject to change between releases (see [\[AMD-ROCm-github\]](#)). For some processors it contains fields needed to implement certain language features such as the flat address aperture bases. It also contains fields used by CP such as managing the allocation of scratch memory.

Kernel Descriptor

A kernel descriptor consists of the information needed by CP to initiate the execution of a kernel, including the entry point address of the machine code that implements the kernel.

Kernel Descriptor for GFX6-GFX10

CP microcode requires the Kernel descriptor to be allocated on 64 byte alignment.

Table 64: Kernel Descriptor for GFX6-GFX10

Bits	Size	Field Name	Description
31:0	4 bytes	GROUP_SEGMENT_FIXED_SIZE	Amount of fixed local address space memory required for a work-group in bytes. This does not include any dynamically allocated local address space memory that may be added when the kernel is dispatched.
63:32	4 bytes	PRIVATE_SEGMENT_FIXED_SIZE	Amount of fixed private address space memory required for a work-item in bytes. If <code>is_dynamic_callstack</code> is 1 then additional space must be added to this value for the call stack.
127:64	8 bytes		Reserved, must be 0.
191:128	8 bytes	KERNEL_CODE_ENTRY_POINT_OFFSET	Byte offset (possibly negative) from base address of kernel descriptor to kernel's entry point instruction which must be 256 byte aligned.
351:272	20 bytes		Reserved, must be 0.
383:352	4 bytes	COMPUTE_PGM_RSRC3	GFX6-9 Reserved, must be 0. GFX10 Compute Shader (CS) program settings used by CP to set up <code>COMPUTE_PGM_RSRC3</code> configuration register. See compute_pgm_rsrc3 for GFX10 .
415:384	4 bytes	COMPUTE_PGM_RSRC1	Compute Shader (CS) program settings used by CP to set up <code>COMPUTE_PGM_RSRC1</code> configuration register. See compute_pgm_rsrc1 for GFX6-GFX10 .
447:416	4 bytes	COMPUTE_PGM_RSRC2	Compute Shader (CS) program settings used by CP to set up <code>COMPUTE_PGM_RSRC2</code> configuration register. See compute_pgm_rsrc2 for GFX6-GFX10 .

Table 65: compute_pgm_rsrc1 for GFX6-GFX10

Bits	Size	Field Name	Description
5:0	6 bits	GRANULATED_WORKITEM_VGPR_COUNT	<p>Number of VGPR register blocks used by each work-item; granularity is device specific:</p> <p>GFX6-GFX9</p> <ul style="list-style-type: none">• <code>vgprs_used</code> 0..256• <code>max(0, ceil(<code>vgprs_used</code> / 4) - 1)</code> <p>GFX10 (wavefront size 64)</p> <ul style="list-style-type: none">• <code>max_vgpr</code> 1..256• <code>max(0, ceil(<code>vgprs_used</code> / 4) - 1)</code> <p>GFX10 (wavefront size 32)</p> <ul style="list-style-type: none">• <code>max_vgpr</code> 1..256• <code>max(0, ceil(<code>vgprs_used</code> / 8) - 1)</code> <p>Where <code>vgprs_used</code> is defined as the highest VGPR number explicitly referenced plus one.</p> <p>Used by CP to set up <code>COMPUTE_PGM_RSRC1.VGPRS</code>.</p> <p>The <i>Assembler</i> calculates this automatically for the selected processor from values provided to the <code>.amdhsa_kernel</code> directive by the <code>.amdhsa_next_free_vgpr</code> nested directive (see <i>AMDHSA Kernel Assembler Directives</i>).</p>
9:6	4 bits	GRANULATED_WAVEFRONT_SGPR_COUNT	<p>Number of SGPR register blocks used by a wavefront; granularity is device specific:</p> <p>GFX6-GFX8</p> <ul style="list-style-type: none">• <code>sgprs_used</code> 0..112• <code>max(0, ceil(<code>sgprs_used</code> / 8) - 1)</code> <p>GFX9</p> <ul style="list-style-type: none">• <code>sgprs_used</code> 0..112
4.26.	User Guide for AMDGPU Backend		1489

Table 66: compute_pgm_rsrc2 for GFX6-GFX10

Bits	Size	Field Name	Description
0	1 bit	ENABLE_SGPR_PRIVATE_SEGMENT_WAVEFRONT_OFFSET	The SEGMENT setup of the SGPR wavefront scratch offset system register (see <i>Initial Kernel Execution State</i>). Used by CP to set up COMPUTE_PGM_RSRC2.SCRATCH_EN.
5:1	5 bits	USER_SGPR_COUNT	The total number of SGPR user data registers requested. This number must match the number of user data registers enabled. Used by CP to set up COMPUTE_PGM_RSRC2.USER_SGPR.
6	1 bit	ENABLE_TRAP_HANDLER	Must be 0. This bit represents COMPUTE_PGM_RSRC2.TRAP_PRESENT, which is set by the CP if the runtime has installed a trap handler.
7	1 bit	ENABLE_SGPR_WORKGROUP_ID_X	Enable the setup of the system SGPR register for the work-group id in the X dimension (see <i>Initial Kernel Execution State</i>). Used by CP to set up COMPUTE_PGM_RSRC2.TGID_X_EN.
8	1 bit	ENABLE_SGPR_WORKGROUP_ID_Y	Enable the setup of the system SGPR register for the work-group id in the Y dimension (see <i>Initial Kernel Execution State</i>). Used by CP to set up COMPUTE_PGM_RSRC2.TGID_Y_EN.
9	1 bit	ENABLE_SGPR_WORKGROUP_ID_Z	Enable the setup of the system SGPR register for the work-group id in the Z dimension (see <i>Initial Kernel Execution State</i>). Used by CP to set up COMPUTE_PGM_RSRC2.TGID_Z_EN.
10	1 bit	ENABLE_SGPR_WORKGROUP_ID_W	Enable the setup of the system SGPR register for work-group information (see <i>Initial Kernel Execution State</i>).

Table 67: compute_pgm_rsrc3 for GFX10

Bits	Size	Field Name	Description
3:0	4 bits	SHARED_VGPR_CNT	Number of shared VGPRs for wavefront size 64. Granularity 8. Value 0-120. compute_pgm_rsrc1.vgprs + shared_vgpr_cnt cannot exceed 64.
31:4	28 bits		Reserved, must be 0.
32	Total size 4 bytes.		

Table 68: Floating Point Rounding Mode Enumeration Values

Enumeration Name	Value	Description
FLOAT_ROUND_MODE_NEAR_EVEN	0	Round Ties To Even
FLOAT_ROUND_MODE_PLUS_INFINITY	1	Round Toward +infinity
FLOAT_ROUND_MODE_MINUS_INFINITY	2	Round Toward -infinity
FLOAT_ROUND_MODE_ZERO	3	Round Toward 0

Table 69: Floating Point Denorm Mode Enumeration Values

Enumeration Name	Value	Description
FLOAT_DENORM_MODE_FLUSH_SRC_DST	0	Flush Source and Destination Denorms
FLOAT_DENORM_MODE_FLUSH_DST	1	Flush Output Denorms
FLOAT_DENORM_MODE_FLUSH_SRC	2	Flush Source Denorms
FLOAT_DENORM_MODE_FLUSH_NONE	3	No Flush

Table 70: System VGPR Work-Item ID Enumeration Values

Enumeration Name	Value	Description
SYSTEM_VGPR_WORKITEM_ID_X	0	Set work-item X dimension ID.
SYSTEM_VGPR_WORKITEM_ID_X_Y	1	Set work-item X and Y dimensions ID.
SYSTEM_VGPR_WORKITEM_ID_X_Y_Z	2	Set work-item X, Y and Z dimensions ID.
SYSTEM_VGPR_WORKITEM_ID_UNDEFINED	3	Undefined.

Initial Kernel Execution State

This section defines the register state that will be set up by the packet processor prior to the start of execution of every wavefront. This is limited by the constraints of the hardware controllers of CP/ADC/SPI.

The order of the SGPR registers is defined, but the compiler can specify which ones are actually setup in the kernel descriptor using the `enable_sgpr_*` bit fields (see [Kernel Descriptor](#)). The register numbers used for enabled registers are dense starting at SGPR0: the first enabled register is SGPR0, the next enabled register is SGPR1 etc.; disabled registers do not have an SGPR number.

The initial SGPRs comprise up to 16 User SRGPs that are set by CP and apply to all wavefronts of the grid. It is possible to specify more than 16 User SGPRs using the `enable_sgpr_*` bit fields, in which case only the first 16 are actually initialized. These are then immediately followed by the System SGPRs that are set up by ADC/SPI and can have different values for each wavefront of the grid dispatch.

SGPR register initial state is defined in [SGPR Register Set Up Order](#).

Table 71: SGPR Register Set Up Order

SGPR Order	Name (kernel descriptor enable field)	Number of SGPRs	Description
First	Private Segment Buffer (enable_sgpr_private_segment_buffer)	4	V# that can be used, together with Scratch Wavefront Offset as an offset, to access the private memory space using a segment address. CP uses the value provided by the runtime.
then	Dispatch Ptr (enable_sgpr_dispatch_ptr)	2	64 bit address of AQL dispatch packet for kernel dispatch actually executing.
then	Queue Ptr (enable_sgpr_queue_ptr)	2	64 bit address of amd_queue_t object for AQL queue on which the dispatch packet was queued.
then	Kernarg Segment Ptr (enable_sgpr_kernarg_segment_ptr)	2	64 bit address of Kernarg segment. This is directly copied from the kernarg_address in the kernel dispatch packet. Having CP load it once avoids loading it at the beginning of every wavefront.
then	Dispatch Id (enable_sgpr_dispatch_id)	2	64 bit Dispatch ID of the dispatch packet being executed.
then	Flat Scratch Init (enable_sgpr_flat_scratch_init)	2	This is 2 SGPRs: GFX6 Not supported. GFX7-GFX8 The first SGPR is a 32 bit byte offset from SH_HIDDEN_PRIVATE_BASE_VIMID to per SPI base of memory for scratch for the queue executing the kernel dispatch. CP obtains this from the runtime. (The Scratch Segment Buffer base address is SH_HIDDEN_PRIVATE_BASE_VIMID plus this offset.) The value of Scratch Wavefront Offset must be added to this offset

The order of the VGPR registers is defined, but the compiler can specify which ones are actually setup in the kernel descriptor using the `enable_vgpr*` bit fields (see [Kernel Descriptor](#)). The register numbers used for enabled registers are dense starting at VGPR0: the first enabled register is VGPR0, the next enabled register is VGPR1 etc.; disabled registers do not have a VGPR number.

VGPR register initial state is defined in [VGPR Register Set Up Order](#).

Table 72: VGPR Register Set Up Order

VGPR Order	Name (kernel descriptor enable field)	Number of VGPRs	Description
First	Work-Item Id X (Always initialized)	1	32 bit work item id in X dimension of work-group for wavefront lane.
then	Work-Item Id Y (<code>enable_vgpr_workitem_id > 0</code>)	1	32 bit work item id in Y dimension of work-group for wavefront lane.
then	Work-Item Id Z (<code>enable_vgpr_workitem_id > 1</code>)	1	32 bit work item id in Z dimension of work-group for wavefront lane.

The setting of registers is done by GPU CP/ADC/SPI hardware as follows:

1. SGPRs before the Work-Group Ids are set by CP using the 16 User Data registers.
2. Work-group Id registers X, Y, Z are set by ADC which supports any combination including none.
3. Scratch Wavefront Offset is set by SPI in a per wavefront basis which is why its value cannot be included with the flat scratch init value which is per queue.
4. The VGPRs are set by SPI which only supports specifying either (X), (X, Y) or (X, Y, Z).

Flat Scratch register pair are adjacent SGPRs so they can be moved as a 64 bit value to the hardware required SGPRn-3 and SGPRn-4 respectively.

The global segment can be accessed either using buffer instructions (GFX6 which has V# 64 bit address support), flat instructions (GFX7-GFX10), or global instructions (GFX9-GFX10).

If buffer operations are used then the compiler can generate a V# with the following properties:

- base address of 0
- no swizzle
- ATC: 1 if IOMMU present (such as APU)
- ptr64: 1
- MTYPE set to support memory coherence that matches the runtime (such as CC for APU and NC for dGPU).

Kernel Prolog

M0

GFX6-GFX8 The M0 register must be initialized with a value at least the total LDS size if the kernel may access LDS via DS or flat operations. Total LDS size is available in dispatch packet. For M0, it is also possible to use maximum possible value of LDS for given target (0x7FFF for GFX6 and 0xFFFF for GFX7-GFX8).

GFX9-GFX10 The M0 register is not used for range checking LDS accesses and so does not need to be initialized in the prolog.

Flat Scratch

If the kernel may use flat operations to access scratch memory, the prolog code must set up `FLAT_SCRATCH` register pair (`FLAT_SCRATCH_LO/FLAT_SCRATCH_HI` which are in `SGPRn-4/SGPRn-3`). Initialization uses Flat Scratch Init and Scratch Wavefront Offset SGPR registers (see *Initial Kernel Execution State*):

GFX6 Flat scratch is not supported.

GFX7-GFX8

1. The low word of Flat Scratch Init is 32 bit byte offset from `SH_HIDDEN_PRIVATE_BASE_VIMID` to the base of scratch backing memory being managed by SPI for the queue executing the kernel dispatch. This is the same value used in the Scratch Segment Buffer V# base address. The prolog must add the value of Scratch Wavefront Offset to get the wavefront's byte scratch backing memory offset from `SH_HIDDEN_PRIVATE_BASE_VIMID`. Since `FLAT_SCRATCH_LO` is in units of 256 bytes, the offset must be right shifted by 8 before moving into `FLAT_SCRATCH_LO`.
2. The second word of Flat Scratch Init is 32 bit byte size of a single work-items scratch memory usage. This is directly loaded from the kernel dispatch packet Private Segment Byte Size and rounded up to a multiple of `DWORD`. Having CP load it once avoids loading it at the beginning of every wavefront. The prolog must move it to `FLAT_SCRATCH_LO` for use as `FLAT_SCRATCH_SIZE`.

GFX9-GFX10 The Flat Scratch Init is the 64 bit address of the base of scratch backing memory being managed by SPI for the queue executing the kernel dispatch. The prolog must add the value of Scratch Wavefront Offset and moved to the `FLAT_SCRATCH` pair for use as the flat scratch base in flat memory instructions.

Memory Model

This section describes the mapping of LLVM memory model onto AMDGPU machine code (see *Memory Model for Concurrent Operations*). *The implementation is WIP.*

The AMDGPU backend supports the memory synchronization scopes specified in *Memory Scopes*.

The code sequences used to implement the memory model are defined in table *AMDHSA Memory Model Code Sequences GFX6-GFX10*.

The sequences specify the order of instructions that a single thread must execute. The `s_waitcnt` and `buffer_wbinvl1_vol` are defined with respect to other memory instructions executed by the same thread. This allows them to be moved earlier or later which can allow them to be combined with other instances of the same instruction, or hoisted/sunk out of loops to improve performance. Only the instructions related to the memory model are given; additional `s_waitcnt` instructions are required to ensure registers are defined before being used. These may be able to be combined with the memory model `s_waitcnt` instructions as described above.

The AMDGPU backend supports the following memory models:

HSA Memory Model [HSA] The HSA memory model uses a single happens-before relation for all address spaces (see *Address Spaces*).

OpenCL Memory Model [OpenCL] The OpenCL memory model which has separate happens-before relations for the global and local address spaces. Only a fence specifying both global and local address space, and `seq_cst` instructions join the relationships. Since the LLVM `memfence` instruction does not allow an address space to be specified the OpenCL fence has to conservatively assume both local and global address space was specified. However, optimizations can often be done to eliminate the additional `s_waitcnt` instructions when there are no intervening memory instructions which access the corresponding address space. The code sequences in the table indicate what can be omitted for the OpenCL memory. The target triple environment is used to determine if the source language is OpenCL (see *OpenCL*).

`ds/flat_load/store/atomic` instructions to local memory are termed LDS operations.

`buffer/global/flat_load/store/atomic` instructions to global memory are termed vector memory operations.

For GFX6-GFX9:

- Each agent has multiple shader arrays (SA).
- Each SA has multiple compute units (CU).
- Each CU has multiple SIMDs that execute wavefronts.
- The wavefronts for a single work-group are executed in the same CU but may be executed by different SIMDs.
- Each CU has a single LDS memory shared by the wavefronts of the work-groups executing on it.
- All LDS operations of a CU are performed as wavefront wide operations in a global order and involve no caching. Completion is reported to a wavefront in execution order.
- The LDS memory has multiple request queues shared by the SIMDs of a CU. Therefore, the LDS operations performed by different wavefronts of a work-group can be reordered relative to each other, which can result in reordering the visibility of vector memory operations with respect to LDS operations of other wavefronts in the same work-group. A `s_waitcnt lgkmcnt(0)` is required to ensure synchronization between LDS operations and vector memory operations between wavefronts of a work-group, but not between operations performed by the same wavefront.
- The vector memory operations are performed as wavefront wide operations and completion is reported to a wavefront in execution order. The exception is that for GFX7-GFX9 `flat_load/store/atomic` instructions can report out of vector memory order if they access LDS memory, and out of LDS operation order if they access global memory.
- The vector memory operations access a single vector L1 cache shared by all SIMDs a CU. Therefore, no special action is required for coherence between the lanes of a single wavefront, or for coherence between wavefronts in the same work-group. A `buffer_wbinvl1_vol` is required for coherence between wavefronts executing in different work-groups as they may be executing on different CUs.
- The scalar memory operations access a scalar L1 cache shared by all wavefronts on a group of CUs. The scalar and vector L1 caches are not coherent. However, scalar operations are used in a restricted way so do not impact the memory model. See *Memory Spaces*.
- The vector and scalar memory operations use an L2 cache shared by all CUs on the same agent.
- The L2 cache has independent channels to service disjoint ranges of virtual addresses.
- Each CU has a separate request queue per channel. Therefore, the vector and scalar memory operations performed by wavefronts executing in different work-groups (which may be executing on different CUs) of an agent can be reordered relative to each other. A `s_waitcnt vmcnt(0)` is required to ensure synchronization between vector memory operations of different CUs. It ensures a previous vector memory operation has completed before executing a subsequent vector memory or LDS operation and so can be used to meet the requirements of acquire and release.
- The L2 cache can be kept coherent with other agents on some targets, or ranges of virtual addresses can be set up to bypass it to ensure system coherence.

For GFX10:

- Each agent has multiple shader arrays (SA).
- Each SA has multiple work-group processors (WGP).
- Each WGP has multiple compute units (CU).
- Each CU has multiple SIMDs that execute wavefronts.

- The wavefronts for a single work-group are executed in the same WGP. In CU wavefront execution mode the wavefronts may be executed by different SIMDs in the same CU. In WGP wavefront execution mode the wavefronts may be executed by different SIMDs in different CUs in the same WGP.
- Each WGP has a single LDS memory shared by the wavefronts of the work-groups executing on it.
- All LDS operations of a WGP are performed as wavefront wide operations in a global order and involve no caching. Completion is reported to a wavefront in execution order.
- The LDS memory has multiple request queues shared by the SIMDs of a WGP. Therefore, the LDS operations performed by different wavefronts of a work-group can be reordered relative to each other, which can result in reordering the visibility of vector memory operations with respect to LDS operations of other wavefronts in the same work-group. A `s_waitcnt lgkmcnt(0)` is required to ensure synchronization between LDS operations and vector memory operations between wavefronts of a work-group, but not between operations performed by the same wavefront.
- The vector memory operations are performed as wavefront wide operations. Completion of load/store/sample operations are reported to a wavefront in execution order of other load/store/sample operations performed by that wavefront.
- The vector memory operations access a vector L0 cache. There is a single L0 cache per CU. Each SIMD of a CU accesses the same L0 cache. Therefore, no special action is required for coherence between the lanes of a single wavefront. However, a `BUFFER_GLO_INV` is required for coherence between wavefronts executing in the same work-group as they may be executing on SIMDs of different CUs that access different L0s. A `BUFFER_GLO_INV` is also required for coherence between wavefronts executing in different work-groups as they may be executing on different WGPs.
- The scalar memory operations access a scalar L0 cache shared by all wavefronts on a WGP. The scalar and vector L0 caches are not coherent. However, scalar operations are used in a restricted way so do not impact the memory model. See *Memory Spaces*.
- The vector and scalar memory L0 caches use an L1 cache shared by all WGPs on the same SA. Therefore, no special action is required for coherence between the wavefronts of a single work-group. However, a `BUFFER_GL1_INV` is required for coherence between wavefronts executing in different work-groups as they may be executing on different SAs that access different L1s.
- The L1 caches have independent quadrants to service disjoint ranges of virtual addresses.
- Each L0 cache has a separate request queue per L1 quadrant. Therefore, the vector and scalar memory operations performed by different wavefronts, whether executing in the same or different work-groups (which may be executing on different CUs accessing different L0s), can be reordered relative to each other. A `s_waitcnt vmcnt(0) & vsnt(0)` is required to ensure synchronization between vector memory operations of different wavefronts. It ensures a previous vector memory operation has completed before executing a subsequent vector memory or LDS operation and so can be used to meet the requirements of acquire, release and sequential consistency.
- The L1 caches use an L2 cache shared by all SAs on the same agent.
- The L2 cache has independent channels to service disjoint ranges of virtual addresses.
- Each L1 quadrant of a single SA accesses a different L2 channel. Each L1 quadrant has a separate request queue per L2 channel. Therefore, the vector and scalar memory operations performed by wavefronts executing in different work-groups (which may be executing on different SAs) of an agent can be reordered relative to each other. A `s_waitcnt vmcnt(0) & vsnt(0)` is required to ensure synchronization between vector memory operations of different SAs. It ensures a previous vector memory operation has completed before executing a subsequent vector memory and so can be used to meet the requirements of acquire, release and sequential consistency.
- The L2 cache can be kept coherent with other agents on some targets, or ranges of virtual addresses can be set up to bypass it to ensure system coherence.

Private address space uses `buffer_load/store` using the scratch V# (GFX6-GFX8), or `scratch_load/store` (GFX9-GFX10). Since only a single thread is accessing the memory, atomic memory orderings are not meaningful and all accesses are treated as non-atomic.

Constant address space uses `buffer/global_load` instructions (or equivalent scalar memory instructions). Since the constant address space contents do not change during the execution of a kernel dispatch it is not legal to perform stores, and atomic memory orderings are not meaningful and all access are treated as non-atomic.

A memory synchronization scope wider than work-group is not meaningful for the group (LDS) address space and is treated as work-group.

The memory model does not support the region address space which is treated as non-atomic.

Acquire memory ordering is not meaningful on store atomic instructions and is treated as non-atomic.

Release memory ordering is not meaningful on load atomic instructions and is treated a non-atomic.

Acquire-release memory ordering is not meaningful on load or store atomic instructions and is treated as acquire and release respectively.

AMDGPU backend only uses scalar memory operations to access memory that is proven to not change during the execution of the kernel dispatch. This includes constant address space and global address space for program scope const variables. Therefore the kernel machine code does not have to maintain the scalar L1 cache to ensure it is coherent with the vector L1 cache. The scalar and vector L1 caches are invalidated between kernel dispatches by CP since constant address space data may change between kernel dispatch executions. See [Memory Spaces](#).

The one exception is if scalar writes are used to spill SGPR registers. In this case the AMDGPU backend ensures the memory location used to spill is never accessed by vector memory operations at the same time. If scalar writes are used then a `s_dcache_wb` is inserted before the `s_endpgm` and before a function return since the locations may be used for vector memory instructions by a future wavefront that uses the same scratch area, or a function call that creates a frame at the same address, respectively. There is no need for a `s_dcache_inv` as all scalar writes are write-before-read in the same thread.

For GFX6-GFX9, scratch backing memory (which is used for the private address space) is accessed with MTYPE NC_NV (non-coherent non-volatile). Since the private address space is only accessed by a single thread, and is always write-before-read, there is never a need to invalidate these entries from the L1 cache. Hence all cache invalidates are done as `*_vol` to only invalidate the volatile cache lines.

For GFX10, scratch backing memory (which is used for the private address space) is accessed with MTYPE NC (non-coherent). Since the private address space is only accessed by a single thread, and is always write-before-read, there is never a need to invalidate these entries from the L0 or L1 caches.

For GFX10, wavefronts are executed in native mode with in-order reporting of loads and sample instructions. In this mode `vmcnt` reports completion of load, atomic with return and sample instructions in order, and the `vsnt` reports the completion of store and atomic without return in order. See `MEM_ORDERED` field in [compute_pgm_rsrc1](#) for [GFX6-GFX10](#).

In GFX10, wavefronts can be executed in WGP or CU wavefront execution mode:

- In WGP wavefront execution mode the wavefronts of a work-group are executed on the SIMDs of both CUs of the WGP. Therefore, explicit management of the per CU L0 caches is required for work-group synchronization. Also accesses to L1 at work-group scope need to be explicitly ordered as the accesses from different CUs are not ordered.
- In CU wavefront execution mode the wavefronts of a work-group are executed on the SIMDs of a single CU of the WGP. Therefore, all global memory access by the work-group access the same L0 which in turn ensures L1 accesses are ordered and so do not require explicit management of the caches for work-group synchronization.

See `WGP_MODE` field in [compute_pgm_rsrc1](#) for [GFX6-GFX10](#) and [Target Features](#).

On dGPU the kernarg backing memory is accessed as UC (uncached) to avoid needing to invalidate the L2 cache. For GFX6-GFX9, this also causes it to be treated as non-volatile and so is not invalidated by `*_vol`. On APU it is

accessed as CC (cache coherent) and so the L2 cache will be coherent with the CPU and other agents.

The memory order also adds the single thread optimization constraints defined in table [AMDHSA Memory Model Single Thread Optimization Constraints GFX6-GFX10](#).

Table 74: AMDHSA Memory Model Single Thread Optimization Constraints GFX6-GFX10

LLVM Memory	Optimization Constraints
Ordering	
unordered	<i>none</i>
monotonic	<i>none</i>
acquire	<ul style="list-style-type: none"> • If a load atomic/atomicrmw then no following load/load atomic/store/ store atomic/atomicrmw/fence instruction can be moved before the acquire. • If a fence then same as load atomic, plus no preceding associated fence-paired-atomic can be moved after the fence.
release	<ul style="list-style-type: none"> • If a store atomic/atomicrmw then no preceding load/load atomic/store/ store atomic/atomicrmw/fence instruction can be moved after the release. • If a fence then same as store atomic, plus no following associated fence-paired-atomic can be moved before the fence.
acq_rel	Same constraints as both acquire and release.
seq_cst	<ul style="list-style-type: none"> • If a load atomic then same constraints as acquire, plus no preceding sequentially consistent load atomic/store atomic/atomicrmw/fence instruction can be moved after the seq_cst. • If a store atomic then the same constraints as release, plus no following sequentially consistent load atomic/store atomic/atomicrmw/fence instruction can be moved before the seq_cst. • If an atomicrmw/fence then same constraints as acq_rel.

Trap Handler ABI

For code objects generated by AMDGPU backend for HSA [HSA] compatible runtimes (such as ROCm [AMD-ROCm]), the runtime installs a trap handler that supports the `s_trap` instruction with the following usage:

Table 75: AMDGPU Trap Handler for AMDHSA OS

Usage	Code Sequence	Trap Handler Inputs	Description
reserved	s_trap 0x00		Reserved by hardware.
debugtrap(arg)	s_trap 0x01	SGPR0-1: queue_ptr VGPR0: arg	Reserved for HSA debugtrap intrinsic (not implemented).
llvm.trap	s_trap 0x02	SGPR0-1: queue_ptr	Causes dispatch to be terminated and its associated queue put into the error state.
llvm.debugtrap	s_trap 0x03		<ul style="list-style-type: none"> • If debugger not installed then behaves as a no-operation. The trap handler is entered and immediately returns to continue execution of the wavefront. • If the debugger is installed, causes the debug trap to be reported by the debugger and the wavefront is put in the halt state until resumed by the debugger.
reserved	s_trap 0x04		Reserved.
reserved	s_trap 0x05		Reserved.
reserved	s_trap 0x06		Reserved.
debugger breakpoint	s_trap 0x07		Reserved for debugger breakpoints.
reserved	s_trap 0x08		Reserved.
reserved	s_trap 0xfe		Reserved.
reserved	s_trap 0xff		Reserved.

AMDPAL

This section provides code conventions used when the target triple OS is `amdpal` (see *Target Triples*) for passing runtime parameters from the application/runtime to each invocation of a hardware shader. These parameters include both generic, application-controlled parameters called *user data* as well as system-generated parameters that are a product of the draw or dispatch execution.

User Data

Each hardware stage has a set of 32-bit *user data registers* which can be written from a command buffer and then loaded into SGPRs when waves are launched via a subsequent dispatch or draw operation. This is the way most arguments are passed from the application/runtime to a hardware shader.

Compute User Data

Compute shader user data mappings are simpler than graphics shaders, and have a fixed mapping.

Note that there are always 10 available *user data entries* in registers - entries beyond that limit must be fetched from memory (via the spill table pointer) by the shader.

Table 76: PAL Compute Shader User Data Registers

User Register	Description
0	Global Internal Table (32-bit pointer)
1	Per-Shader Internal Table (32-bit pointer)
2 - 11	Application-Controlled User Data (10 32-bit values)
12	Spill Table (32-bit pointer)
13 - 14	Thread Group Count (64-bit pointer)
15	GDS Range

Graphics User Data

Graphics pipelines support a much more flexible user data mapping:

Table 77: PAL Graphics Shader User Data Registers

User Register	Description
0	Global Internal Table (32-bit pointer)
•	Per-Shader Internal Table (32-bit pointer)
• 1-15	Application Controlled User Data (1-15 Contiguous 32-bit Values in Registers)
•	Spill Table (32-bit pointer)
•	Draw Index (First Stage Only)
•	Vertex Offset (First Stage Only)
•	Instance Offset (First Stage Only)

The placement of the global internal table remains fixed in the first *user data SGPR register*. Otherwise all parameters are optional, and can be mapped to any desired *user data SGPR register*, with the following restrictions:

- Draw Index, Vertex Offset, and Instance Offset can only be used by the first active hardware stage in a graphics pipeline (i.e. where the API vertex shader runs).
- Application-controlled user data must be mapped into a contiguous range of user data registers.
- The application-controlled user data range supports compaction remapping, so only *entries* that are actually consumed by the shader must be assigned to corresponding *registers*. Note that in order to support an efficient runtime implementation, the remapping must pack *registers* in the same order as *entries*, with unused *entries* removed.

Global Internal Table

The global internal table is a table of *shader resource descriptors* (SRDs) that define how certain engine-wide, runtime-managed resources should be accessed from a shader. The majority of these resources have HW-defined formats, and it is up to the compiler to write/read data as required by the target hardware.

The following table illustrates the required format:

Table 78: PAL Global Internal Table

Offset	Description
0-3	Graphics Scratch SRD
4-7	Compute Scratch SRD
8-11	ES/GS Ring Output SRD
12-15	ES/GS Ring Input SRD
16-19	GS/VS Ring Output #0
20-23	GS/VS Ring Output #1
24-27	GS/VS Ring Output #2
28-31	GS/VS Ring Output #3
32-35	GS/VS Ring Input SRD
36-39	Tessellation Factor Buffer SRD
40-43	Off-Chip LDS Buffer SRD
44-47	Off-Chip Param Cache Buffer SRD
48-51	Sample Position Buffer SRD
52	vaRange::ShadowDescriptorTable High Bits

The pointer to the global internal table passed to the shader as user data is a 32-bit pointer. The top 32 bits should be assumed to be the same as the top 32 bits of the pipeline, so the shader may use the program counter's top 32 bits.

Unspecified OS

This section provides code conventions used when the target triple OS is empty (see [Target Triples](#)).

Trap Handler ABI

For code objects generated by AMDGPU backend for non-amdhsa OS, the runtime does not install a trap handler. The `llvm.trap` and `llvm.debugtrap` instructions are handled as follows:

Table 79: AMDGPU Trap Handler for Non-AMDHSA OS

Usage	Code Sequence	Description
<code>llvm.trap</code>	<code>s_endpgm</code>	Causes wavefront to be terminated.
<code>llvm.debugtrap</code>	<i>none</i>	Compiler warning given that there is no trap handler installed.

4.26.5 Source Languages

OpenCL

When the language is OpenCL the following differences occur:

1. The OpenCL memory model is used (see [Memory Model](#)).
2. The AMDGPU backend appends additional arguments to the kernel's explicit arguments for the AMDHSA OS (see [OpenCL kernel implicit arguments appended for AMDHSA OS](#)).
3. Additional metadata is generated (see [Code Object Metadata](#)).

Table 80: OpenCL kernel implicit arguments appended for AMDHSA OS

Position	Byte Size	Byte Alignment	Description
1	8	8	OpenCL Global Offset X
2	8	8	OpenCL Global Offset Y
3	8	8	OpenCL Global Offset Z
4	8	8	OpenCL address of printf buffer
5	8	8	OpenCL address of virtual queue used by <code>enqueue_kernel</code> .
6	8	8	OpenCL address of <code>AqlWrap</code> struct used by <code>enqueue_kernel</code> .
7	8	8	Pointer argument used for Multi-gird synchronization.

HCC

When the language is HCC the following differences occur:

1. The HSA memory model is used (see [Memory Model](#)).

Assembler

AMDGPU backend has LLVM-MC based assembler which is currently in development. It supports AMDGCN GFX6-GFX10.

This section describes general syntax for instructions and operands.

<code>v_cmpx_u_f64</code>	<code>vcc,</code>	<code>src0,</code>	<code>vsrc1</code>

attr

Interpolation attribute and channel:

Syntax	Description
attr{0..32}.x	Attribute 0..32 with <i>x</i> channel.
attr{0..32}.y	Attribute 0..32 with <i>y</i> channel.
attr{0..32}.z	Attribute 0..32 with <i>z</i> channel.
attr{0..32}.w	Attribute 0..32 with <i>w</i> channel.

Examples:

```
v_interp_p1_f32 v1, v0, attr0.x
v_interp_p1_f32 v1, v0, attr32.w
```

imm16

An *integer_number*. The value is truncated to 16 bits.

imm32

An *integer_number*. The value is truncated to 32 bits.

imm32

An *integer_number* or a *floating-point_number*. The value is converted to *f32* as described [here](#).

hwreg

Bits of a hardware register being accessed.

The bits of this operand have the following meaning:

Bits	Description
5:0	Register <i>id</i> .
10:6	First bit <i>offset</i> (0..31).
15:11	<i>Size</i> in bits (1..32).

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below.

Syntax	Description
hwreg({0..63})	All bits of a register indicated by its <i>id</i> .
hwreg(<name>)	All bits of a register indicated by its <i>name</i> .
hwreg({0..63}, {0..31}, {1..32})	Register bits indicated by register <i>id</i> , first bit <i>offset</i> and <i>size</i> .
hwreg(<name>, {0..31}, {1..32})	Register bits indicated by register <i>name</i> , first bit <i>offset</i> and <i>size</i> .

Register *id*, *offset* and *size* must be specified as positive *integer numbers*.

Defined register *names* include:

Name	Description
HW_REG_MODE	Shader writeable mode bits.
HW_REG_STATUS	Shader read-only status.
HW_REG_TRAPSTS	Trap status.
HW_REG_HW_ID	Id of wave, simd, compute unit, etc.
HW_REG_GPR_ALLOC	Per-wave SGPR and VGPR allocation.
HW_REG_LDS_ALLOC	Per-wave LDS allocation.
HW_REG_IB_STS	Counters of outstanding instructions.

Examples:

```
s_getreg_b32 s2, 0x6
s_getreg_b32 s2, hwreg(15)
s_getreg_b32 s2, hwreg(51, 1, 31)
s_getreg_b32 s2, hwreg(HW_REG_LDS_ALLOC, 0, 1)
```

label

A branch target which is a 16-bit signed integer treated as a PC-relative dword offset.

This operand may be specified as:

- An *integer_number*. The number is truncated to 16 bits.
- An *absolute_expression* which must start with an *integer_number*. The value of the expression is truncated to 16 bits.
- A *symbol* (for example, a label). The value is handled as a 16-bit PC-relative dword offset to be resolved by a linker.

Examples:

```
offset = 30
s_branch loop_end
s_branch 2 + offset
s_branch 32
loop_end:
```

msg

A 16-bit message code. The bits of this operand have the following meaning:

Bits	Description
3:0	Message <i>type</i> .
6:4	Optional <i>operation</i> .
9:7	Optional <i>parameters</i> .
15:10	Unused.

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below:

Syntax	Description
<code>sendmsg(<type>)</code>	A message identified by its <i>type</i> .
<code>sendmsg(<type>, <op>)</code>	A message identified by its <i>type</i> and <i>operation</i> .
<code>sendmsg(<type>, <op>, <stream>)</code>	A message identified by its <i>type</i> and <i>operation</i> with a stream <i>id</i> .

Type may be specified using message *name* or message *id*.

Op may be specified using operation *name* or operation *id*.

Stream *id* is an integer in the range 0..3.

Message *id*, operation *id* and stream *id* must be specified as positive *integer numbers*.

Each message type supports specific operations:

Message name	Message Id	Supported Operations	Operation Id	Stream Id
MSG_INTERRUPT	1	-	-	-
MSG_GS	2	GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_GS_DONE	3	GS_OP_NOP	0	-
		GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_SYMSG	15	SYMSG_OP_ECC_ERR_INTERRUPT	1	-
		SYMSG_OP_REG_RD	2	-
		SYMSG_OP_HOST_TRAP_ACK	3	-
		SYMSG_OP_TTRACE_PC	4	-

Examples:

```
s_sendmsg 0x12
s_sendmsg sendmsg(MSG_INTERRUPT)
s_sendmsg sendmsg(2, GS_OP_CUT)
s_sendmsg sendmsg(MSG_GS, GS_OP_EMIT)
s_sendmsg sendmsg(MSG_GS, 2)
s_sendmsg sendmsg(MSG_GS_DONE, GS_OP_EMIT_CUT, 1)
s_sendmsg sendmsg(MSG_SYMSG, SYMSG_OP_TTRACE_PC)
```

param

Interpolation parameter to read:

Syntax	Description
<code>p0</code>	Parameter <i>P0</i> .
<code>p10</code>	Parameter <i>P10</i> .
<code>p20</code>	Parameter <i>P20</i> .

imm16

An *integer_number*. The value is truncated to 16 bits and then sign-extended to 32 bits.

tgt

An export target:

Syntax	Description
pos{0..3}	Copy vertex position 0..3.
param{0..31}	Copy vertex parameter 0..31.
mrt{0..7}	Copy pixel color to the MRTs 0..7.
mrtz	Copy pixel depth (Z) data.
null	Copy nothing.

imm16

An *integer_number*. The value is truncated to 16 bits and then zero-extended to 32 bits.

waitcnt

Counts of outstanding instructions to wait for.

The bits of this operand have the following meaning:

Bits	Description
3:0	VM_CNT: vector memory operations count.
6:4	EXP_CNT: export count.
12:8	LGKM_CNT: LDS, GDS, Constant and Message count.

This operand may be specified as a positive 16-bit *integer_number* or as a combination of the following symbolic helpers:

Syntax	Description
vmcnt(<N>)	VM_CNT value. <i>N</i> must not exceed the largest VM_CNT value.
expcnt(<N>)	EXP_CNT value. <i>N</i> must not exceed the largest EXP_CNT value.
lgkmcnt(<N>)	LGKM_CNT value. <i>N</i> must not exceed the largest LGKM_CNT value.
vmcnt_sat(<N>)	VM_CNT value computed as min(<i>N</i> , the largest VM_CNT value).
expcnt_sat(<N>)	EXP_CNT value computed as min(<i>N</i> , the largest EXP_CNT value).
lgkmcnt_sat(<N>)	LGKM_CNT value computed as min(<i>N</i> , the largest LGKM_CNT value).

These helpers may be specified in any order. Ampersands and commas may be used as optional separators.

N is either an *integer number* or an *absolute expression*.

Examples:

```
s_waitcnt 0
s_waitcnt vmcnt(1)
s_waitcnt expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1) expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1), expcnt(2), lgkmcnt(3)
s_waitcnt vmcnt(1) & lgkmcnt_sat(100) & expcnt(2)
```

vaddr

This is an optional operand which may specify a 64-bit address, offset and/or index.

Size: 0, 1 or 2 dwords. Size is controlled by modifiers *addr64*, *offen* and *idxen*:

- If only *addr64* is specified, this operand supplies a 64-bit address. Size is 2 dwords.
- If only *idxen* is specified, this operand supplies an index. Size is 1 dword.
- If only *offen* is specified, this operand supplies an offset. Size is 1 dword.
- If both *idxen* and *offen* are specified, index is in the first register and offset is in the second. Size is 2 dwords.
- If none of these modifiers are specified, this operand must be set to *off*.
- All other combinations of these modifiers are illegal.

Operands: *v*, *off*

vaddr

An offset from the start of GDS/LDS memory.

Size: 1 dword.

Operands: *v*

vaddr

A 64-bit flat address.

Size: 2 dwords.

Operands: *v*

vaddr

Image address which includes from one to four dimensional coordinates and other data used to locate a position in the image.

Size: 1, 2, 3, 4, 8 or 16 dwords. Actual size depends on opcode and specific image being handled.

Note 1. Image format and dimensions are encoded in the image resource constant but not in the instruction.

Note 2. Actually image address size may vary from 1 to 13 dwords, but assembler currently supports a limited range of register sequences.

Operands: *v*

sbase

A 64-bit base address for scalar memory operations.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *vcc*, *trap*

sbase

A 128-bit buffer resource constant for scalar memory operations which provides a base address, a size and a stride.

Size: 4 dwords.

Operands: *s*, *tmp*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 2 data elements for 32-bit-per-pixel surfaces or 4 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 1 data element for 32-bit-per-pixel surfaces or 2 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Image data to store by an *image_store* instruction.

Size: depends on *dmask* which may specify from 1 to 4 data elements. Each data element occupies 1 dword.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 3 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

If *lds* is specified, this operand is ignored by H/W and data are stored directly into LDS.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Note that *tfe* and *lds* cannot be used together.

Operands: *v*

vdst

Data returned by a 32-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 1 dword.

Operands: *v*

vdst

Data returned by a 64-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 2 dwords.

Operands: *v*

vdst

Image data to load by an *image_gather4* instruction.

Size: 4 data elements by default. Each data element occupies 1 dword. *tfe* adds one more dword if specified.

Operands: *v*

vdst

Image data to load by an *image* instruction.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Operands: *v*

soffset

An unsigned byte offset.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *vcc*, *trap*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*

soffset

An unsigned offset added to the base address to get memory address.

- If offset is specified as a register, it supplies an unsigned byte offset but 2 lsb's are ignored.
- If offset is specified as an *uimm32*, it supplies a 32-bit unsigned byte offset but 2 lsb's are ignored.
- If offset is specified as an *uimm8*, it supplies an 8-bit unsigned dword offset.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *vcc*, *trap*, *uimm8*, *uimm32*

srsrc

Buffer resource constant which defines the address and characteristics of the buffer in memory.

Size: 4 dwords.

Operands: *s*, *tmp*

srsrc

Image resource constant which defines the location of the image buffer in memory, its dimensions, tiling, and data format.

Size: 8 dwords by default, 4 dwords if *r128* is specified.

Operands: *s*, *tmp*

ssamp

Sampler constant used to specify filtering options applied to the image data after it is read.

Size: 4 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 4 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 8 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *vcc*, *trap*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *vcc*, *trap*, *m0*, *exec*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *trap*

sdst

Instruction output.

Size: 16 dwords.

Operands: *s*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *vcc*, *trap*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *vcc*, *trap*, *exec*

src

Instruction input.

Size: 1 dword.

Operands: *v*, *s*, *flat_scratch*, *vcc*, *trap*, *m0*, *exec*, *vccz*, *execz*, *scc*, *lds_direct*, *constant*, *literal*

src

Instruction input.

Size: 1 dword.

Operands: *v*, *s*, *flat_scratch*, *vcc*, *trap*, *m0*, *exec*, *vccz*, *execz*, *scc*, *lds_direct*, *iconst*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, constant, literal*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, lds_direct, constant*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, constant*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, lds_direct*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, iconst*

src

Instruction input.

Size: 2 dwords.

Operands: *v, s, flat_scratch, vcc, trap, exec, vccz, execz, scc, constant, literal*

src

Instruction input.

Size: 2 dwords.

Operands: *v, s, flat_scratch, vcc, trap, exec, vccz, execz, scc, constant*

src

Instruction input.

Size: 2 dwords.

Operands: *v, s, flat_scratch, vcc, trap, exec, vccz, execz, scc, iconst*

vsrc

Data to copy to export buffers. This is an optional operand. Must be specified as *off* if not used.

compr modifier indicates use of compressed (16-bit) data. This limits number of source operands from 4 to 2:

- *src0* and *src1* must specify the first register (or *off*).
- *src2* and *src3* must specify the second register (or *off*).

An example:

```
exp mrtz v3, v3, off, off compr
```

Size: 1 dword.

Operands: *v, off*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, constant, literal*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, vcc, trap*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, iconst, literal*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, vcc, trap, m0, exec*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, vcc, trap, m0, iconst*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, vcc, trap, m0, exec, vccz, execz, scc, lds_direct, constant, literal*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s, flat_scratch, vcc, trap, exec, vccz, execz, scc, constant, literal*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *vcc*, *trap*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *vcc*, *trap*, *exec*, *vccz*, *execz*, *scc*, *constant*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *vcc*, *trap*, *exec*

vcc

Vector condition code.

Size: 2 dwords.

Operands: *vcc*

vdata

Instruction input.

Size: 4 dwords.

Operands: *v*

vdata

Instruction input.

Size: 1 dword.

Operands: *v*

vdata

Instruction input.

Size: 2 dwords.

Operands: *v*

vdata

Instruction input.

Size: 3 dwords.

Operands: *v*

vdst

Instruction output.

Size: 4 dwords.

Operands: *v*

vdst

Instruction output.

Size: 1 dword.

Operands: *v*

vdst

Instruction output.

Size: 2 dwords.

Operands: *v*

vdst

Instruction output.

Size: 3 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 4 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*, *lds_direct*

vsrc

Instruction input.

Size: 2 dwords.

Operands: *v*

m

This operand may be used with floating point operand modifiers *abs* and *neg*.

opt

This is an optional operand. It must be used if and only if *glc* is specified.

dst

This is an input operand. It may optionally serve as a destination if *glc* is specified.

Type deviation

Type of this operand differs from type *implied by the opcode*. This tag specifies actual operand type.

attr

Interpolation attribute and channel:

Syntax	Description
<code>attr{0..32}.x</code>	Attribute 0..32 with <i>x</i> channel.
<code>attr{0..32}.y</code>	Attribute 0..32 with <i>y</i> channel.
<code>attr{0..32}.z</code>	Attribute 0..32 with <i>z</i> channel.
<code>attr{0..32}.w</code>	Attribute 0..32 with <i>w</i> channel.

Examples:

```
v_interp_p1_f32 v1, v0, attr0.x
v_interp_p1_f32 v1, v0, attr32.w
```

imm16

An *integer_number*. The value is truncated to 16 bits.

imm32

An *integer_number*. The value is truncated to 32 bits.

imm32

An *integer_number* or a *floating-point_number*. The number is converted to *f16* as described [here](#).

imm32

An *integer_number* or a *floating-point_number*. The value is converted to *f32* as described [here](#).

hwreg

Bits of a hardware register being accessed.

The bits of this operand have the following meaning:

Bits	Description
5:0	Register <i>id</i> .
10:6	First bit <i>offset</i> (0..31).
15:11	<i>Size</i> in bits (1..32).

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below.

Syntax	Description
hwreg({0..63})	All bits of a register indicated by its <i>id</i> .
hwreg(<name>)	All bits of a register indicated by its <i>name</i> .
hwreg({0..63}, {0..31}, {1..32})	Register bits indicated by register <i>id</i> , first bit <i>offset</i> and <i>size</i> .
hwreg(<name>, {0..31}, {1..32})	Register bits indicated by register <i>name</i> , first bit <i>offset</i> and <i>size</i> .

Register *id*, *offset* and *size* must be specified as positive *integer numbers*.

Defined register *names* include:

Name	Description
HW_REG_MODE	Shader writeable mode bits.
HW_REG_STATUS	Shader read-only status.
HW_REG_TRAPSTS	Trap status.
HW_REG_HW_ID	Id of wave, simd, compute unit, etc.
HW_REG_GPR_ALLOC	Per-wave SGPR and VGPR allocation.
HW_REG_LDS_ALLOC	Per-wave LDS allocation.
HW_REG_IB_STS	Counters of outstanding instructions.

Examples:

```
s_getreg_b32 s2, 0x6
s_getreg_b32 s2, hwreg(15)
s_getreg_b32 s2, hwreg(51, 1, 31)
s_getreg_b32 s2, hwreg(HW_REG_LDS_ALLOC, 0, 1)
```

imm4

A positive *integer_number*. The value is truncated to 4 bits.

This operand is a mask which controls indexing mode for operands of subsequent instructions. Value 1 enables indexing and value 0 disables it.

Bit	Meaning
0	Enables or disables <i>src0</i> indexing.
1	Enables or disables <i>src1</i> indexing.
2	Enables or disables <i>src2</i> indexing.
3	Enables or disables <i>dst</i> indexing.

label

A branch target which is a 16-bit signed integer treated as a PC-relative dword offset.

This operand may be specified as:

- An *integer_number*. The number is truncated to 16 bits.
- An *absolute_expression* which must start with an *integer_number*. The value of the expression is truncated to 16 bits.
- A *symbol* (for example, a label). The value is handled as a 16-bit PC-relative dword offset to be resolved by a linker.

Examples:

```
offset = 30
s_branch loop_end
s_branch 2 + offset
s_branch 32
loop_end:
```

msg

A 16-bit message code. The bits of this operand have the following meaning:

Bits	Description
3:0	Message <i>type</i> .
6:4	Optional <i>operation</i> .
9:7	Optional <i>parameters</i> .
15:10	Unused.

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below:

Syntax	Description
<code>sendmsg(<type>)</code>	A message identified by its <i>type</i> .
<code>sendmsg(<type>, <op>)</code>	A message identified by its <i>type</i> and <i>operation</i> .
<code>sendmsg(<type>, <op>, <stream>)</code>	A message identified by its <i>type</i> and <i>operation</i> with a stream <i>id</i> .

Type may be specified using message *name* or message *id*.

Op may be specified using operation *name* or operation *id*.

Stream *id* is an integer in the range 0..3.

Message *id*, operation *id* and stream *id* must be specified as positive *integer numbers*.

Each message type supports specific operations:

Message name	Message Id	Supported Operations	Operation Id	Stream Id
MSG_INTERRUPT	1	-	-	-
MSG_GS	2	GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_GS_DONE	3	GS_OP_NOP	0	-
		GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_SYMSG	15	SYMSG_OP_ECC_ERR_INTERRUPT	1	-
		SYMSG_OP_REG_RD	2	-
		SYMSG_OP_HOST_TRAP_ACK	3	-
		SYMSG_OP_TTRACE_PC	4	-

Examples:

```
s_sendmsg 0x12
s_sendmsg sendmsg(MSG_INTERRUPT)
s_sendmsg sendmsg(2, GS_OP_CUT)
s_sendmsg sendmsg(MSG_GS, GS_OP_EMIT)
s_sendmsg sendmsg(MSG_GS, 2)
s_sendmsg sendmsg(MSG_GS_DONE, GS_OP_EMIT_CUT, 1)
s_sendmsg sendmsg(MSG_SYMSG, SYMSG_OP_TTRACE_PC)
```

param

Interpolation parameter to read:

Syntax	Description
<code>p0</code>	Parameter <i>P0</i> .
<code>p10</code>	Parameter <i>P10</i> .
<code>p20</code>	Parameter <i>P20</i> .

imm3

A bit mask which indicates request permissions.

This operand must be specified as an *integer_number*. The value is truncated to 7 bits, but only 3 low bits are significant.

Bit Number	Description
0	Request <i>read</i> permission.
1	Request <i>write</i> permission.
2	Request <i>execute</i> permission.

imm16

An *integer_number*. The value is truncated to 16 bits and then sign-extended to 32 bits.

tgt

An export target:

Syntax	Description
pos{0..3}	Copy vertex position 0..3.
param{0..31}	Copy vertex parameter 0..31.
mrt{0..7}	Copy pixel color to the MRTs 0..7.
mrtz	Copy pixel depth (Z) data.
null	Copy nothing.

imm16

An *integer_number*. The value is truncated to 16 bits and then zero-extended to 32 bits.

waitcnt

Counts of outstanding instructions to wait for.

The bits of this operand have the following meaning:

Bits	Description
3:0	VM_CNT: vector memory operations count.
6:4	EXP_CNT: export count.
11:8	LGKM_CNT: LDS, GDS, Constant and Message count.

This operand may be specified as a positive 16-bit *integer_number* or as a combination of the following symbolic helpers:

Syntax	Description
<code>vmcnt(<N>)</code>	VM_CNT value. <i>N</i> must not exceed the largest VM_CNT value.
<code>expcnt(<N>)</code>	EXP_CNT value. <i>N</i> must not exceed the largest EXP_CNT value.
<code>lgkmcnt(<N>)</code>	LGKM_CNT value. <i>N</i> must not exceed the largest LGKM_CNT value.
<code>vmcnt_sat(<N>)</code>	VM_CNT value computed as $\min(N, \text{the largest VM_CNT value})$.
<code>expcnt_sat(<N>)</code>	EXP_CNT value computed as $\min(N, \text{the largest EXP_CNT value})$.
<code>lgkmcnt_sat(<N>)</code>	LGKM_CNT value computed as $\min(N, \text{the largest LGKM_CNT value})$.

These helpers may be specified in any order. Ampersands and commas may be used as optional separators.

N is either an *integer number* or an *absolute expression*.

Examples:

```
s_waitcnt 0
s_waitcnt vmcnt(1)
s_waitcnt expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1) expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1), expcnt(2), lgkmcnt(3)
s_waitcnt vmcnt(1) & lgkmcnt_sat(100) & expcnt(2)
```

vaddr

This is an optional operand which may specify offset and/or index.

Size: 0, 1 or 2 dwords. Size is controlled by modifiers *offen* and *idxen*:

- If only *idxen* is specified, this operand supplies an index. Size is 1 dword.
- If only *offen* is specified, this operand supplies an offset. Size is 1 dword.
- If both modifiers are specified, index is in the first register and offset is in the second. Size is 2 dwords.
- If none of these modifiers are specified, this operand must be set to *off*.

Operands: *v*, *off*

vaddr

An offset from the start of GDS/LDS memory.

Size: 1 dword.

Operands: *v*

vaddr

A 64-bit flat address.

Size: 2 dwords.

Operands: *v*

vaddr

Image address which includes from one to four dimensional coordinates and other data used to locate a position in the image.

Size: 1, 2, 3, 4, 8 or 16 dwords. Actual size depends on opcode and specific image being handled.

Note 1. Image format and dimensions are encoded in the image resource constant but not in the instruction.

Note 2. Actually image address size may vary from 1 to 13 dwords, but assembler currently supports a limited range of register sequences.

Operands: *v*

sbase

A 64-bit base address for scalar memory operations.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*

sbase

A 128-bit buffer resource constant for scalar memory operations which provides a base address, a size and a stride.

Size: 4 dwords.

Operands: *s*, *tmp*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

16-bit data to store by a buffer instruction.

Size: depends on GFX8 GPU revision:

- 4 dwords for GFX8.0. This H/W supports no packing.
- 2 dwords for GFX8.1+. This H/W supports data packing.

Operands: *v*

vdata

16-bit data to store by a buffer instruction.

Size: 1 dword.

Operands: *v*

vdata

16-bit data to store by a buffer instruction.

Size: depends on GFX8 GPU revision:

- 2 dwords for GFX8.0. This H/W supports no packing.
- 1 dword for GFX8.1+. This H/W supports data packing.

Operands: *v*

vdata

16-bit data to store by a buffer instruction.

Size: depends on GFX8 GPU revision:

- 3 dwords for GFX8.0. This H/W supports no packing.
- 2 dwords for GFX8.1+. This H/W supports data packing.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 2 data elements for 32-bit-per-pixel surfaces or 4 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 1 data element for 32-bit-per-pixel surfaces or 2 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Image data to store by an *image_store* instruction.

Size: depends on *dmask* which may specify from 1 to 4 data elements. Each data element occupies 1 dword.

Operands: *v*

vdata

Image data to store by an *image_store* instruction.

Size: depends on *dmask* and *dl6*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies either 32 bits or 16 bits depending on *dl6*.
- *dl6* has different meaning for GFX8.0 and GFX8.1:
 - For GFX8.0 this modifier does not affect size of data elements in registers. Data in registers are stored in low 16 bits, high 16 bits are unused. There is no packing.

- Starting from GFX8.1 this modifier specifies that data elements in registers are packed; each value occupies 16 bits.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 3 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer and converted to a 16-bit format.

Size: depends on GFX8 GPU revision and *tfe*:

- 4 dwords for GFX8.0. This H/W supports no packing.
- 2 dwords for GFX8.1+. This H/W supports data packing.
- *tfe* adds one dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer and converted to a 16-bit format.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer and converted to a 16-bit format.

Size: depends on GFX8 GPU revision and *tfe*:

- 2 dwords for GFX8.0. This H/W supports no packing.
- 1 dword for GFX8.1+. This H/W supports data packing.
- *tfe* adds one dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer and converted to a 16-bit format.

Size: depends on GFX8 GPU revision and *tfe*:

- 3 dwords for GFX8.0. This H/W supports no packing.
- 2 dwords for GFX8.1+. This H/W supports data packing.
- *tfe* adds one dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

If *lds* is specified, this operand is ignored by H/W and data are stored directly into LDS.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Note that *tfe* and *lds* cannot be used together.

Operands: *v*

vdst

Data returned by a 32-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 1 dword.

Operands: *v*

vdst

Data returned by a 64-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 2 dwords.

Operands: *v*

vdst

Image data to load by an *image_gather4* instruction.

Size: 4 data elements by default. Each data element occupies either 32 bits or 16 bits depending on *d16*.

d16 and *tfe* affect operand size as follows:

- *d16* has different meaning for GFX8.0 and GFX8.1:
 - For GFX8.0 this modifier does not affect size of data elements in registers. Data in registers are stored in low 16 bits, high 16 bits are unused. There is no packing.
 - Starting from GFX8.1 this modifier specifies that data elements in registers are packed; each value occupies 16 bits.
- *tfe* adds one dword if specified.

Operands: *v*

vdst

Image data to load by an image instruction.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Image data to load by an image instruction.

Size: depends on *dmask*, *tfe* and *d16*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies either 32 bits or 16 bits depending on *d16*.
- *d16* has different meaning for GFX8.0 and GFX8.1:
 - For GFX8.0 this modifier does not affect size of data elements in registers. Data in registers are stored in low 16 bits, high 16 bits are unused. There is no packing.
 - Starting from GFX8.1 this modifier specifies that data elements in registers are packed; each value occupies 16 bits.
- *tfe* adds 1 dword if specified.

Operands: *v*

soffset

An unsigned byte offset.

Size: 1 dword.

Operands: *s, flat_scratch, xnack, vcc, trap, m0, exec, vccz, execz, scc, constant*

soffset

An unsigned byte offset added to the base address to get memory address.

Size: 1 dword.

Operands: *s, flat_scratch, xnack, vcc, trap, m0, uimm20*

soffset

An unsigned byte offset added to the base address to get memory address.

Size: 1 dword.

Operands: *m0, uimm20*

srsrc

Buffer resource constant which defines the address and characteristics of the buffer in memory.

Size: 4 dwords.

Operands: *s, tmp*

srsrc

Image resource constant which defines the location of the image buffer in memory, its dimensions, tiling, and data format.

Size: 8 dwords by default, 4 dwords if *r128* is specified.

Operands: *s, tmp*

ssamp

Sampler constant used to specify filtering options applied to the image data after it is read.

Size: 4 dwords.

Operands: *s, tmp*

sdata

Instruction input.

Size: 4 dwords.

Operands: *s*, *tmp*

sdata

Instruction input.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*

sdata

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*

sdst

Instruction output.

Size: 4 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 8 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*, *m0*, *exec*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *trap*

sdst

Instruction output.

Size: 16 dwords.

Operands: *s*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*, *exec*

src

Instruction input.

Size: 1 dword.

Operands: *v*, *s*, *flat_scratch*, *xnack*, *vcc*, *trap*, *m0*, *exec*, *vccz*, *execz*, *scc*, *lds_direct*, *constant*, *literal*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, xnack, vcc, trap, m0, exec, vccz, execz, scc, constant, literal*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, xnack, vcc, trap, m0, exec, vccz, execz, scc, lds_direct, constant*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, xnack, vcc, trap, m0, exec, vccz, execz, scc, constant*

src

Instruction input.

Size: 2 dwords.

Operands: *v, s, flat_scratch, xnack, vcc, trap, exec, vccz, execz, scc, constant, literal*

src

Instruction input.

Size: 2 dwords.

Operands: *v, s, flat_scratch, xnack, vcc, trap, exec, vccz, execz, scc, constant*

vsrc

Data to copy to export buffers. This is an optional operand. Must be specified as *off* if not used.

compr modifier indicates use of compressed (16-bit) data. This limits number of source operands from 4 to 2:

- src0 and src1 must specify the first register (or *off*).
- src2 and src3 must specify the second register (or *off*).

An example:

```
exp mrtz v3, v3, off, off compr
```

Size: 1 dword.

Operands: *v, off*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, xnack, vcc, trap, m0, exec, vccz, execz, scc, constant, literal*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, xnack, vcc, trap*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, xnack, vcc, trap, m0, exec*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, xnack, vcc, trap, m0, iconst*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s, flat_scratch, xnack, vcc, trap, m0, exec, vccz, execz, scc, constant*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s, flat_scratch, xnack, vcc, trap, exec, vccz, execz, scc, constant, literal*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*, *exec*, *vccz*, *execz*, *scc*, *constant*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *trap*, *exec*

vcc

Vector condition code.

Size: 2 dwords.

Operands: *vcc*

vdata

Instruction input.

Size: 4 dwords.

Operands: *v*

vdata

Instruction input.

Size: 1 dword.

Operands: *v*

vdata

Instruction input.

Size: 2 dwords.

Operands: *v*

vdata

Instruction input.

Size: 3 dwords.

Operands: *v*

vdst

Instruction output.

Size: 4 dwords.

Operands: *v*

vdst

Instruction output.

Size: 1 dword.

Operands: *v*

vdst

Instruction output.

Size: 2 dwords.

Operands: *v*

vdst

Instruction output.

Size: 3 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 4 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*, *lds_direct*

vsrc

Instruction input.

Size: 2 dwords.

Operands: *v*

m

This operand may be used with floating point operand modifiers *abs* and *neg*.

m

This operand may be used with integer operand modifier *sext*.

m

This operand may be used with floating point operand modifiers *abs* and *neg*.

opt

This is an optional operand. It must be used if and only if *glc* is specified.

dst

This is an input operand. It may optionally serve as a destination if *glc* is specified.

Type deviation

Type of this operand differs from *type implied by the opcode*. This tag specifies actual operand *type*.

Syntax of GFX9 Instructions

attr

Interpolation attribute and channel:

Syntax	Description
<code>attr{0..32}.x</code>	Attribute 0..32 with <i>x</i> channel.
<code>attr{0..32}.y</code>	Attribute 0..32 with <i>y</i> channel.
<code>attr{0..32}.z</code>	Attribute 0..32 with <i>z</i> channel.
<code>attr{0..32}.w</code>	Attribute 0..32 with <i>w</i> channel.

Examples:

```
v_interp_p1_f32 v1, v0, attr0.x
v_interp_p1_f32 v1, v0, attr32.w
```

imm16

An *integer_number*. The value is truncated to 16 bits.

imm32

An *integer_number*. The value is truncated to 32 bits.

imm32

An *integer_number* or a *floating-point_number*. The number is converted to *f16* as described [here](#).

imm32

An *integer_number* or a *floating-point_number*. The value is converted to *f32* as described [here](#).

hwreg

Bits of a hardware register being accessed.

The bits of this operand have the following meaning:

Bits	Description
5:0	Register <i>id</i> .
10:6	First bit <i>offset</i> (0..31).
15:11	<i>Size</i> in bits (1..32).

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below.

Syntax	Description
hwreg({0..63})	All bits of a register indicated by its <i>id</i> .
hwreg(<name>)	All bits of a register indicated by its <i>name</i> .
hwreg({0..63}, {0..31}, {1..32})	Register bits indicated by register <i>id</i> , first bit <i>offset</i> and <i>size</i> .
hwreg(<name>, {0..31}, {1..32})	Register bits indicated by register <i>name</i> , first bit <i>offset</i> and <i>size</i> .

Register *id*, *offset* and *size* must be specified as positive *integer numbers*.

Defined register *names* include:

Name	Description
HW_REG_MODE	Shader writeable mode bits.
HW_REG_STATUS	Shader read-only status.
HW_REG_TRAPSTS	Trap status.
HW_REG_HW_ID	Id of wave, simd, compute unit, etc.
HW_REG_GPR_ALLOC	Per-wave SGPR and VGPR allocation.
HW_REG_LDS_ALLOC	Per-wave LDS allocation.
HW_REG_IB_STS	Counters of outstanding instructions.
HW_REG_SH_MEM_BASES	Memory aperture.

Examples:

```
s_getreg_b32 s2, 0x6
s_getreg_b32 s2, hwreg(15)
s_getreg_b32 s2, hwreg(51, 1, 31)
s_getreg_b32 s2, hwreg(HW_REG_LDS_ALLOC, 0, 1)
```

imm4

A positive *integer_number*. The value is truncated to 4 bits.

This operand is a mask which controls indexing mode for operands of subsequent instructions. Value 1 enables indexing and value 0 disables it.

Bit	Meaning
0	Enables or disables <i>src0</i> indexing.
1	Enables or disables <i>src1</i> indexing.
2	Enables or disables <i>src2</i> indexing.
3	Enables or disables <i>dst</i> indexing.

label

A branch target which is a 16-bit signed integer treated as a PC-relative dword offset.

This operand may be specified as:

- An *integer_number*. The number is truncated to 16 bits.
- An *absolute_expression* which must start with an *integer_number*. The value of the expression is truncated to 16 bits.
- A *symbol* (for example, a label). The value is handled as a 16-bit PC-relative dword offset to be resolved by a linker.

Examples:

```
offset = 30
s_branch loop_end
s_branch 2 + offset
s_branch 32
loop_end:
```

msg

A 16-bit message code. The bits of this operand have the following meaning:

Bits	Description
3:0	Message <i>type</i> .
6:4	Optional <i>operation</i> .
9:7	Optional <i>parameters</i> .
15:10	Unused.

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below:

Syntax	Description
sendmsg(<type>)	A message identified by its <i>type</i> .
sendmsg(<type>, <op>)	A message identified by its <i>type</i> and <i>operation</i> .
sendmsg(<type>, <op>, <stream>)	A message identified by its <i>type</i> and <i>operation</i> with a stream <i>id</i> .

Type may be specified using message *name* or message *id*.

Op may be specified using operation *name* or operation *id*.

Stream *id* is an integer in the range 0..3.

Message *id*, operation *id* and stream *id* must be specified as positive *integer numbers*.

Each message type supports specific operations:

Message name	Message Id	Supported Operations	Operation Id	Stream Id
MSG_INTERRUPT	1	-	-	-
MSG_GS	2	GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_GS_DONE	3	GS_OP_NOP	0	-
		GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_GS_ALLOC_REQ	9	-	-	-
MSG_GET_DOORBELL	10	-	-	-
MSG_SYSMSG	15	SYSMSG_OP_ECC_ERR_INTERRUPT	-	-
		SYSMSG_OP_REG_RD	2	-
		SYSMSG_OP_HOST_TRAP_ACK	3	-
		SYSMSG_OP_TTRACE_PC	4	-

Examples:

```

s_sendmsg 0x12
s_sendmsg sendmsg(MSG_INTERRUPT)
s_sendmsg sendmsg(MSG_GET_DOORBELL)
s_sendmsg sendmsg(2, GS_OP_CUT)
s_sendmsg sendmsg(MSG_GS, GS_OP_EMIT)
s_sendmsg sendmsg(MSG_GS, 2)

```

(continues on next page)

(continued from previous page)

```
s_sendmsg sendmsg(MSG_GS_DONE, GS_OP_EMIT_CUT, 1)
s_sendmsg sendmsg(MSG_SYSMMSG, SYSMMSG_OP_TTRACE_PC)
```

param

Interpolation parameter to read:

Syntax	Description
p0	Parameter <i>P0</i> .
p10	Parameter <i>P10</i> .
p20	Parameter <i>P20</i> .

imm3

A bit mask which indicates request permissions.

This operand must be specified as an *integer_number*. The value is truncated to 7 bits, but only 3 low bits are significant.

Bit Number	Description
0	Request <i>read</i> permission.
1	Request <i>write</i> permission.
2	Request <i>execute</i> permission.

imm16

An *integer_number*. The value is truncated to 16 bits and then sign-extended to 32 bits.

tgt

An export target:

Syntax	Description
pos{0..3}	Copy vertex position 0..3.
param{0..31}	Copy vertex parameter 0..31.
mrt{0..7}	Copy pixel color to the MRTs 0..7.
mrtz	Copy pixel depth (Z) data.
null	Copy nothing.

imm16

An *integer_number*. The value is truncated to 16 bits and then zero-extended to 32 bits.

waitcnt

Counts of outstanding instructions to wait for.

The bits of this operand have the following meaning:

Bits	Description
3:0	VM_CNT: vector memory operations count, lower bits.
6:4	EXP_CNT: export count.
11:8	LGKM_CNT: LDS, GDS, Constant and Message count.
15:14	VM_CNT: vector memory operations count, upper bits.

This operand may be specified as a positive 16-bit *integer_number* or as a combination of the following symbolic helpers:

Syntax	Description
vmcnt(<N>)	VM_CNT value. <i>N</i> must not exceed the largest VM_CNT value.
expcnt(<N>)	EXP_CNT value. <i>N</i> must not exceed the largest EXP_CNT value.
lgkmcnt(<N>)	LGKM_CNT value. <i>N</i> must not exceed the largest LGKM_CNT value.
vmcnt_sat(<N>)	VM_CNT value computed as min(<i>N</i> , the largest VM_CNT value).
expcnt_sat(<N>)	EXP_CNT value computed as min(<i>N</i> , the largest EXP_CNT value).
lgkmcnt_sat(<N>)	LGKM_CNT value computed as min(<i>N</i> , the largest LGKM_CNT value).

These helpers may be specified in any order. Ampersands and commas may be used as optional separators.

N is either an *integer number* or an *absolute expression*.

Examples:

```

s_waitcnt 0
s_waitcnt vmcnt(1)
s_waitcnt expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1) expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1), expcnt(2), lgkmcnt(3)
s_waitcnt vmcnt(1) & lgkmcnt_sat(100) & expcnt(2)

```

vaddr

This is an optional operand which may specify offset and/or index.

Size: 0, 1 or 2 dwords. Size is controlled by modifiers *offen* and *idxen*:

- If only *idxen* is specified, this operand supplies an index. Size is 1 dword.
- If only *offen* is specified, this operand supplies an offset. Size is 1 dword.
- If both modifiers are specified, index is in the first register and offset is in the second. Size is 2 dwords.
- If none of these modifiers are specified, this operand must be set to *off*.

Operands: *v*, *off*

vaddr

An offset from the start of GDS/LDS memory.

Size: 1 dword.

Operands: *v*

vaddr

A 64-bit flat address.

Size: 2 dwords.

Operands: *v*

vaddr

Image address which includes from one to four dimensional coordinates and other data used to locate a position in the image.

Size: 1, 2, 3, 4, 8 or 16 dwords. Actual size depends on opcode, specific image being handled and *a16*.

Note 1. Image format and dimensions are encoded in the image resource constant but not in the instruction.

Note 2. Actually image address size may vary from 1 to 13 dwords, but assembler currently supports a limited range of register sequences.

Operands: *v*

sbase

A 64-bit base address for scalar memory operations.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

sbase

A 128-bit buffer resource constant for scalar memory operations which provides a base address, a size and a stride.

Size: 4 dwords.

Operands: *s*, *tmp*

sbase

This operand is ignored by H/W and *flat_scratch* is supplied instead.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 2 data elements for 32-bit-per-pixel surfaces or 4 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 1 data element for 32-bit-per-pixel surfaces or 2 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Image data to store by an *image_store* instruction.

Size: depends on *dmask* which may specify from 1 to 4 data elements. Each data element occupies 1 dword.

Operands: *v*

vdata

Image data to store by an *image_store* instruction.

Size: depends on *dmask* and *d16*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies either 32 bits or 16 bits depending on *d16*.
- *d16* specifies that data in registers are packed; each value occupies 16 bits.

Operands: *v*

sdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 4 dwords.

Operands: *s*, *tmp*

sdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

sdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

vdst

Instruction output: data read from a memory buffer.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 3 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

If *lds* is specified, this operand is ignored by H/W and data are stored directly into LDS.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Note that *tfe* and *lds* cannot be used together.

Operands: *v*

vdst

Data returned by a 32-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 1 dword.

Operands: *v*

vdst

Data returned by a 64-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 2 dwords.

Operands: *v*

vdst

Image data to load by an *image_gather4* instruction.

Size: 4 data elements by default. Each data element occupies either 32 bits or 16 bits depending on *d16*.

d16 and *tfe* affect operand size as follows:

- *d16* specifies that data elements in registers are packed; each value occupies 16 bits.
- *tfe* adds one dword if specified.

Operands: *v*

vdst

Image data to load by an image instruction.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Image data to load by an image instruction.

Size: depends on *dmask*, *tfe* and *d16*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies either 32 bits or 16 bits depending on *d16*.
- *d16* specifies that data elements in registers are packed; each value occupies 16 bits.
- *tfe* adds 1 dword if specified.

Operands: *v*

soffset

An unsigned byte offset.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*

soffset

An unsigned byte offset added to the base address to get memory address.

Warning: Assembler currently supports 20-bit offsets only. Use *uimm20* instead of *uimm21*.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *m0*, *uimm21*

soffset

An offset added to the base address to get memory address.

- If offset is specified as a register, it supplies an unsigned byte offset.
- If offset is specified as a 21-bit immediate, it supplies a signed byte offset.

Warning: Assembler currently supports 20-bit unsigned offsets only. Use *uimm20* instead of *simm21*.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *ttmp*, *m0*, *simm21*

srsrc

Buffer resource constant which defines the address and characteristics of the buffer in memory.

Size: 4 dwords.

Operands: *s*, *ttmp*

srsrc

Image resource constant which defines the location of the image buffer in memory, its dimensions, tiling, and data format.

Size: 8 dwords.

Operands: *s*, *ttmp*

saddr

An optional 64-bit flat global address. Must be specified as *off* if not used.

See *vaddr* for description of available addressing modes.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *ttmp*, *exec*, *off*

saddr

An optional 32-bit flat scratch offset. Must be specified as *off* if not used.

Either this operand or *vaddr* must be set to *off*.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *ttmp*, *exec*, *off*

ssamp

Sampler constant used to specify filtering options applied to the image data after it is read.

Size: 4 dwords.

Operands: *s*, *tmp*

sdata

Instruction input.

Size: 4 dwords.

Operands: *s*, *tmp*

sdata

Instruction input.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

sdata

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

sdst

Instruction output.

Size: 4 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 8 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *m0*, *exec*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *tmp*

sdst

Instruction output.

Size: 16 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *exec*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, xnack, vcc, tmp, m0, exec, vccz, execz, scc, lds_direct, constant, literal*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, xnack, vcc, tmp, m0, exec, vccz, execz, scc, constant, literal*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, xnack, vcc, tmp, m0, exec, vccz, execz, scc, lds_direct, constant*

src

Instruction input.

Size: 1 dword.

Operands: *v, s, flat_scratch, xnack, vcc, tmp, m0, exec, vccz, execz, scc, constant*

src

Instruction input.

Size: 2 dwords.

Operands: *v, s, flat_scratch, xnack, vcc, tmp, exec, vccz, execz, scc, constant, literal*

src

Instruction input.

Size: 2 dwords.

Operands: *v, s, flat_scratch, xnack, vcc, tmp, exec, vccz, execz, scc, constant*

vsrc

Data to copy to export buffers. This is an optional operand. Must be specified as *off* if not used.

compr modifier indicates use of compressed (16-bit) data. This limits number of source operands from 4 to 2:

- src0 and src1 must specify the first register (or *off*).
- src2 and src3 must specify the second register (or *off*).

An example:

```
exp mrtz v3, v3, off, off compr
```

Size: 1 dword.

Operands: *v*, *off*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *ttmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*, *literal*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *ttmp*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *ttmp*, *m0*, *exec*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *ttmp*, *m0*, *iconst*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *exec*, *vccz*, *execz*, *scc*, *constant*, *literal*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *exec*, *vccz*, *execz*, *scc*, *constant*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *flat_scratch*, *xnack*, *vcc*, *tmp*, *exec*

vaddr

A 64-bit flat global address or a 32-bit offset depending on addressing mode:

- Address = *vaddr* + *offset13s*. *vaddr* is a 64-bit address. This mode is indicated by *saddr* set to *off*.
- Address = *saddr* + *vaddr* + *offset13s*. *vaddr* is a 32-bit offset. This mode is used when *saddr* is not *off*.

Warning: Assembler currently expects a 64-bit *vaddr* regardless of addressing mode. This have to be fixed.

Size: 1 or 2 dwords.

Operands: *v*

vaddr

An optional 32-bit flat scratch offset. Must be specified as *off* if not used.

Either this operand or *saddr* must be set to *off*.

Size: 1 dword.

Operands: *v*, *off*

vcc

Vector condition code.

Size: 2 dwords.

Operands: *vcc*

vdata

Instruction input.

Size: 4 dwords.

Operands: *v*

vdata

Instruction input.

Size: 1 dword.

Operands: *v*

vdata

Instruction input.

Size: 2 dwords.

Operands: *v*

vdata

Instruction input.

Size: 3 dwords.

Operands: *v*

vdst

Instruction output.

Size: 4 dwords.

Operands: *v*

vdst

Instruction output.

Size: 1 dword.

Operands: *v*

vdst

Instruction output.

Size: 2 dwords.

Operands: *v*

vdst

Instruction output.

Size: 3 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 4 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*, *lds_direct*

vsrc

Instruction input.

Size: 2 dwords.

Operands: *v*

fx

This is an *f32* or *f16* operand depending on instruction modifiers:

- Operand size is controlled by *m_op_sel_hi*.
- Location of 16-bit operand is controlled by *m_op_sel*.

m

This operand may be used with floating point operand modifiers *abs* and *neg*.

m

This operand may be used with integer operand modifier *sext*.

m

This operand may be used with floating point operand modifiers *abs* and *neg*.

opt

This is an optional operand. It must be used if and only if *glc* is specified.

dst

This is an input operand. It may optionally serve as a destination if *glc* is specified.

Type deviation

Type of this operand differs from type *implied by the opcode*. This tag specifies actual operand type.

<code>v_cmpx_u_f32</code>	<code>src0,</code>	<code>vsrc1</code>
<code>v_cmpx_u_f64</code>	<code>src0,</code>	<code>vsrc1</code>

attr

Interpolation attribute and channel:

Syntax	Description
<code>attr{0..32}.x</code>	Attribute 0..32 with <i>x</i> channel.
<code>attr{0..32}.y</code>	Attribute 0..32 with <i>y</i> channel.
<code>attr{0..32}.z</code>	Attribute 0..32 with <i>z</i> channel.
<code>attr{0..32}.w</code>	Attribute 0..32 with <i>w</i> channel.

Examples:

```
v_interp_pl_f32 v1, v0, attr0.x
v_interp_pl_f32 v1, v0, attr32.w
```

imm16

An *integer_number*. The value is truncated to 16 bits.

imm32

An *integer_number*. The value is truncated to 32 bits.

imm32

An *integer_number* or a *floating-point_number*. The number is converted to *f16* as described [here](#).

imm32

An *integer_number* or a *floating-point_number*. The value is converted to *f32* as described [here](#).

hwreg

Bits of a hardware register being accessed.

The bits of this operand have the following meaning:

Bits	Description
5:0	Register <i>id</i> .
10:6	First bit <i>offset</i> (0..31).
15:11	<i>Size</i> in bits (1..32).

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below.

Syntax	Description
<code>hwreg({0..63})</code>	All bits of a register indicated by its <i>id</i> .
<code>hwreg(<name>)</code>	All bits of a register indicated by its <i>name</i> .
<code>hwreg({0..63}, {0..31}, {1..32})</code>	Register bits indicated by register <i>id</i> , first bit <i>offset</i> and <i>size</i> .
<code>hwreg(<name>, {0..31}, {1..32})</code>	Register bits indicated by register <i>name</i> , first bit <i>offset</i> and <i>size</i> .

Register *id*, *offset* and *size* must be specified as positive *integer numbers*.

Defined register *names* include:

Name	Description
HW_REG_MODE	Shader writeable mode bits.
HW_REG_STATUS	Shader read-only status.
HW_REG_TRAPSTS	Trap status.
HW_REG_HW_ID	Id of wave, simd, compute unit, etc.
HW_REG_GPR_ALLOC	Per-wave SGPR and VGPR allocation.
HW_REG_LDS_ALLOC	Per-wave LDS allocation.
HW_REG_IB_STS	Counters of outstanding instructions.
HW_REG_SH_MEM_BASES	Memory aperture.
HW_REG_TBA_LO	tba_lo register.
HW_REG_TBA_HI	tba_hi register.
HW_REG_TMA_LO	tma_lo register.
HW_REG_TMA_HI	tma_hi register.
HW_REG_FLAT_SCR_LO	flat_scratch_lo register.
HW_REG_FLAT_SCR_HI	flat_scratch_hi register.
HW_REG_XNACK_MASK	xnack_mask register.
HW_REG_POPS_PACKER	pops_packer register.

Examples:

```
s_getreg_b32 s2, 0x6
s_getreg_b32 s2, hwreg(15)
s_getreg_b32 s2, hwreg(51, 1, 31)
s_getreg_b32 s2, hwreg(HW_REG_LDS_ALLOC, 0, 1)
```

label

A branch target which is a 16-bit signed integer treated as a PC-relative dword offset.

This operand may be specified as:

- An *integer_number*. The number is truncated to 16 bits.
- An *absolute_expression* which must start with an *integer_number*. The value of the expression is truncated to 16 bits.
- A *symbol* (for example, a label). The value is handled as a 16-bit PC-relative dword offset to be resolved by a linker.

Examples:

```
offset = 30
s_branch loop_end
s_branch 2 + offset
s_branch 32
loop_end:
```

msg

A 16-bit message code. The bits of this operand have the following meaning:

Bits	Description
3:0	Message <i>type</i> .
6:4	Optional <i>operation</i> .
9:7	Optional <i>parameters</i> .
15:10	Unused.

This operand may be specified as a positive 16-bit *integer_number* or using the syntax described below:

Syntax	Description
sendmsg(<type>)	A message identified by its <i>type</i> .
sendmsg(<type>, <op>)	A message identified by its <i>type</i> and <i>operation</i> .
sendmsg(<type>, <op>, <stream>)	A message identified by its <i>type</i> and <i>operation</i> with a stream <i>id</i> .

Type may be specified using message *name* or message *id*.

Op may be specified using operation *name* or operation *id*.

Stream *id* is an integer in the range 0..3.

Message *id*, operation *id* and stream *id* must be specified as positive *integer numbers*.

Each message type supports specific operations:

Message name	Message Id	Supported Operations	Operation Id	Stream Id
MSG_INTERRUPT	1	-	-	-
MSG_GS	2	GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_GS_DONE	3	GS_OP_NOP	0	-
		GS_OP_CUT	1	Optional
		GS_OP_EMIT	2	Optional
		GS_OP_EMIT_CUT	3	Optional
MSG_GS_ALLOC_REQ	9	-	-	-
MSG_GET_DOORBELL	10	-	-	-
MSG_SYMSG	15	SYMSG_OP_ECC_ERR_INTERRUPT	-	-
		SYMSG_OP_REG_RD	2	-
		SYMSG_OP_HOST_TRAP_ACK	3	-
		SYMSG_OP_TTRACE_PC	4	-

Examples:

```
s_sendmsg 0x12
s_sendmsg sendmsg(MSG_INTERRUPT)
s_sendmsg sendmsg(MSG_GET_DOORBELL)
s_sendmsg sendmsg(2, GS_OP_CUT)
s_sendmsg sendmsg(MSG_GS, GS_OP_EMIT)
s_sendmsg sendmsg(MSG_GS, 2)
s_sendmsg sendmsg(MSG_GS_DONE, GS_OP_EMIT_CUT, 1)
s_sendmsg sendmsg(MSG_SYMSG, SYMSG_OP_TTRACE_PC)
```

param

Interpolation parameter to read:

Syntax	Description
p0	Parameter <i>P0</i> .
p10	Parameter <i>P10</i> .
p20	Parameter <i>P20</i> .

imm3

A bit mask which indicates request permissions.

This operand must be specified as an *integer_number*. The value is truncated to 7 bits, but only 3 low bits are significant.

Bit Number	Description
0	Request <i>read</i> permission.
1	Request <i>write</i> permission.
2	Request <i>execute</i> permission.

imm16

An *integer_number*. The value is truncated to 16 bits and then sign-extended to 32 bits.

tgt

An export target:

Syntax	Description
pos{0..4}	Copy vertex position 0..4.
param{0..31}	Copy vertex parameter 0..31.
mrt{0..7}	Copy pixel color to the MRTs 0..7.
mrtz	Copy pixel depth (Z) data.
prim	Copy primitive (connectivity) data.
null	Copy nothing.

imm16

An *integer_number*. The value is truncated to 16 bits and then zero-extended to 32 bits.

vcc

Vector condition code. This operand depends on wavefront size:

- Should be *vcc_lo* if wavefront size is 32.
- Should be *vcc* if wavefront size is 64.

waitcnt

Counts of outstanding instructions to wait for.

The bits of this operand have the following meaning:

Bits	Description
3:0	VM_CNT: vector memory operations count, lower bits.
6:4	EXP_CNT: export count.
11:8	LGKM_CNT: LDS, GDS, Constant and Message count.
15:14	VM_CNT: vector memory operations count, upper bits.

This operand may be specified as a positive 16-bit *integer_number* or as a combination of the following symbolic helpers:

Syntax	Description
vmcnt(<N>)	VM_CNT value. <i>N</i> must not exceed the largest VM_CNT value.
expcnt(<N>)	EXP_CNT value. <i>N</i> must not exceed the largest EXP_CNT value.
lgkmcnt(<N>)	LGKM_CNT value. <i>N</i> must not exceed the largest LGKM_CNT value.
vmcnt_sat(<N>)	VM_CNT value computed as min(<i>N</i> , the largest VM_CNT value).
expcnt_sat(<N>)	EXP_CNT value computed as min(<i>N</i> , the largest EXP_CNT value).
lgkmcnt_sat(<N>)	LGKM_CNT value computed as min(<i>N</i> , the largest LGKM_CNT value).

These helpers may be specified in any order. Ampersands and commas may be used as optional separators.

N is either an *integer number* or an *absolute expression*.

Examples:

```

s_waitcnt 0
s_waitcnt vmcnt(1)
s_waitcnt expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1) expcnt(2) lgkmcnt(3)
s_waitcnt vmcnt(1), expcnt(2), lgkmcnt(3)
s_waitcnt vmcnt(1) & lgkmcnt_sat(100) & expcnt(2)

```

vaddr

This is an optional operand which may specify offset and/or index.

Size: 0, 1 or 2 dwords. Size is controlled by modifiers *offen* and *idxen*:

- If only *idxen* is specified, this operand supplies an index. Size is 1 dword.
- If only *offen* is specified, this operand supplies an offset. Size is 1 dword.
- If both modifiers are specified, index is in the first register and offset is in the second. Size is 2 dwords.
- If none of these modifiers are specified, this operand must be set to *off*.

Operands: *v*, *off*

vaddr

An offset from the start of GDS/LDS memory.

Size: 1 dword.

Operands: *v*

vaddr

A 64-bit flat address.

Size: 2 dwords.

Operands: *v*

vaddr

Image address which includes from one to four dimensional coordinates and other data used to locate a position in the image.

This operand may be specified using either *standard VGPR syntax* or special *NSA VGPR syntax*.

Size: 1-13 dwords. Actual size depends on syntax, opcode, *dim* and *a16*.

- If specified using *NSA VGPR syntax*, the size is 1-13 dwords.
- If specified using *standard VGPR syntax*, the size is 1, 2, 3, 4, 8 or 16 dwords. Note that assembler currently supports a limited range of register sequences.

Operands: *v*

sbase

A 64-bit base address for scalar memory operations.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*

sbase

A 128-bit buffer resource constant for scalar memory operations which provides a base address, a size and a stride.

Size: 4 dwords.

Operands: *s*, *tmp*

sbase

This operand is ignored by H/W and *flat_scratch* is supplied instead.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 2 data elements for 32-bit-per-pixel surfaces or 4 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify 1 data element for 32-bit-per-pixel surfaces or 2 data elements for 64-bit-per-pixel surfaces. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Note. The surface data format is indicated in the image resource constant but not in the instruction.

Operands: *v*

vdata

Image data to store by an *image_store* instruction.

Size: depends on *dmask* which may specify from 1 to 4 data elements. Each data element occupies 1 dword.

Operands: *v*

vdata

Image data to store by an *image_store* instruction.

Size: depends on *dmask* and *d16*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies either 32 bits or 16 bits depending on *d16*.
- *d16* specifies that data in registers are packed; each value occupies 16 bits.

Operands: *v*

sdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 4 dwords.

Operands: *s*, *tmp*

sdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*

sdata

Input data for an atomic instruction.

Optionally may serve as an output data:

- If *glc* is specified, gets the memory value before the operation.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*

vdst

Instruction output: data read from a memory buffer.

Size: 4 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 2 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

Size: 3 dwords by default. *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Instruction output: data read from a memory buffer.

If *lds* is specified, this operand is ignored by H/W and data are stored directly into LDS.

Size: 1 dword by default. *tfe* adds 1 dword if specified.

Note that *tfe* and *lds* cannot be used together.

Operands: *v*

vdst

Data returned by a 32-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 1 dword.

Operands: *v*

vdst

Data returned by a 64-bit atomic flat instruction.

This is an optional operand. It must be used if and only if *glc* is specified.

Size: 2 dwords.

Operands: *v*

vdst

Image data to load by an *image_gather4* instruction.

Size: 4 data elements by default. Each data element occupies either 32 bits or 16 bits depending on *d16*.

d16 and *tfe* affect operand size as follows:

- *d16* specifies that data elements in registers are packed; each value occupies 16 bits.
- *tfe* adds one dword if specified.

Operands: *v*

vdst

Image data to load by an image instruction.

Size: depends on *dmask* and *tfe*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies 1 dword.
- *tfe* adds 1 dword if specified.

Operands: *v*

vdst

Image data to load by an image instruction.

Size: depends on *dmask*, *tfe* and *d16*:

- *dmask* may specify from 1 to 4 data elements. Each data element occupies either 32 bits or 16 bits depending on *d16*.
- *d16* specifies that data elements in registers are packed; each value occupies 16 bits.
- *tfe* adds 1 dword if specified.

Operands: *v*

soffset

An unsigned byte offset.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*, *m0*, *vccz*, *execz*, *scc*, *constant*

soffset

An unsigned byte offset added to the base address to get memory address.

Warning: Assembler currently supports 20-bit offsets only. Use *uimm20* instead of *uimm21*.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*, *m0*, *uimm21*

soffset

An offset added to the base address to get memory address.

- If offset is specified as a register, it supplies an unsigned byte offset.
- If offset is specified as a 21-bit immediate, it supplies a signed byte offset.

Warning: Assembler currently supports 20-bit unsigned offsets only. Use *uimm20* instead of *simm21*.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*, *m0*, *simm21*

srsrc

Buffer resource constant which defines the address and characteristics of the buffer in memory.

Size: 4 dwords.

Operands: *s*, *tmp*

srsrc

Image resource constant which defines the location of the image buffer in memory, its dimensions, tiling, and data format.

Size: 8 dwords by default, 4 dwords if *r128* is specified.

Operands: *s*, *tmp*

saddr

An optional 64-bit flat global address. Must be specified as *off* if not used.

See *vaddr* for description of available addressing modes.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*, *null*, *off*

saddr

An optional 32-bit flat scratch offset. Must be specified as *off* if not used.

Either this operand or *vaddr* must be set to *off*.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*, *off*

ssamp

Sampler constant used to specify filtering options applied to the image data after it is read.

Size: 4 dwords.

Operands: *s*, *tmp*

sdata

Instruction input.

Size: 4 dwords.

Operands: *s*, *tmp*

sdata

Instruction input.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*

sdata

Instruction input.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*

sdst

Instruction output.

Size: 4 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 8 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*, *m0*, *exec*

sdst

Instruction output.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*

sdst

Instruction output.

Size: 16 dwords.

Operands: *s*, *tmp*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*

sdst

Instruction output.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*, *exec*

src

Instruction input.

Size: 1 dword.

Operands: *v*, *s*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*

src

Instruction input.

Size: 1 dword.

Operands: *v*, *s*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *lds_direct*, *constant*, *literal*

src

Instruction input.

Size: 1 dword.

Operands: *v*, *s*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*, *literal*

src

Instruction input.

Size: 1 dword.

Operands: *v*, *s*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *lds_direct*, *constant*

src

Instruction input.

Size: 2 dwords.

Operands: *v*, *s*, *vcc*, *tmp*, *exec*, *vccz*, *execz*, *scc*, *constant*, *literal*

vsrc

Data to copy to export buffers. This is an optional operand. Must be specified as *off* if not used.

compr modifier indicates use of compressed (16-bit) data. This limits number of source operands from 4 to 2:

- *src0* and *src1* must specify the first register (or *off*).
- *src2* and *src3* must specify the second register (or *off*).

An example:

```
exp mrtz v3, v3, off, off compr
```

Size: 1 dword.

Operands: *v*, *off*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*, *literal*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *null*, *m0*, *exec*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *constant*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *m0*, *iconst*

ssrc

Instruction input.

Size: 1 dword.

Operands: *s*, *vcc*, *tmp*, *m0*, *exec*, *vccz*, *execz*, *scc*, *lds_direct*, *constant*, *literal*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*, *exec*, *vccz*, *execz*, *scc*, *constant*, *literal*

ssrc

Instruction input.

Size: 2 dwords.

Operands: *s*, *vcc*, *tmp*

vaddr

A 64-bit flat global address or a 32-bit offset depending on addressing mode:

- Address = *vaddr* + *offset12s*. *vaddr* is a 64-bit address. This mode is indicated by *saddr* set to *off*.
- Address = *saddr* + *vaddr* + *offset12s*. *vaddr* is a 32-bit offset. This mode is used when *saddr* is not *off*.

Warning: Assembler currently expects a 64-bit *vaddr* regardless of addressing mode. This have to be fixed.

Size: 1 or 2 dwords.

Operands: *v*

vaddr

An optional 32-bit flat scratch offset. Must be specified as *off* if not used.

Either this operand or *saddr* must be set to *off*.

Size: 1 dword.

Operands: *v*, *off*

vdata

Instruction input.

Size: 4 dwords.

Operands: *v*

vdata

Instruction input.

Size: 1 dword.

Operands: *v*

vdata

Instruction input.

Size: 2 dwords.

Operands: *v*

vdata

Instruction input.

Size: 3 dwords.

Operands: *v*

vdst

Instruction output.

Size: 4 dwords.

Operands: *v*

vdst

Instruction output.

Size: 1 dword.

Operands: *v*

vdst

Instruction output.

Size: 2 dwords.

Operands: *v*

vdst

Instruction output.

Size: 3 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 4 dwords.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*

vsrc

Instruction input.

Size: 1 dword.

Operands: *v*, *lds_direct*

vsrc

Instruction input.

Size: 2 dwords.

Operands: *v*

sdst

Instruction output.

Size: 1 dword if wavefront size is 32, otherwise 2 dwords.

Operands: *s*, *vcc*, *tmp*

ssrc

Instruction input.

Size: 1 dword if wavefront size is 32, otherwise 2 dwords.

Operands: *s*, *vcc*, *tmp*

fx

This is an *f32* or *f16* operand depending on instruction modifiers:

- Operand size is controlled by *m_op_sel_hi*.
- Location of 16-bit operand is controlled by *m_op_sel*.

m

This operand may be used with floating point operand modifiers *abs* and *neg*.

m

This operand may be used with integer operand modifier *sext*.

m

This operand may be used with floating point operand modifiers *abs* and *neg*.

opt

This is an optional operand. It must be used if and only if *glc* is specified.

dst

This is an input operand. It may optionally serve as a destination if *glc* is specified.

Type deviation

Type of this operand differs from type *implied by the opcode*. This tag specifies actual operand type.

Conventions

The following notation is used throughout this document:

Notation	Description
{0..N}	Any integer value in the range from 0 to N (inclusive).
<x>	Syntax and meaning of <i>x</i> is explained elsewhere.

Modifiers

DS Modifiers

offset8

Specifies an immediate unsigned 8-bit offset, in bytes. The default value is 0.

Used with DS instructions which have 2 addresses.

Syntax	Description
offset: {0..0xFF}	Specifies an unsigned 8-bit offset as a positive <i>integer number</i> .

Examples:

```
offset:255
offset:0xff
```

offset16

Specifies an immediate unsigned 16-bit offset, in bytes. The default value is 0.

Used with DS instructions which have 1 address.

Syntax	Description
offset: {0..0xFFFF}	Specifies an unsigned 16-bit offset as a positive <i>integer number</i> .

Examples:

```
offset:65535
offset:0xffff
```

swizzle pattern

This is a special modifier which may be used with `ds_swizzle_b32` instruction only. It specifies a swizzle pattern in numeric or symbolic form. The default value is 0.

See AMD documentation for more information.

Syntax	Description
offset:{0..0xFFFF}	Specifies a 16-bit swizzle pattern.
offset:swizzle(QUAD_PERM,{0..3},{0..3},{0..3},{0..3})	Specifies a quad permute mode pattern. Each number is a lane <i>id</i> .
offset:swizzle(BITMASK_PERM, "<mask>")	Specifies a bitmask permute mode pattern. The pattern converts a 5-bit lane <i>id</i> to another lane <i>id</i> with which the lane interacts. <i>mask</i> is a 5 character sequence which specifies how to transform the bits of the lane <i>id</i> . The following characters are allowed: <ul style="list-style-type: none"> • "0" - set bit to 0. • "1" - set bit to 1. • "p" - preserve bit. • "i" - inverse bit.
offset:swizzle(BROADCAST,{2..32},{0..N})	Specifies a broadcast mode. Broadcasts the value of any particular lane to all lanes in its group. The first numeric parameter is a group size and must be equal to 2, 4, 8, 16 or 32. The second numeric parameter is an index of the lane being broadcasted. The index must not exceed group size.
offset:swizzle(SWAP,{1..16})	Specifies a swap mode. Swaps the neighboring groups of 1, 2, 4, 8 or 16 lanes.
offset:swizzle(REVERSE,{2..32})	Specifies a reverse mode. Reverses the lanes for groups of 2, 4, 8, 16 or 32 lanes.

Numeric parameters may be specified as either *integer numbers* or *absolute expressions*.

Examples:

```
offset:255
offset:0xffff
offset:swizzle(QUAD_PERM, 0, 1, 2, 3)
offset:swizzle(BITMASK_PERM, "01pi0")
offset:swizzle(BROADCAST, 2, 0)
offset:swizzle(SWAP, 8)
offset:swizzle(REVERSE, 30 + 2)
```

gds

Specifies whether to use GDS or LDS memory (LDS is the default).

Syntax	Description
<code>gds</code>	Use GDS memory.

EXP Modifiers

done

Specifies if this is the last export from the shader to the target. By default, *exp* instruction does not finish an export sequence.

Syntax	Description
<code>done</code>	Indicates the last export operation.

compr

Indicates if the data are compressed (data are not compressed by default).

Syntax	Description
<code>compr</code>	Data are compressed.

vm

Specifies valid mask flag state (off by default).

Syntax	Description
<code>vm</code>	Set valid mask flag.

FLAT Modifiers

offset12

Specifies an immediate unsigned 12-bit offset, in bytes. The default value is 0.

Cannot be used with *global/scratch* opcodes. GFX9 only.

Syntax	Description
<code>offset:{0..4095}</code>	Specifies a 12-bit unsigned offset as a positive <i>integer number</i> .

Examples:

```
offset:4095
offset:0xff
```

offset13s

Specifies an immediate signed 13-bit offset, in bytes. The default value is 0.

Can be used with *global/scratch* opcodes only. GFX9 only.

Syntax	Description
offset:{-4096..4095}	Specifies a 13-bit signed offset as an <i>integer number</i> .

Examples:

```
offset:-4000
offset:0x10
```

offset12s

Specifies an immediate signed 12-bit offset, in bytes. The default value is 0.

Can be used with *global/scratch* opcodes only.

GFX10 only.

Syntax	Description
offset:{-2048..2047}	Specifies a 12-bit signed offset as an <i>integer number</i> .

Examples:

```
offset:-2000
offset:0x10
```

offset11

Specifies an immediate unsigned 11-bit offset, in bytes. The default value is 0.

Cannot be used with *global/scratch* opcodes.

GFX10 only.

Syntax	Description
offset:{0..2047}	Specifies an 11-bit unsigned offset as a positive <i>integer number</i> .

Examples:

```
offset:2047
offset:0xff
```

dlc

See a description [here](#). GFX10 only.

glc

See a description [here](#).

slc

See a description [here](#).

tfe

See a description [here](#).

nv

See a description [here](#).

MIMG Modifiers**dmask**

Specifies which channels (image components) are used by the operation. By default, no channels are used.

Syn-tax	Description
dmask: {0..15}	Specifies image channels as a positive <i>integer number</i> . Each bit corresponds to one of 4 image components (RGBA). If the specified bit value is 0, the component is not used, value 1 means that the component is used.

This modifier has some limitations depending on instruction kind:

Instruction Kind	Valid dmask Values
32-bit atomic <i>cmpswap</i>	0x3
32-bit atomic instructions except for <i>cmpswap</i>	0x1
64-bit atomic <i>cmpswap</i>	0xF
64-bit atomic instructions except for <i>cmpswap</i>	0x3
<i>gather4</i>	0x1, 0x2, 0x4, 0x8
Other instructions	any value

Examples:

```
dmask:0xf
dmask:0b1111
dmask:3
```

unorm

Specifies whether the address is normalized or not (the address is normalized by default).

Syntax	Description
unorm	Force the address to be unnormalized.

glc

See a description [here](#).

slc

See a description [here](#).

r128

Specifies texture resource size. The default size is 256 bits.

GFX7, GFX8 and GFX10 only.

Syntax	Description
r128	Specifies 128 bits texture resource size.

Warning: Using this modifier should decrease *rsrc* operand size from 8 to 4 dwords, but assembler does not currently support this feature.

tfe

See a description [here](#).

lwe

Specifies LOD warning status (LOD warning is disabled by default).

Syntax	Description
lwe	Enables LOD warning.

da

Specifies if an array index must be sent to TA. By default, array index is not sent.

Syntax	Description
da	Send an array-index to TA.

d16

Specifies data size: 16 or 32 bits (32 bits by default). Not supported by GFX7.

Syn-tax	Description
d16	Enables 16-bits data mode. On loads, convert data in memory to 16-bit format before storing it in VGPRs. For stores, convert 16-bit data in VGPRs to 32 bits before going to memory. Note that GFX8.0 does not support data packing. Each 16-bit data element occupies 1 VGPR. GFX8.1, GFX9 and GFX10 support data packing. Each pair of 16-bit data elements occupies 1 VGPR.

a16

Specifies size of image address components: 16 or 32 bits (32 bits by default). GFX9 and GFX10 only.

Syntax	Description
a16	Enables 16-bits image address components.

dim

Specifies surface dimension. This is a mandatory modifier. There is no default value.
GFX10 only.

Syntax	Description
dim:1D	One-dimensional image.
dim:2D	Two-dimensional image.
dim:3D	Three-dimensional image.
dim:CUBE	Cubemap array.
dim:1D_ARRAY	One-dimensional image array.
dim:2D_ARRAY	Two-dimensional image array.
dim:2D_MSAA	Two-dimensional multi-sample auto-aliasing image.
dim:2D_MSAA_ARRAY	Two-dimensional multi-sample auto-aliasing image array.

The following table defines an alternative syntax which is supported for compatibility with SP3 assembler:

Syntax	Description
dim:SQ_RSRC_IMG_1D	One-dimensional image.
dim:SQ_RSRC_IMG_2D	Two-dimensional image.
dim:SQ_RSRC_IMG_3D	Three-dimensional image.
dim:SQ_RSRC_IMG_CUBE	Cubemap array.
dim:SQ_RSRC_IMG_1D_ARRAY	One-dimensional image array.
dim:SQ_RSRC_IMG_2D_ARRAY	Two-dimensional image array.
dim:SQ_RSRC_IMG_2D_MSAA	Two-dimensional multi-sample auto-aliasing image.
dim:SQ_RSRC_IMG_2D_MSAA_ARRAY	Two-dimensional multi-sample auto-aliasing image array.

dlc

See a description [here](#). GFX10 only.

Miscellaneous Modifiers

dlc

Controls device level cache policy for memory operations. Used for synchronization. When specified, forces operation to bypass device level cache making the operation device level coherent. By default, instructions use device level cache.

GFX10 only.

Syntax	Description
dlc	Bypass device level cache.

glc

This modifier has different meaning for loads, stores, and atomic operations. The default value is off (0).

See AMD documentation for details.

Syntax	Description
glc	Set glc bit to 1.

lds

Specifies where to store the result: VGPRs or LDS (VGPRs by default).

Syntax	Description
lds	Store result in LDS.

nv

Specifies if instruction is operating on non-volatile memory. By default, memory is volatile.

GFX9 only.

Syntax	Description
nv	Indicates that instruction operates on non-volatile memory.

slc

Specifies cache policy. The default value is off (0).

See AMD documentation for details.

Syntax	Description
slc	Set slc bit to 1.

tfe

Controls access to partially resident textures. The default value is off (0).

See AMD documentation for details.

Syntax	Description
tfe	Set tfe bit to 1.

MUBUF/MTBUF Modifiers

idxen

Specifies whether address components include an index. By default, no components are used.

Can be used together with *offen*.

Cannot be used with *addr64*.

Syntax	Description
idxen	Address components include an index.

offen

Specifies whether address components include an offset. By default, no components are used.

Can be used together with *idxen*.

Cannot be used with *addr64*.

Syntax	Description
offen	Address components include an offset.

addr64

Specifies whether a 64-bit address is used. By default, no address is used.

GFX7 only. Cannot be used with *offen* and *idxen* modifiers.

Syntax	Description
addr64	A 64-bit address is used.

offset12

Specifies an immediate unsigned 12-bit offset, in bytes. The default value is 0.

Syntax	Description
offset:{0..0xFFF}	Specifies a 12-bit unsigned offset as a positive <i>integer number</i> .

Examples:

```
offset:0
offset:0x10
```

glc

See a description [here](#).

slc

See a description [here](#).

lds

nfmt

TBD

SMRD/SMEM Modifiers

glc

See a description [here](#).

nv

See a description [here](#). GFX9 only.

dlc

See a description [here](#). GFX10 only.

VINTRP Modifiers**high**

Specifies which half of the LDS word to use. Low half of LDS word is used by default. GFX9 and GFX10 only.

Syntax	Description
high	Use high half of LDS word.

DPP8 Modifiers

GFX10 only.

dpp8_sel

Selects which lane to pull data from, within a group of 8 lanes. This is a mandatory modifier. There is no default value.

GFX10 only.

The *dpp8_sel* modifier must specify exactly 8 values, each ranging from 0 to 7. First value selects which lane to read from to supply data into lane 0. Second value controls value for lane 1 and so on.

Syntax	Description
dpp8:[{0..7},{0..7},{0..7},{0..7},{0..7},{0..7},{0..7},{0..7}]	Select lanes to read from.

Examples:

```
dpp8: [7, 6, 5, 4, 3, 2, 1, 0]
dpp8: [0, 1, 0, 1, 0, 1, 0, 1]
```

fi

Controls interaction with inactive lanes for *dpp8* instructions. The default value is zero.

Note. *Inactive* lanes are those whose *exec* mask bit is zero.

GFX10 only.

Syntax	Description
fi:0	Fetch zero when accessing data from inactive lanes.
fi:1	Fetch pre-exist values from inactive lanes.

DPP/DPP16 Modifiers

GFX8, GFX9 and GFX10 only.

dpp_ctrl

Specifies how data are shared between threads. This is a mandatory modifier. There is no default value.

GFX8 and GFX9 only. Use *dpp16_ctrl* for GFX10.

Note. The lanes of a wavefront are organized in four *rows* and four *banks*.

Syntax	Description
quad_perm:[{0..3},{0..3},{0..3},{0..3}]	Full permute of 4 threads.
row_mirror	Mirror threads within row.
row_half_mirror	Mirror threads within 1/2 row (8 threads).
row_bcast:15	Broadcast 15th thread of each row to next row.
row_bcast:31	Broadcast thread 31 to rows 2 and 3.
wave_shl:1	Wavefront left shift by 1 thread.
wave_rol:1	Wavefront left rotate by 1 thread.
wave_shr:1	Wavefront right shift by 1 thread.
wave_ror:1	Wavefront right rotate by 1 thread.
row_shl:{1..15}	Row shift left by 1-15 threads.
row_shr:{1..15}	Row shift right by 1-15 threads.
row_ror:{1..15}	Row rotate right by 1-15 threads.

Note: Numeric parameters may be specified as either *integer numbers* or *absolute expressions*.

Examples:

```
quad_perm:[0, 1, 2, 3]
row_shl:3
```

dpp16_ctrl

Specifies how data are shared between threads. This is a mandatory modifier. There is no default value.

GFX10 only. Use *dpp_ctrl* for GFX8 and GFX9.

Note. The lanes of a wavefront are organized in four *rows* and four *banks*. (There are only two rows in *wave32* mode.)

Syntax	Description
quad_perm:[{0..3},{0..3},{0..3},{0..3}]	Full permute of 4 threads.
row_mirror	Mirror threads within row.
row_half_mirror	Mirror threads within 1/2 row (8 threads).
row_share:{0..15}	Share the value from the specified lane with other lanes in the row.
row_xmask:{0..15}	Fetch from XOR(current lane id, specified lane id).
row_shl:{1..15}	Row shift left by 1-15 threads.
row_shr:{1..15}	Row shift right by 1-15 threads.
row_ror:{1..15}	Row rotate right by 1-15 threads.

Note: Numeric parameters may be specified as either *integer numbers* or *absolute expressions*.

Examples:

```
quad_perm:[0, 1, 2, 3]
row_shl:3
```

row_mask

Controls which rows are enabled for data sharing. By default, all rows are enabled.

Note. The lanes of a wavefront are organized in four *rows* and four *banks*. (There are only two rows in *wave32* mode.)

Syntax	Description
row_mask:{0..15}	Specifies a <i>row mask</i> as a positive <i>integer number</i> . Each of 4 bits in the mask controls one row (0 - disabled, 1 - enabled). In <i>wave32</i> mode the values should be limited to {0..7}.

Examples:

```
row_mask:0xf
row_mask:0b1010
row_mask:0b1111
```

bank_mask

Controls which banks are enabled for data sharing. By default, all banks are enabled.

Note. The lanes of a wavefront are organized in four *rows* and four *banks*. (There are only two rows in *wave32* mode.)

Syntax	Description
bank_mask:{0..15}	Specifies a <i>bank mask</i> as a positive <i>integer number</i> . Each of 4 bits in the mask controls one bank (0 - disabled, 1 - enabled).

Examples:

```
bank_mask:0x3
bank_mask:0b0011
bank_mask:0b1111
```

bound_ctrl

Controls data sharing when accessing an invalid lane. By default, data sharing with invalid lanes is disabled.

Syntax	Description
bound_ctrl:0	Enables data sharing with invalid lanes. Accessing data from an invalid lane will return zero.

fi

Controls interaction with *inactive* lanes for *dpp16* instructions. The default value is zero.

Note. *Inactive* lanes are those whose *exec* mask bit is zero.

GFX10 only.

Syntax	Description
fi:0	Interaction with inactive lanes is controlled by <i>bound_ctrl</i> .
fi:1	Fetch pre-exist values from inactive lanes.

SDWA Modifiers

GFX8, GFX9 and GFX10 only.

clamp

See a description [here](#).

omod

See a description [here](#).

GFX9 and GFX10 only.

dst_sel

Selects which bits in the destination are affected. By default, all bits are affected.

Syntax	Description
dst_sel:DWORD	Use bits 31:0.
dst_sel:BYTE_0	Use bits 7:0.
dst_sel:BYTE_1	Use bits 15:8.
dst_sel:BYTE_2	Use bits 23:16.
dst_sel:BYTE_3	Use bits 31:24.
dst_sel:WORD_0	Use bits 15:0.
dst_sel:WORD_1	Use bits 31:16.

dst_unused

Controls what to do with the bits in the destination which are not selected by *dst_sel*. By default, unused bits are preserved.

Syntax	Description
dst_unused:UNUSED_PAD	Pad with zeros.
dst_unused:UNUSED_SEXT	Sign-extend upper bits, zero lower bits.
dst_unused:UNUSED_PRESERVE	Preserve bits.

src0_sel

Controls which bits in the src0 are used. By default, all bits are used.

Syntax	Description
src0_sel:DWORD	Use bits 31:0.
src0_sel:BYTE_0	Use bits 7:0.
src0_sel:BYTE_1	Use bits 15:8.
src0_sel:BYTE_2	Use bits 23:16.
src0_sel:BYTE_3	Use bits 31:24.
src0_sel:WORD_0	Use bits 15:0.
src0_sel:WORD_1	Use bits 31:16.

src1_sel

Controls which bits in the src1 are used. By default, all bits are used.

Syntax	Description
src1_sel:DWORD	Use bits 31:0.
src1_sel:BYTE_0	Use bits 7:0.
src1_sel:BYTE_1	Use bits 15:8.
src1_sel:BYTE_2	Use bits 23:16.
src1_sel:BYTE_3	Use bits 31:24.
src1_sel:WORD_0	Use bits 15:0.
src1_sel:WORD_1	Use bits 31:16.

SDWA Operand Modifiers

Operand modifiers are not used separately. They are applied to source operands. GFX8, GFX9 and GFX10 only.

abs

See a description [here](#).

neg

See a description [here](#).

sext

Sign-extends value of a (sub-dword) operand to fill all 32 bits. Has no effect for 32-bit operands.

Valid for integer operands only.

Syntax	Description
<code>sext(<operand>)</code>	Sign-extend operand value.

Examples:

```
sext (v4)
sext (v255)
```

VOP3 Modifiers

op_sel

Selects the low [15:0] or high [31:16] operand bits for source and destination operands. By default, low bits are used for all operands.

The number of values specified with the `op_sel` modifier must match the number of instruction operands (both source and destination). First value controls `src0`, second value controls `src1` and so on, except that the last value controls destination. The value 0 selects the low bits, while 1 selects the high bits.

Note. `op_sel` modifier affects 16-bit operands only. For 32-bit operands the value specified by `op_sel` must be 0.

GFX9 and GFX10 only.

Syntax	Description
<code>op_sel:[{0..1},{0..1}]</code>	Select operand bits for instructions with 1 source operand.
<code>op_sel:[{0..1},{0..1},{0..1}]</code>	Select operand bits for instructions with 2 source operands.
<code>op_sel:[{0..1},{0..1},{0..1},{0..1}]</code>	Select operand bits for instructions with 3 source operands.

Examples:

```
op_sel: [0, 0]
op_sel: [0, 1]
```

clamp

Clamp meaning depends on instruction.

For `v_cmp` instructions, clamp modifier indicates that the compare signals if a floating point exception occurs. By default, signaling is disabled. Not supported by GFX7.

For integer operations, clamp modifier indicates that the result must be clamped to the largest and smallest representable value. By default, there is no clamping. Integer clamping is not supported by GFX7.

For floating point operations, clamp modifier indicates that the result must be clamped to the range [0.0, 1.0]. By default, there is no clamping.

Note. Clamp modifier is applied after *output modifiers* (if any).

Syntax	Description
clamp	Enables clamping (or signaling).

omod

Specifies if an output modifier must be applied to the result. By default, no output modifiers are applied.

Note. Output modifiers are applied before *clamping* (if any).

Output modifiers are valid for f32 and f64 floating point results only. They must not be used with f16.

Note. `v_cvt_f16_f32` is an exception. This instruction produces f16 result but accepts output modifiers.

Syntax	Description
mul:2	Multiply the result by 2.
mul:4	Multiply the result by 4.
div:2	Multiply the result by 0.5.

VOP3 Operand Modifiers

Operand modifiers are not used separately. They are applied to source operands.

abs

Computes absolute value of its operand. Applied before *neg* (if any). Valid for floating point operands only.

Syntax	Description
abs(<operand>)	Get absolute value of operand.
<operand>	The same as above.

Examples:

```
abs (v36)
|v36|
```

neg

Computes negative value of its operand. Applied after *abs* (if any). Valid for floating point operands only.

Syntax	Description
neg(<operand>)	Get negative value of operand.
-<operand>	The same as above.

Examples:

```
neg (v[0])
-v4
```

VOP3P Modifiers

This section describes modifiers of *regular* VOP3P instructions.

`v_mad_mix_f32`, `v_mad_mixhi_f16` and `v_mad_mixlo_f16` instructions use these modifiers *in a special manner*.

GFX9 and GFX10 only.

op_sel

Selects the low [15:0] or high [31:16] operand bits as input to the operation which results in the lower-half of the destination. By default, low bits are used for all operands.

The number of values specified by the `op_sel` modifier must match the number of source operands. First value controls `src0`, second value controls `src1` and so on.

The value 0 selects the low bits, while 1 selects the high bits.

Syntax	Description
<code>op_sel:[{0..1}]</code>	Select operand bits for instructions with 1 source operand.
<code>op_sel:[{0..1},{0..1}]</code>	Select operand bits for instructions with 2 source operands.
<code>op_sel:[{0..1},{0..1},{0..1}]</code>	Select operand bits for instructions with 3 source operands.

Examples:

```
op_sel:[0,0]
op_sel:[0,1,0]
```

op_sel_hi

Selects the low [15:0] or high [31:16] operand bits as input to the operation which results in the upper-half of the destination. By default, high bits are used for all operands.

The number of values specified by the `op_sel_hi` modifier must match the number of source operands. First value controls `src0`, second value controls `src1` and so on.

The value 0 selects the low bits, while 1 selects the high bits.

Syntax	Description
<code>op_sel_hi:[{0..1}]</code>	Select operand bits for instructions with 1 source operand.
<code>op_sel_hi:[{0..1},{0..1}]</code>	Select operand bits for instructions with 2 source operands.
<code>op_sel_hi:[{0..1},{0..1},{0..1}]</code>	Select operand bits for instructions with 3 source operands.

Examples:

```
op_sel_hi:[0,0]
op_sel_hi:[0,0,1]
```

neg_lo

Specifies whether to change sign of operand values selected by *op_sel*. These values are then used as input to the operation which results in the upper-half of the destination.

The number of values specified by this modifier must match the number of source operands. First value controls src0, second value controls src1 and so on.

The value 0 indicates that the corresponding operand value is used unmodified, the value 1 indicates that negative value of the operand must be used.

By default, operand values are used unmodified.

This modifier is valid for floating point operands only.

Syntax	Description
<code>neg_lo:[{0..1}]</code>	Select affected operands for instructions with 1 source operand.
<code>neg_lo:[{0..1},{0..1}]</code>	Select affected operands for instructions with 2 source operands.
<code>neg_lo:[{0..1},{0..1},{0..1}]</code>	Select affected operands for instructions with 3 source operands.

Examples:

```
neg_lo: [0]
neg_lo: [0, 1]
```

neg_hi

Specifies whether to change sign of operand values selected by *op_sel_hi*. These values are then used as input to the operation which results in the upper-half of the destination.

The number of values specified by this modifier must match the number of source operands. First value controls src0, second value controls src1 and so on.

The value 0 indicates that the corresponding operand value is used unmodified, the value 1 indicates that negative value of the operand must be used.

By default, operand values are used unmodified.

This modifier is valid for floating point operands only.

Syntax	Description
<code>neg_hi:[{0..1}]</code>	Select affected operands for instructions with 1 source operand.
<code>neg_hi:[{0..1},{0..1}]</code>	Select affected operands for instructions with 2 source operands.
<code>neg_hi:[{0..1},{0..1},{0..1}]</code>	Select affected operands for instructions with 3 source operands.

Examples:

```
neg_hi: [1, 0]
neg_hi: [0, 1, 1]
```

clamp

See a description [here](#).

VOP3P V_MAD_MIX Modifiers

v_mad_mix_f32, *v_mad_mixhi_f16* and *v_mad_mixlo_f16* instructions use *op_sel* and *op_sel_hi* modifiers in a manner different from *regular* VOP3P instructions.

See a description below.

GFX9 and GFX10 only.

m_op_sel

This operand has meaning only for 16-bit source operands as indicated by *m_op_sel_hi*. It specifies to select either the low [15:0] or high [31:16] operand bits as input to the operation.

The number of values specified by the *op_sel* modifier must match the number of source operands. First value controls src0, second value controls src1 and so on.

The value 0 indicates the low bits, the value 1 indicates the high 16 bits.

By default, low bits are used for all operands.

Syntax	Description
op_sel:[{0..1},{0..1},{0..1}]	Select location of each 16-bit source operand.

Examples:

```
op_sel:[0,1]
```

m_op_sel_hi

Selects the size of source operands: either 32 bits or 16 bits. By default, 32 bits are used for all source operands.

The number of values specified by the *op_sel_hi* modifier must match the number of source operands. First value controls src0, second value controls src1 and so on.

The value 0 indicates 32 bits, the value 1 indicates 16 bits.

The location of 16 bits in the operand may be specified by *m_op_sel*.

Syntax	Description
op_sel_hi:[{0..1},{0..1},{0..1}]	Select size of each source operand.

Examples:

```
op_sel_hi:[1,1,1]
```

abs

See a description [here](#).

neg

See a description [here](#).

clamp

See a description [here](#).

Conventions

The following notation is used throughout this document:

Notation	Description
{0..N}	Any integer value in the range from 0 to N (inclusive).
<x>	Syntax and meaning of <i>x</i> is explained elsewhere.

Operands

v

Vector registers. There are 256 32-bit vector registers.

A sequence of *vector* registers may be used to operate with more than 32 bits of data.

Assembler currently supports sequences of 1, 2, 3, 4, 8 and 16 *vector* registers.

Syntax	Description
<code>v<N></code>	A single 32-bit <i>vector</i> register. <i>N</i> must be a decimal integer number.
<code>v[<N>]</code>	A single 32-bit <i>vector</i> register. <i>N</i> may be specified as an <i>integer number</i> or an <i>absolute expression</i> .
<code>v[<N>:<K>]</code>	A sequence of (<i>K-N+1</i>) <i>vector</i> registers. <i>N</i> and <i>K</i> may be specified as <i>integer numbers</i> or <i>absolute expressions</i> .
<code>[v<N>, v<N+1>, ... v<K>]</code>	A sequence of (<i>K-N+1</i>) <i>vector</i> registers. Register indices must be specified as decimal integer numbers.

Note. *N* and *K* must satisfy the following conditions:

- $N \leq K$.
- $0 \leq N \leq 255$.
- $0 \leq K \leq 255$.
- $K-N+1$ must be equal to 1, 2, 3, 4, 8 or 16.

Examples:

```
v255
v[0]
v[0:1]
v[1:1]
v[0:3]
v[2*2]
v[1-1:2-1]
[v252]
[v252, v253, v254, v255]
```

Image instructions may use special *NSA* (Non-Sequential Address) syntax for *image addresses*:

Syntax	Description
<code>[v<A>, v, ... v<X>]</code>	A sequence of <i>vector</i> registers. At least one register must be specified. In contrast with standard syntax described above, registers in this sequence are not required to have consecutive indices. Moreover, the same register may appear in the list more than once.

Note. Register indices must be in the range 0..255. They must be specified as decimal integer numbers.

Examples:

```
[v32, v1, v2]
[v4, v4, v4, v4]
```

S

Scalar 32-bit registers. The number of available *scalar* registers depends on GPU:

GPU	Number of <i>scalar</i> registers
GFX7	104
GFX8	102
GFX9	102
GFX10	106

A sequence of *scalar* registers may be used to operate with more than 32 bits of data. Assembler currently supports sequences of 1, 2, 4, 8 and 16 *scalar* registers.

Pairs of *scalar* registers must be even-aligned (the first register must be even). Sequences of 4 and more *scalar* registers must be quad-aligned.

Syntax	Description
<code>s<N></code>	A single 32-bit <i>scalar</i> register. <i>N</i> must be a decimal integer number.
<code>s[<N>]</code>	A single 32-bit <i>scalar</i> register. <i>N</i> may be specified as an <i>integer number</i> or an <i>absolute expression</i> .
<code>s[<N>:<K>]</code>	A sequence of $(K-N+1)$ <i>scalar</i> registers. <i>N</i> and <i>K</i> may be specified as <i>integer numbers</i> or <i>absolute expressions</i> .
<code>[s<N>, s<N+1>, ... s<K>]</code>	A sequence of $(K-N+1)$ <i>scalar</i> registers. Register indices must be specified as decimal integer numbers.

Note. *N* and *K* must satisfy the following conditions:

- *N* must be properly aligned based on sequence size.
- $N \leq K$.
- $0 \leq N < SMAX$, where *SMAX* is the number of available *scalar* registers.
- $0 \leq K < SMAX$, where *SMAX* is the number of available *scalar* registers.
- $K-N+1$ must be equal to 1, 2, 4, 8 or 16.

Examples:

```
s0
s[0]
s[0:1]
s[1:1]
s[0:3]
s[2*2]
s[1-1:2-1]
[s4]
[s4, s5, s6, s7]
```

Examples of *scalar* registers with an invalid alignment:

```
s[1:2]
s[2:5]
```

trap

A set of trap handler registers:

- *ttmp*
- *tba*
- *tma*

ttmp

Trap handler temporary scalar registers, 32-bits wide. The number of available *ttmp* registers depends on GPU:

GPU	Number of <i>ttmp</i> registers
GFX7	12
GFX8	12
GFX9	16
GFX10	16

A sequence of *ttmp* registers may be used to operate with more than 32 bits of data. Assembler currently supports sequences of 1, 2, 4, 8 and 16 *ttmp* registers.

Pairs of *ttmp* registers must be even-aligned (the first register must be even). Sequences of 4 and more *ttmp* registers must be quad-aligned.

Syntax	Description
ttmp<N>	A single 32-bit <i>ttmp</i> register. <i>N</i> must be a decimal integer number.
ttmp[<N>]	A single 32-bit <i>ttmp</i> register. <i>N</i> may be specified as an <i>integer number</i> or an <i>absolute expression</i> .
ttmp[<N>:<K>]	A sequence of (<i>K-N+1</i>) <i>ttmp</i> registers. <i>N</i> and <i>K</i> may be specified as <i>integer numbers</i> or <i>absolute expressions</i> .
[ttmp<N>, ttmp<N+1>, ... ttmp<K>]	A sequence of (<i>K-N+1</i>) <i>ttmp</i> registers. Register indices must be specified as decimal integer numbers.

Note. *N* and *K* must satisfy the following conditions:

- *N* must be properly aligned based on sequence size.
- $N \leq K$.
- $0 \leq N < TMAX$, where *TMAX* is the number of available *ttmp* registers.
- $0 \leq K < TMAX$, where *TMAX* is the number of available *ttmp* registers.
- *K-N+1* must be equal to 1, 2, 4, 8 or 16.

Examples:

```
ttmp0
ttmp[0]
ttmp[0:1]
ttmp[1:1]
ttmp[0:3]
ttmp[2*2]
```

(continues on next page)

(continued from previous page)

```
ttmp[1-1:2-1]
[ttmp4]
[ttmp4,ttmp5,ttmp6,ttmp7]
```

Examples of *ttmp* registers with an invalid alignment:

```
ttmp[1:2]
ttmp[2:5]
```

tba

Trap base address, 64-bits wide. Holds the pointer to the current trap handler program.

Syntax	Description	Availability
<i>tba</i>	64-bit <i>trap base address</i> register.	GFX7, GFX8
[<i>tba</i>]	64-bit <i>trap base address</i> register (an alternative syntax).	GFX7, GFX8
[<i>tba_lo</i> , <i>tba_hi</i>]	64-bit <i>trap base address</i> register (an alternative syntax).	GFX7, GFX8

High and low 32 bits of *trap base address* may be accessed as separate registers:

Syntax	Description	Availability
<i>tba_lo</i>	Low 32 bits of <i>trap base address</i> register.	GFX7, GFX8
<i>tba_hi</i>	High 32 bits of <i>trap base address</i> register.	GFX7, GFX8
[<i>tba_lo</i>]	Low 32 bits of <i>trap base address</i> register (an alternative syntax).	GFX7, GFX8
[<i>tba_hi</i>]	High 32 bits of <i>trap base address</i> register (an alternative syntax).	GFX7, GFX8

Note that *tba*, *tba_lo* and *tba_hi* are not accessible as assembler registers in GFX9 and GFX10, but *tba* is readable/writable with the help of *s_get_reg* and *s_set_reg* instructions.

tma

Trap memory address, 64-bits wide.

Syntax	Description	Availability
<i>tma</i>	64-bit <i>trap memory address</i> register.	GFX7, GFX8
[<i>tma</i>]	64-bit <i>trap memory address</i> register (an alternative syntax).	GFX7, GFX8
[<i>tma_lo</i> , <i>tma_hi</i>]	64-bit <i>trap memory address</i> register (an alternative syntax).	GFX7, GFX8

High and low 32 bits of *trap memory address* may be accessed as separate registers:

Syntax	Description	Availability
<i>tma_lo</i>	Low 32 bits of <i>trap memory address</i> register.	GFX7, GFX8
<i>tma_hi</i>	High 32 bits of <i>trap memory address</i> register.	GFX7, GFX8
[<i>tma_lo</i>]	Low 32 bits of <i>trap memory address</i> register (an alternative syntax).	GFX7, GFX8
[<i>tma_hi</i>]	High 32 bits of <i>trap memory address</i> register (an alternative syntax).	GFX7, GFX8

Note that *tma*, *tma_lo* and *tma_hi* are not accessible as assembler registers in GFX9 and GFX10, but *tma* is readable/writable with the help of *s_get_reg* and *s_set_reg* instructions.

flat_scratch

Flat scratch address, 64-bits wide. Holds the base address of scratch memory.

Syntax	Description
flat_scratch	64-bit <i>flat scratch</i> address register.
[flat_scratch]	64-bit <i>flat scratch</i> address register (an alternative syntax).
[flat_scratch_lo,flat_scratch_hi]	64-bit <i>flat scratch</i> address register (an alternative syntax).

High and low 32 bits of *flat scratch* address may be accessed as separate registers:

Syntax	Description
flat_scratch_lo	Low 32 bits of <i>flat scratch</i> address register.
flat_scratch_hi	High 32 bits of <i>flat scratch</i> address register.
[flat_scratch_lo]	Low 32 bits of <i>flat scratch</i> address register (an alternative syntax).
[flat_scratch_hi]	High 32 bits of <i>flat scratch</i> address register (an alternative syntax).

xnack

Xnack mask, 64-bits wide. Holds a 64-bit mask of which threads received an *XNACK* due to a vector memory operation.

Warning: GFX7 does not support *xnack* feature. For availability of this feature in other GPUs, refer [this table](#).

Syntax	Description
xnack_mask	64-bit <i>xnack mask</i> register.
[xnack_mask]	64-bit <i>xnack mask</i> register (an alternative syntax).
[xnack_mask_lo,xnack_mask_hi]	64-bit <i>xnack mask</i> register (an alternative syntax).

High and low 32 bits of *xnack mask* may be accessed as separate registers:

Syntax	Description
xnack_mask_lo	Low 32 bits of <i>xnack mask</i> register.
xnack_mask_hi	High 32 bits of <i>xnack mask</i> register.
[xnack_mask_lo]	Low 32 bits of <i>xnack mask</i> register (an alternative syntax).
[xnack_mask_hi]	High 32 bits of <i>xnack mask</i> register (an alternative syntax).

vcc

Vector condition code, 64-bits wide. A bit mask with one bit per thread; it holds the result of a vector compare operation.

Note that GFX10 H/W does not use high 32 bits of *vcc* in *wave32* mode.

Syntax	Description
vcc	64-bit <i>vector condition code</i> register.
[vcc]	64-bit <i>vector condition code</i> register (an alternative syntax).
[vcc_lo,vcc_hi]	64-bit <i>vector condition code</i> register (an alternative syntax).

High and low 32 bits of *vector condition code* may be accessed as separate registers:

Syntax	Description
vcc_lo	Low 32 bits of <i>vector condition code</i> register.
vcc_hi	High 32 bits of <i>vector condition code</i> register.
[vcc_lo]	Low 32 bits of <i>vector condition code</i> register (an alternative syntax).
[vcc_hi]	High 32 bits of <i>vector condition code</i> register (an alternative syntax).

m0

A 32-bit memory register. It has various uses, including register indexing and bounds checking.

Syntax	Description
m0	A 32-bit <i>memory</i> register.
[m0]	A 32-bit <i>memory</i> register (an alternative syntax).

exec

Execute mask, 64-bits wide. A bit mask with one bit per thread, which is applied to vector instructions and controls which threads execute and which ignore the instruction.

Note that GFX10 H/W does not use high 32 bits of *exec* in *wave32* mode.

Syntax	Description
exec	64-bit <i>execute mask</i> register.
[exec]	64-bit <i>execute mask</i> register (an alternative syntax).
[exec_lo,exec_hi]	64-bit <i>execute mask</i> register (an alternative syntax).

High and low 32 bits of *execute mask* may be accessed as separate registers:

Syntax	Description
exec_lo	Low 32 bits of <i>execute mask</i> register.
exec_hi	High 32 bits of <i>execute mask</i> register.
[exec_lo]	Low 32 bits of <i>execute mask</i> register (an alternative syntax).
[exec_hi]	High 32 bits of <i>execute mask</i> register (an alternative syntax).

VCCZ

A single bit flag indicating that the *vcc* is all zeros.

Note. When GFX10 operates in *wave32* mode, this register reflects state of *vcc_lo*.

execz

A single bit flag indicating that the *exec* is all zeros.

Note. When GFX10 operates in *wave32* mode, this register reflects state of *exec_lo*.

scc

A single bit flag indicating the result of a scalar compare operation.

lds_direct

A special operand which supplies a 32-bit value fetched from *LDS* memory using *m0* as an address.

null

This is a special operand which may be used as a source or a destination.

When used as a destination, the result of the operation is discarded.

When used as a source, it supplies zero value.

GFX10 only.

Warning: Due to a H/W bug, this operand cannot be used with VALU instructions in first generation of GFX10.

constant

A set of integer and floating-point *inline* constants and values:

- *iconst*
- *fconst*
- *ival*

In contrast with *literals*, these operands are encoded as a part of instruction.

If a number may be encoded as either a *literal* or a *constant*, assembler selects the latter encoding as more efficient.

iconst

An *integer number* encoded as an *inline constant*.

Only a small fraction of integer numbers may be encoded as *inline constants*. They are enumerated in the table below. Other integer numbers have to be encoded as *literals*.

Integer *inline constants* are converted to *expected operand type* as described [here](#).

Value	Note
{0..64}	Positive integer inline constants.
{-16..-1}	Negative integer inline constants.

Warning: GFX7 does not support inline constants for *f16* operands.

fconst

A *floating-point number* encoded as an *inline constant*.

Only a small fraction of floating-point numbers may be encoded as *inline constants*. They are enumerated in the table below. Other floating-point numbers have to be encoded as *literals*.

Floating-point *inline constants* are converted to *expected operand type* as described [here](#).

Value	Note	Availability
0.0	The same as integer constant 0.	All GPUs
0.5	Floating-point constant 0.5	All GPUs
1.0	Floating-point constant 1.0	All GPUs
2.0	Floating-point constant 2.0	All GPUs
4.0	Floating-point constant 4.0	All GPUs
-0.5	Floating-point constant -0.5	All GPUs
-1.0	Floating-point constant -1.0	All GPUs
-2.0	Floating-point constant -2.0	All GPUs
-4.0	Floating-point constant -4.0	All GPUs
0.1592	$1.0/(2.0*\pi)$. Use only for 16-bit operands.	GFX8, GFX9, GFX10
0.15915494	$1.0/(2.0*\pi)$. Use only for 16- and 32-bit operands.	GFX8, GFX9, GFX10
0.15915494309189532	$1.0/(2.0*\pi)$.	GFX8, GFX9, GFX10

Warning: GFX7 does not support inline constants for *f16* operands.

ival

A symbolic operand encoded as an *inline constant*. These operands provide read-only access to H/W registers.

Syntax	Note	Availability
shared_base	Base address of shared memory region.	GFX9, GFX10
shared_limit	Address of the end of shared memory region.	GFX9, GFX10
private_base	Base address of private memory region.	GFX9, GFX10
private_limit	Address of the end of private memory region.	GFX9, GFX10
pops_exiting_wave_id	A dedicated counter for POPS.	GFX9, GFX10

literal

A literal is a 64-bit value which is encoded as a separate 32-bit dword in the instruction stream.

If a number may be encoded as either a *literal* or an *inline constant*, assembler selects the latter encoding as more efficient.

Literals may be specified as *integer numbers*, *floating-point numbers* or *expressions* (expressions are currently supported for 32-bit operands only).

A 64-bit literal value is converted by assembler to an *expected operand type* as described [here](#).

An instruction may use only one literal but several operands may refer the same literal.

uimm8

A 8-bit positive *integer number*. The value is encoded as part of the opcode so it is free to use.

uimm32

A 32-bit positive *integer number*. The value is stored as a separate 32-bit dword in the instruction stream.

uimm20

A 20-bit positive *integer number*.

uimm21

A 21-bit positive *integer number*.

Warning: Assembler currently supports 20-bit offsets only. Use *uimm20* as a replacement.

simm21

A 21-bit *integer number*.

Warning: Assembler currently supports 20-bit unsigned offsets only. Use *uimm20* as a replacement.

off

A special entity which indicates that the value of this operand is not used.

Syntax	Description
off	Indicates an unused operand.

Numbers

Integer Numbers

Integer numbers are 64 bits wide. They may be specified in binary, octal, hexadecimal and decimal formats:

Format	Syntax
Decimal	<code>[-]?[1-9][0-9]*</code>
Binary	<code>[-]?0b[01]+</code>
Octal	<code>[-]?0[0-7]+</code>
Hexadecimal	<code>[-]?0x[0-9a-fA-F]+</code>
	<code>[-]?[0x]?[0-9][0-9a-fA-F]*[hH]</code>

Examples:

```
-1234
0b1010
010
0xff
0ffh
```

Floating-Point Numbers

All floating-point numbers are handled as double (64 bits wide).

Floating-point numbers may be specified in hexadecimal and decimal formats:

Format	Syntax	Note
Decimal	<code>[-]?[0-9]*[.][0-9]*([eE][+-]?[0-9]*)?</code>	Must include either a decimal separator or an exponent.
Hexadecimal	<code>[-]0x[0-9a-fA-F]*([.][0-9a-fA-F]*)?[pP][+-]?[0-9a-fA-F]+</code>	

Examples:

```
-1.234
234e2
-0x1afp-10
0x.1afp10
```

Expressions

An expression specifies an address or a numeric value. There are two kinds of expressions:

- *Absolute*.
- *Relocatable*.

Absolute Expressions

The value of an absolute expression remains the same after program relocation. Absolute expressions must not include unassigned and relocatable values such as labels.

Examples:

```
x = -1
y = x + 10
```

Relocatable Expressions

The value of a relocatable expression depends on program relocation.

Note that use of relocatable expressions is limited with branch targets and 32-bit *literals*.

Addition information about relocation may be found [here](#).

Examples:

```
y = x + 10 // x is not yet defined. Undefined symbols are assumed to be PC-relative.
z = .
```

Expression Data Type

Expressions and operands of expressions are interpreted as 64-bit integers.

Expressions may include 64-bit *floating-point numbers* (double). However these operands are also handled as 64-bit integers using binary representation of specified floating-point numbers. No conversion from floating-point to integer is performed.

Examples:

```
x = 0.1 // x is assigned an integer 4591870180066957722 which is a binary
↳ representation of 0.1.
y = x + x // y is a sum of two integer values; it is not equal to 0.2!
```

Syntax

Expressions are composed of *symbols*, *integer numbers*, *floating-point numbers*, *binary operators*, *unary operators* and subexpressions.

Expressions may also use "." which is a reference to the current PC (program counter).

The syntax of expressions is shown below:

```
expr ::= expr binop expr | primaryexpr ;

primaryexpr ::= '(' expr ')' | symbol | number | '.' | unop primaryexpr ;

binop ::= '&&'
        | '|'
        | '^'
        | '&'
        | '!'
        | '=='
        | '!='
        | '<>'
        | '<'
        | '<='
        | '>'
        | '>='
        | '<<'
        | '>>'
        | '+'
        | '-'
        | '*'
        | '/'
        | '%' ;

unop ::= '~'
        | '+'
        | '-'
        | '!' ;
```

Binary Operators

Binary operators are described in the following table. They operate on and produce 64-bit integers. Operators with higher priority are performed first.

Operator	Priority	Meaning
*	5	Integer multiplication.
/	5	Integer division.
%	5	Integer signed remainder.
+	4	Integer addition.
-	4	Integer subtraction.
<<	3	Integer shift left.
>>	3	Logical shift right.
==	2	Equality comparison.
!=	2	Inequality comparison.
<>	2	Inequality comparison.
<	2	Signed less than comparison.
<=	2	Signed less than or equal comparison.
>	2	Signed greater than comparison.
>=	2	Signed greater than or equal comparison.
	1	Bitwise or.
^	1	Bitwise xor.
&	1	Bitwise and.
&&	0	Logical and.
	0	Logical or.

Unary Operators

Unary operators are described in the following table. They operate on and produce 64-bit integers.

Operator	Meaning
!	Logical negation.
~	Bitwise negation.
+	Integer unary plus.
-	Integer unary minus.

Symbols

A symbol is a named 64-bit value, representing a relocatable address or an absolute (non-relocatable) number.

Symbol names have the following syntax: [a-zA-Z_ .] [a-zA-Z0-9_\$.@]*

The table below provides several examples of syntax used for symbol definition.

Syntax	Meaning
.globl <S>	Declares a global symbol S without assigning it a value.
.set <S>, <E>	Assigns the value of an expression E to a symbol S.
<S> = <E>	Assigns the value of an expression E to a symbol S.
<S>:	Declares a label S and assigns it the current PC value.

A symbol may be used before it is declared or assigned; unassigned symbols are assumed to be PC-relative.

Addition information about symbols may be found [here](#).

Conversions

This section describes what happens when a 64-bit *integer number*, a *floating-point numbers* or a *symbol* is used for an operand which has a different type or size.

Depending on operand kind, this conversion is performed by either assembler or AMDGPU H/W:

- Values encoded as *inline constants* are handled by H/W.
- Values encoded as *literals* are converted by assembler.

Inline Constants

Integer Inline Constants

Integer *inline constants* may be thought of as 64-bit *integer numbers*; when used as operands they are truncated to the size of *expected operand type*. No data type conversions are performed.

Examples:

```
// GFX9
v_add_u16 v0, -1, 0    // v0 = 0xFFFF
v_add_f16 v0, -1, 0    // v0 = 0xFFFF (NaN)

v_add_u32 v0, -1, 0    // v0 = 0xFFFFFFFF
v_add_f32 v0, -1, 0    // v0 = 0xFFFFFFFF (NaN)
```

Floating-Point Inline Constants

Floating-point *inline constants* may be thought of as 64-bit *floating-point numbers*; when used as operands they are converted to a floating-point number of *expected operand size*.

Examples:

```
// GFX9
v_add_f16 v0, 1.0, 0    // v0 = 0x3C00 (1.0)
v_add_u16 v0, 1.0, 0    // v0 = 0x3C00

v_add_f32 v0, 1.0, 0    // v0 = 0x3F800000 (1.0)
v_add_u32 v0, 1.0, 0    // v0 = 0x3F800000
```

Literals

Integer Literals

Integer *literals* are specified as 64-bit *integer numbers*.

When used as operands they are converted to *expected operand type* as described below.

Expected type	Condition	Result	Note
i16, u16, b16	<code>cond(num, 16)</code>	<code>num.u16</code>	Truncate to 16 bits.
i32, u32, b32	<code>cond(num, 32)</code>	<code>num.u32</code>	Truncate to 32 bits.
i64	<code>cond(num, 32) & 1, num.i32</code>		Truncate to 32 bits and then sign-extend the result to 64 bits.
u64, b64	<code>cond(num, 32) & 0, num.u32</code>		Truncate to 32 bits and then zero-extend the result to 64 bits.
f16	<code>cond(num, 16)</code>	<code>num.u16</code>	Use low 16 bits as an f16 value.
f32	<code>cond(num, 32)</code>	<code>num.u32</code>	Use low 32 bits as an f32 value.
f64	<code>cond(num, 32)</code>	<code>num.u32, 0</code>	Use low 32 bits of the number as high 32 bits of the result; low 32 bits of the result are zeroed.

The condition `cond(X,S)` indicates if a 64-bit number X can be converted to a smaller size S by truncation of upper bits. There are two cases when the conversion is possible:

- The truncated bits are all 0.
- The truncated bits are all 1 and the value after truncation has its MSB bit set.

Examples of valid literals:

```
// GFX9
v_add_u16 v0, 0xff00, v0           // Literal value after conversion:
v_add_u16 v0, 0xffffffffffff00, v0 // 0xff00
v_add_u16 v0, -256, v0            // 0xff00
s_bfe_i64 s[0:1], 0xffefffff, s3   // Literal value after conversion:
s_bfe_u64 s[0:1], 0xffefffff, s3   // 0xffffffffffffefffff
v_ceil_f64_e32 v[0:1], 0xffefffff // 0x00000000ffffefffff (-1.
↪ 7976922776554302e308)
```

Examples of invalid literals:

```
// GFX9
v_add_u16 v0, 0x1ff00, v0           // truncated bits are not all 0 or 1
v_add_u16 v0, 0xffffffffffff00ff, v0 // truncated bits do not match MSB of the
↪ result
```

Floating-Point Literals

Floating-point *literals* are specified as 64-bit *floating-point numbers*.

When used as operands they are converted to *expected operand type* as described below.

Ex-pected type	Con-dition	Result	Note
i16, u16, b16	<code>cond(num.f16,num)</code>	<code>num.f16</code>	Convert to f16 and use bits of the result as an integer value.
i32, u32, b32	<code>cond(num.f32,num)</code>	<code>num.f32</code>	Convert to f32 and use bits of the result as an integer value.
i64, u64, b64	false	-	Conversion disabled because of an unclear semantics.
f16	<code>cond(num.f16,num)</code>	<code>num.f16</code>	Convert to f16.
f32	<code>cond(num.f32,num)</code>	<code>num.f32</code>	Convert to f32.
f64	true	<code>{num.u32.bits}</code>	Use high 32 bits of the number as high 32 bits of the result; zero-fill low 32 bits of the result. Note that the result may differ from the original number.

The condition `cond(X,S)` indicates if an f64 number *X* can be converted to a smaller *S*-bit floating-point type without overflow or underflow. Precision lost is allowed.

Examples of valid literals:

```
// GFX9

v_add_f16 v1, 65500.0, v2
v_add_f32 v1, 65600.0, v2

// Literal value before conversion: 1.7976931348623157e308 (0x7fefffffffffffffff)
// Literal value after conversion:  1.7976922776554302e308 (0x7feffff000000000)
v_ceil_f64 v[0:1], 1.7976931348623157e308
```

Examples of invalid literals:

```
// GFX9

v_add_f16 v1, 65600.0, v2    // overflow
```

Expressions

Expressions operate with and result in 64-bit integers.

When used as operands they are truncated to *expected operand size*. No data type conversions are performed.

Examples:

```
// GFX9

x = 0.1
v_sqrt_f32 v0, x           // v0 = [low 32 bits of 0.1 (double)]
v_sqrt_f32 v0, (0.1 + 0)   // the same as above
v_sqrt_f32 v0, 0.1         // v0 = [0.1 (double) converted to float]
```

AMDGPU Instruction Syntax

- *Instructions*
 - *Syntax*
 - *Opcode Mnemonic*
 - *Type and Size Suffices*
 - *Encoding Suffices*
- *Operands*
 - *Syntax*
- *Modifiers*
 - *Syntax*

Instructions

Syntax

An instruction has the following syntax:

<opcode mnemonic> <operand0>, <operand1>, ... <modifier0> <modifier1> ...

Operands are normally comma-separated while *modifiers* are space-separated.

The order of *operands* and *modifiers* is fixed. Most *modifiers* are optional and may be omitted.

Opcode Mnemonic

Opcode mnemonic describes opcode semantics and may include one or more suffices in this order:

- *Destination operand type suffix.*
- *Source operand type suffix.*
- *Encoding suffix.*

Type and Size Suffices

Instructions which operate with data have an implied type of *data* operands. This data type is specified as a suffix of instruction mnemonic.

There are instructions which have 2 type suffices: the first is the data type of the destination operand, the second is the data type of source *data* operand(s).

Note that data type specified by an instruction does not apply to other kinds of operands such as *addresses*, *offsets* and so on.

The following table enumerates the most frequently used type suffices.

Type Suffixes	Packed instruction?	Data Type
_b512, _b256, _b128, _b64, _b32, _b16, _b8	No	Bits.
_u64, _u32, _u16, _u8	No	Unsigned integer.
_i64, _i32, _i16, _i8	No	Signed integer.
_f64, _f32, _f16	No	Floating-point.
_b16, _u16, _i16, _f16	Yes	Packed.

Instructions which have no type suffixes are assumed to operate with typeless data. The size of data is specified by size suffixes:

Size Suffix	Implied data type	Required register size in dwords
-	b32	1
x2	b64	2
x3	b96	3
x4	b128	4
x8	b256	8
x16	b512	16
x	b32	1
xy	b64	2
xyz	b96	3
xyzw	b128	4
d16_x	b16	1
d16_xy	b16x2	2 for GFX8.0, 1 for GFX8.1 and GFX9
d16_xyz	b16x3	3 for GFX8.0, 2 for GFX8.1 and GFX9
d16_xyzw	b16x4	4 for GFX8.0, 2 for GFX8.1 and GFX9

Warning: There are exceptions from rules described above. Operands which have type different from type specified by the opcode are *tagged* in the description.

Examples of instructions with different types of source and destination operands:

```
s_bcvt0_i32_b64
v_cvt_f32_u32
```

Examples of instructions with one data type:

```
v_max3_f32
v_max3_i16
```

Examples of instructions which operate with packed data:

```
v_pk_add_u16
v_pk_add_i16
v_pk_add_f16
```

Examples of typeless instructions which operate on b128 data:

```
buffer_store_dwordx4
flat_load_dwordx4
```

Encoding Suffices

Most *VOP1*, *VOP2* and *VOPC* instructions have several variants: they may also be encoded in *VOP3*, *DPP* and *SDWA* formats.

The assembler will automatically use optimal encoding based on instruction operands. To force specific encoding, one can add a suffix to the opcode of the instruction:

Encoding	Encoding Suffix
Native 32-bit encoding (<i>VOP1</i> , <i>VOP2</i> or <i>VOPC</i>)	<code>_e32</code>
<i>VOP3</i> (64-bit) encoding	<code>_e64</code>
<i>DPP</i> encoding	<code>_dpp</code>
<i>SDWA</i> encoding	<code>_sdwa</code>

These suffices are used in this reference to indicate the assumed encoding. When no suffix is specified, a native encoding is implied.

Operands

Syntax

Syntax of most operands is described *in this document*.

For detailed information about operands follow *operand links* in GPU-specific documents:

- [GFX7](#)
- [GFX8](#)
- [GFX9](#)
- [GFX10](#)

Modifiers

Syntax

Syntax of modifiers is described *in this document*.

Information about modifiers supported for individual instructions may be found in GPU-specific documents:

- [GFX10](#)

AMDGPU Instructions Notation

- *Introduction*
- *Instructions*
 - *Notation*
- *Opcode*
 - *Notation*
- *Operands*
 - *Notation*
- *Modifiers*
 - *Notation*

Introduction

This is an overview of notation used to describe the syntax of AMDGPU assembler instructions.

This notation mimics the *syntax of assembler instructions* except that instead of real operands and modifiers it provides references to their description.

Instructions

Notation

This is the notation used to describe AMDGPU instructions:

<opcode description> <operands description> <modifiers description>

Opcode

Notation

TBD

Operands

An instruction may have zero or more *operands*. They are comma-separated in the description:

<description of operand 0>, <description of operand 1>, ...

The order of *operands* is fixed. *Operands* cannot be omitted except for special cases described below.

Notation

An operand is described using the following notation:

`<name><tag0><tag1>...`

Where:

- *name* is a link to a description of the operand.
- *tags* are optional. They are used to indicate special operand properties:

Operand tag	Meaning
:opt	An optional operand.
:m	An operand which may be used with <i>VOP3 operand modifiers</i> or <i>SDWA operand modifiers</i> .
:dst	An input operand which may also serve as a destination if <i>glc</i> modifier is specified.
:fx	This is an <i>f32</i> or <i>f16</i> operand depending on <i>m_op_sel_hi</i> modifier.
:<type>	Operand <i>type</i> differs from <i>type implied by the opcode name</i> . This tag specifies actual operand <i>type</i> .

Examples:

```
src1:m           // src1 operand may be used with operand modifiers
vdata:dst        // vdata operand may be used as both source and destination
vdst:u32         // vdst operand has u32 type
```

Modifiers

An instruction may have zero or more optional *modifiers*. They are space-separated in the description:

`<description of modifier 0> <description of modifier 1> ...`

The order of *modifiers* is fixed.

Notation

A *modifier* is described using the following notation:

`<name>`

Where *name* is a link to a description of the *modifier*.

An instruction has the following *syntax*:

`<opcode> <operand0>, <operand1>, ... <modifier0> <modifier1> ...`

Operands are normally comma-separated while *modifiers* are space-separated.

The order of *operands* and *modifiers* is fixed. Most *modifiers* are optional and may be omitted.

See detailed instruction syntax description for *GFX7*, *GFX8*, *GFX9* and *GFX10*.

Note that features under development are not included in this description.

For more information about instructions, their semantics and supported combinations of operands, refer to one of instruction set architecture manuals [AMD-GCN-GFX6], [AMD-GCN-GFX7], [AMD-GCN-GFX8], [AMD-GCN-GFX9] and [AMD-GCN-GFX10].

Operands

Detailed description of operands may be found [here](#).

Modifiers

Detailed description of modifiers may be found [here](#).

Instruction Examples

DS

```
ds_add_u32 v2, v4 offset:16
ds_write_src2_b64 v2 offset0:4 offset1:8
ds_cmpst_f32 v2, v4, v6
ds_min_rtn_f64 v[8:9], v2, v[4:5]
```

For full list of supported instructions, refer to "LDS/GDS instructions" in ISA Manual.

FLAT

```
flat_load_dword v1, v[3:4]
flat_store_dwordx3 v[3:4], v[5:7]
flat_atomic_swap v1, v[3:4], v5 glc
flat_atomic_cmpswap v1, v[3:4], v[5:6] glc slc
flat_atomic_fmax_x2 v[1:2], v[3:4], v[5:6] glc
```

For full list of supported instructions, refer to "FLAT instructions" in ISA Manual.

MUBUF

```
buffer_load_dword v1, off, s[4:7], s1
buffer_store_dwordx4 v[1:4], v2, ttmp[4:7], s1 offen offset:4 glc tfe
buffer_store_format_xy v[1:2], off, s[4:7], s1
buffer_wbinvl1
buffer_atomic_inc v1, v2, s[8:11], s4 idxen offset:4 slc
```

For full list of supported instructions, refer to "MUBUF Instructions" in ISA Manual.

SMRD/SMEM

```
s_load_dword s1, s[2:3], 0xfc
s_load_dwordx8 s[8:15], s[2:3], s4
s_load_dwordx16 s[88:103], s[2:3], s4
s_dcache_inv_vol
s_mentime s[4:5]
```

For full list of supported instructions, refer to "Scalar Memory Operations" in ISA Manual.

SOP1

```
s_mov_b32 s1, s2
s_mov_b64 s[0:1], 0x80000000
s_cmov_b32 s1, 200

s_andn2_b32 s2, s4, s6
s_lshr_b64 s[2:3], s[4:5], s6
s_ashr_i32 s2, s4, s6
s_bfm_b64 s[2:3], s4, s6
s_bfe_i64 s[2:3], s[4:5], s6
s_cbranch_g_fork s[4:5], s[6:7]
```

For full list of supported instructions, refer to "SOP2 Instructions" in ISA Manual.

SOPC

```
s_cmp_eq_i32 s1, s2
s_bitcmp1_b32 s1, s2
s_bitcmp0_b64 s[2:3], s4
s_setvskip s3, s5
```

For full list of supported instructions, refer to "SOPC Instructions" in ISA Manual.

SOPP

```
s_barrier
s_nop 2
s_endpgm
s_waitcnt 0 ; Wait for all counters to be 0
s_waitcnt vmcnt(0) & expcnt(0) & lgkmcnt(0) ; Equivalent to above
s_waitcnt vmcnt(1) ; Wait for vmcnt counter to be 1.
s_sethalt 9
s_sleep 10
s_sendmsg 0x1
s_sendmsg sendmsg(MSG_INTERRUPT)
s_trap 1
```

For full list of supported instructions, refer to "SOPP Instructions" in ISA Manual.

Unless otherwise mentioned, little verification is performed on the operands of SOPP Instructions, so it is up to the programmer to be familiar with the range or acceptable values.

VALU

For vector ALU instruction opcodes (VOP1, VOP2, VOP3, VOPC, VOP_DPP, VOP_SDWA), the assembler will automatically use optimal encoding based on its operands. To force specific encoding, one can add a suffix to the opcode of the instruction:

- `_e32` for 32-bit VOP1/VOP2/VOPC
- `_e64` for 64-bit VOP3
- `_dpp` for VOP_DPP
- `_sdwa` for VOP_SDWA

VOP1/VOP2/VOP3/VOPC examples:

```
v_mov_b32 v1, v2
v_mov_b32_e32 v1, v2
v_nop
v_cvt_f64_i32_e32 v[1:2], v2
v_floor_f32_e32 v1, v2
v_bfrev_b32_e32 v1, v2
v_add_f32_e32 v1, v2, v3
v_mul_i32_i24_e64 v1, v2, 3
v_mul_i32_i24_e32 v1, -3, v3
v_mul_i32_i24_e32 v1, -100, v3
v_addc_u32 v1, s[0:1], v2, v3, s[2:3]
v_max_f16_e32 v1, v2, v3
```

VOP_DPP examples:

```
v_mov_b32 v0, v0 quad_perm:[0,2,1,1]
v_sin_f32 v0, v0 row_shl:1 row_mask:0xa bank_mask:0x1 bound_ctrl:0
v_mov_b32 v0, v0 wave_shl:1
v_mov_b32 v0, v0 row_mirror
v_mov_b32 v0, v0 row_bcast:31
v_mov_b32 v0, v0 quad_perm:[1,3,0,1] row_mask:0xa bank_mask:0x1 bound_ctrl:0
v_add_f32 v0, v0, |v0| row_shl:1 row_mask:0xa bank_mask:0x1 bound_ctrl:0
v_max_f16 v1, v2, v3 row_shl:1 row_mask:0xa bank_mask:0x1 bound_ctrl:0
```

VOP_SDWA examples:

```
v_mov_b32 v1, v2 dst_sel:BYTE_0 dst_unused:UNUSED_PRESERVE src0_sel:DWORD
v_min_u32 v200, v200, v1 dst_sel:WORD_1 dst_unused:UNUSED_PAD src0_sel:BYTE_1 src1_
↪sel:DWORD
v_sin_f32 v0, v0 dst_unused:UNUSED_PAD src0_sel:WORD_1
v_fract_f32 v0, |v0| dst_sel:DWORD dst_unused:UNUSED_PAD src0_sel:WORD_1
v_cmpx_le_u32 vcc, v1, v2 src0_sel:BYTE_2 src1_sel:WORD_0
```

For full list of supported instructions, refer to "Vector ALU instructions".

Code Object V2 Predefined Symbols (-mattr=code-object-v3)

Warning: Code Object V2 is not the default code object version emitted by this version of LLVM. For a description of the predefined symbols available with the default configuration (Code Object V3) see [Code Object V3 Predefined Symbols \(-mattr=+code-object-v3\)](#).

The AMDGPU assembler defines and updates some symbols automatically. These symbols do not affect code generation.

.option.machine_version_major

Set to the GFX major generation number of the target being assembled for. For example, when assembling for a "GFX9" target this will be set to the integer value "9". The possible GFX major generation numbers are presented in *Processors*.

.option.machine_version_minor

Set to the GFX minor generation number of the target being assembled for. For example, when assembling for a "GFX810" target this will be set to the integer value "1". The possible GFX minor generation numbers are presented in *Processors*.

.option.machine_version_stepping

Set to the GFX stepping generation number of the target being assembled for. For example, when assembling for a "GFX704" target this will be set to the integer value "4". The possible GFX stepping generation numbers are presented in *Processors*.

.kernel.vgpr_count

Set to zero each time a `.amdgpu_hsa_kernel (name)` directive is encountered. At each instruction, if the current value of this symbol is less than or equal to the maximum VPGR number explicitly referenced within that instruction then the symbol value is updated to equal that VGPR number plus one.

.kernel.sgpr_count

Set to zero each time a `.amdgpu_hsa_kernel (name)` directive is encountered. At each instruction, if the current value of this symbol is less than or equal to the maximum VPGR number explicitly referenced within that instruction then the symbol value is updated to equal that SGPR number plus one.

Code Object V2 Directives (-mattr=-code-object-v3)

Warning: Code Object V2 is not the default code object version emitted by this version of LLVM. For a description of the directives supported with the default configuration (Code Object V3) see [Code Object V3 Directives \(-mattr=+code-object-v3\)](#).

AMDGPU ABI defines auxiliary data in output code object. In assembly source, one can specify them with assembler directives.

.hsa_code_object_version major, minor

major and *minor* are integers that specify the version of the HSA code object that will be generated by the assembler.

.hsa_code_object_isa [major, minor, stepping, vendor, arch]

major, *minor*, and *stepping* are all integers that describe the instruction set architecture (ISA) version of the assembly program.

vendor and *arch* are quoted strings. *vendor* should always be equal to "AMD" and *arch* should always be equal to "AMDGPU".

By default, the assembler will derive the ISA version, *vendor*, and *arch* from the value of the `-mcpu` option that is passed to the assembler.

.amdgpu_hsa_kernel (name)

This directives specifies that the symbol with given name is a kernel entry point (label) and the object should contain corresponding symbol of type STT_AMDGPU_HSA_KERNEL.

.amd_kernel_code_t

This directive marks the beginning of a list of key / value pairs that are used to specify the `amd_kernel_code_t` object that will be emitted by the assembler. The list must be terminated by the `.end_amd_kernel_code_t` directive. For any `amd_kernel_code_t` values that are unspecified a default value will be used. The default value for all keys is 0, with the following exceptions:

- `amd_code_version_major` defaults to 1.
- `amd_kernel_code_version_minor` defaults to 2.
- `amd_machine_kind` defaults to 1.
- `amd_machine_version_major`, `machine_version_minor`, and `amd_machine_version_stepping` are derived from the value of the `-mcpu` option that is passed to the assembler.

- *kernel_code_entry_byte_offset* defaults to 256.
- *wavefront_size* defaults 6 for all targets before GFX10. For GFX10 onwards defaults to 6 if target feature *wavefrontsize64* is enabled, otherwise 5. Note that wavefront size is specified as a power of two, so a value of *n* means a size of 2^n .
- *call_convention* defaults to -1.
- *kernarg_segment_alignment*, *group_segment_alignment*, and *private_segment_alignment* default to 4. Note that alignments are specified as a power of 2, so a value of *n* means an alignment of 2^n .
- *enable_wgp_mode* defaults to 1 if target feature *cumode* is disabled for GFX10 onwards.
- *enable_mem_ordered* defaults to 1 for GFX10 onwards.

The *.amd_kernel_code_t* directive must be placed immediately after the function label and before any instructions.

For a full list of *amd_kernel_code_t* keys, refer to AMDGPU ABI document, comments in `lib/Target/AMDGPU/AmdKernelCodeT.h` and `test/CodeGen/AMDGPU/hsa.s`.

Code Object V2 Example Source Code (-mattr=-code-object-v3)

Warning: Code Object V2 is not the default code object version emitted by this version of LLVM. For a description of the directives supported with the default configuration (Code Object V3) see [Code Object V3 Example Source Code \(-mattr=+code-object-v3\)](#).

Here is an example of a minimal assembly source file, defining one HSA kernel:

```
.hsa_code_object_version 1,0
.hsa_code_object_isa

.hsatext
.globl hello_world
.p2align 8
.amdgpu_hsa_kernel hello_world

hello_world:

    .amd_kernel_code_t
        enable_sgpr_kernarg_segment_ptr = 1
        is_ptr64 = 1
        compute_pgm_rsrc1_vgprs = 0
        compute_pgm_rsrc1_sgprs = 0
        compute_pgm_rsrc2_user_sgpr = 2
        compute_pgm_rsrc1_wgp_mode = 0
        compute_pgm_rsrc1_mem_ordered = 0
        compute_pgm_rsrc1_fwd_progress = 1
    .end_amd_kernel_code_t

    s_load_dwordx2 s[0:1], s[0:1] 0x0
    v_mov_b32 v0, 3.14159
    s_waitcnt lgkmcnt(0)
    v_mov_b32 v1, s0
    v_mov_b32 v2, s1
    flat_store_dword v[1:2], v0
    s_endpgm
```

(continues on next page)

(continued from previous page)

```
.Lfunc_end0:  
    .size    hello_world, .Lfunc_end0-hello_world
```

Code Object V3 Predefined Symbols (-mattr=+code-object-v3)

The AMDGPU assembler defines and updates some symbols automatically. These symbols do not affect code generation.

.amdgcgcn.gfx_generation_number

Set to the GFX major generation number of the target being assembled for. For example, when assembling for a "GFX9" target this will be set to the integer value "9". The possible GFX major generation numbers are presented in *Processors*.

.amdgcgcn.gfx_generation_minor

Set to the GFX minor generation number of the target being assembled for. For example, when assembling for a "GFX810" target this will be set to the integer value "1". The possible GFX minor generation numbers are presented in *Processors*.

.amdgcgcn.gfx_generation_stepping

Set to the GFX stepping generation number of the target being assembled for. For example, when assembling for a "GFX704" target this will be set to the integer value "4". The possible GFX stepping generation numbers are presented in *Processors*.

.amdgcgcn.next_free_vgpr

Set to zero before assembly begins. At each instruction, if the current value of this symbol is less than or equal to the maximum VGPR number explicitly referenced within that instruction then the symbol value is updated to equal that VGPR number plus one.

May be used to set the *.amdhsa_next_free_vgpr* directive in *AMDHSA Kernel Assembler Directives*.

May be set at any time, e.g. manually set to zero at the start of each kernel.

.amdgcgcn.next_free_sgpr

Set to zero before assembly begins. At each instruction, if the current value of this symbol is less than or equal to the maximum SGPR number explicitly referenced within that instruction then the symbol value is updated to equal that SGPR number plus one.

May be used to set the *.amdhsa_next_free_sgpr* directive in *AMDHSA Kernel Assembler Directives*.

May be set at any time, e.g. manually set to zero at the start of each kernel.

Code Object V3 Directives (-mattr=+code-object-v3)

Directives which begin with `.amdgc`n are valid for all `amdgc`n architecture processors, and are not OS-specific. Directives which begin with `.amdhsa` are specific to `amdgc`n architecture processors when the `amdhsa` OS is specified. See *Target Triples* and *Processors*.

`.amdgc`n_target <target>

Optional directive which declares the target supported by the containing assembler source file. Valid values are described in *Code Object Target Identification*. Used by the assembler to validate command-line options such as `-triple`, `-mcpu`, and those which specify target features.

`.amdhsa`_kernel <name>

Creates a correctly aligned AMDHSA kernel descriptor and a symbol, `<name>.kd`, in the current location of the current section. Only valid when the OS is `amdhsa`. `<name>` must be a symbol that labels the first instruction to execute, and does not need to be previously defined.

Marks the beginning of a list of directives used to generate the bytes of a kernel descriptor, as described in *Kernel Descriptor*. Directives which may appear in this list are described in *AMDHSA Kernel Assembler Directives*. Directives may appear in any order, must be valid for the target being assembled for, and cannot be repeated. Directives support the range of values specified by the field they reference in *Kernel Descriptor*. If a directive is not specified, it is assumed to have its default value, unless it is marked as "Required", in which case it is an error to omit the directive. This list of directives is terminated by an `.end_amdhsa_kernel` directive.

Directive	Default	Support
<code>.amdhsa_group_segment_fixed_size</code>	0	GFX6-
<code>.amdhsa_private_segment_fixed_size</code>	0	GFX6-

`.amdgpu_metadata`

Optional directive which declares the contents of the NT_AMDGPU_METADATA note record (see *AMDGPU Code Object V3 ELF Note Records*).

The contents must be in the [YAML] markup format, with the same structure and semantics described in *Code Object V3 Metadata (-mattr+=code-object-v3)*.

This directive is terminated by an `.end_amdgpu_metadata` directive.

Code Object V3 Example Source Code (-mattr+=code-object-v3)

Here is an example of a minimal assembly source file, defining one HSA kernel:

```
.amdgc_target "amdgc-aml-amdhsa--gfx900+xnack" // optional

.text
.globl hello_world
.p2align 8
.type hello_world,@function
hello_world:
    s_load_dwordx2 s[0:1], s[0:1] 0x0
    v_mov_b32 v0, 3.14159
    s_waitcnt lgkmcnt(0)
    v_mov_b32 v1, s0
    v_mov_b32 v2, s1
    flat_store_dword v[1:2], v0
    s_endpgm
.Lfunc_end0:
    .size    hello_world, .Lfunc_end0-hello_world

.rodata
.p2align 6
```

(continues on next page)

(continued from previous page)

```
.amdhsa_kernel hello_world
    .amdhsa_user_sgpr_kernarg_segment_ptr 1
    .amdhsa_next_free_vgpr .amdgcnext_free_vgpr
    .amdhsa_next_free_sgpr .amdgcnext_free_sgpr
.end_amdhsa_kernel

.amdgpu_metadata
---
amdhsa.version:
- 1
- 0
amdhsa.kernels:
- .name: hello_world
  .symbol: hello_world.kd
  .kernarg_segment_size: 48
  .group_segment_fixed_size: 0
  .private_segment_fixed_size: 0
  .kernarg_segment_align: 4
  .wavefront_size: 64
  .sgpr_count: 2
  .vgpr_count: 3
  .max_flat_workgroup_size: 256
...
.end_amdgpu_metadata
```

If an assembly source file contains multiple kernels and/or functions, the *.amdgcnext_free_vgpr* and *.amdgcnext_free_sgpr* symbols may be reset using the *.set <symbol>, <expression>* directive. For example, in the case of two kernels, where function1 is only called from kernell it is sufficient to group the function with the kernel that calls it and reset the symbols between the two connected components:

```
.amdgcnext_target "amdgcnext-amd-amdhsa--gfx900+xnack" // optional

// gpr tracking symbols are implicitly set to zero

.text
.globl kern0
.p2align 8
.type kern0,@function
kern0:
    // ...
    s_endpgm
.Lkern0_end:
    .size kern0, .Lkern0_end-kern0

.rodata
.p2align 6
.amdhsa_kernel kern0
    // ...
    .amdhsa_next_free_vgpr .amdgcnext_free_vgpr
    .amdhsa_next_free_sgpr .amdgcnext_free_sgpr
.end_amdhsa_kernel

// reset symbols to begin tracking usage in func1 and kern1
.set .amdgcnext_free_vgpr, 0
.set .amdgcnext_free_sgpr, 0
```

(continues on next page)

(continued from previous page)

```

.text
.hidden func1
.global func1
.p2align 2
.type func1,@function
func1:
    // ...
    s_setpc_b64 s[30:31]
.Lfunc1_end:
.size func1, .Lfunc1_end-func1

.globl kern1
.p2align 8
.type kern1,@function
kern1:
    // ...
    s_getpc_b64 s[4:5]
    s_add_u32 s4, s4, func1@rel32@lo+4
    s_addc_u32 s5, s5, func1@rel32@lo+4
    s_swappc_b64 s[30:31], s[4:5]
    // ...
    s_endpgm
.Lkern1_end:
.size kern1, .Lkern1_end-kern1

.rodata
.p2align 6
.amdhsa_kernel kern1
    // ...
    .amdhsa_next_free_vgpr .amdgcnext_free_vgpr
    .amdhsa_next_free_sgpr .amdgcnext_free_sgpr
.end_amdhsa_kernel

```

These symbols cannot identify connected components in order to automatically track the usage for each kernel. However, in some cases careful organization of the kernels and functions in the source file means there is minimal additional effort required to accurately calculate GPR usage.

4.26.6 Additional Documentation

4.27 Stack maps and patch points in LLVM

- *Definitions*
- *Motivation*
- *Intrinsics*
 - *'llvm.experimental.stackmap' Intrinsic*
 - *'llvm.experimental.patchpoint.*' Intrinsic*
- *Stack Map Format*
 - *Stack Map Section*

- *Stack Map Usage*
 - *Direct Stack Map Entries*
- *Supported Architectures*

4.27.1 Definitions

In this document we refer to the "runtime" collectively as all components that serve as the LLVM client, including the LLVM IR generator, object code consumer, and code patcher.

A stack map records the location of `live values` at a particular instruction address. These `live values` do not refer to all the LLVM values live across the stack map. Instead, they are only the values that the runtime requires to be live at this point. For example, they may be the values the runtime will need to resume program execution at that point independent of the compiled function containing the stack map.

LLVM emits stack map data into the object code within a designated *Stack Map Section*. This stack map data contains a record for each stack map. The record stores the stack map's instruction address and contains an entry for each mapped value. Each entry encodes a value's location as a register, stack offset, or constant.

A patch point is an instruction address at which space is reserved for patching a new instruction sequence at run time. Patch points look much like calls to LLVM. They take arguments that follow a calling convention and may return a value. They also imply stack map generation, which allows the runtime to locate the patchpoint and find the location of `live values` at that point.

4.27.2 Motivation

This functionality is currently experimental but is potentially useful in a variety of settings, the most obvious being a runtime (JIT) compiler. Example applications of the patchpoint intrinsics are implementing an inline call cache for polymorphic method dispatch or optimizing the retrieval of properties in dynamically typed languages such as JavaScript.

The intrinsics documented here are currently used by the JavaScript compiler within the open source WebKit project, see the [FTL JIT](#), but they are designed to be used whenever stack maps or code patching are needed. Because the intrinsics have experimental status, compatibility across LLVM releases is not guaranteed.

The stack map functionality described in this document is separate from the functionality described in *Computing stack maps*. *GCFUNCTIONMetadata* provides the location of pointers into a collected heap captured by the *GCRoot* intrinsic, which can also be considered a "stack map". Unlike the stack maps defined above, the *GCFUNCTIONMetadata* stack map interface does not provide a way to associate live register values of arbitrary type with an instruction address, nor does it specify a format for the resulting stack map. The stack maps described here could potentially provide richer information to a garbage collecting runtime, but that usage will not be discussed in this document.

4.27.3 Intrinsics

The following two kinds of intrinsics can be used to implement stack maps and patch points: `llvm.experimental.stackmap` and `llvm.experimental.patchpoint`. Both kinds of intrinsics generate a stack map record, and they both allow some form of code patching. They can be used independently (i.e. `llvm.experimental.patchpoint` implicitly generates a stack map without the need for an additional call to `llvm.experimental.stackmap`). The choice of which to use depends on whether it is necessary to reserve space for code patching and whether any of the intrinsic arguments should be lowered according to calling conventions. `llvm.experimental.stackmap` does not reserve any space, nor does it expect any call arguments. If the runtime patches code at the stack map's address, it will destructively overwrite the program text. This is unlike `llvm.experimental.patchpoint`, which reserves space for in-place patching without overwriting surrounding code.

The `llvm.experimental.patchpoint` intrinsic also lowers a specified number of arguments according to its calling convention. This allows patched code to make in-place function calls without marshaling.

Each instance of one of these intrinsics generates a stack map record in the [Stack Map Section](#). The record includes an ID, allowing the runtime to uniquely identify the stack map, and the offset within the code from the beginning of the enclosing function.

'llvm.experimental.stackmap' Intrinsic

Syntax:

```
declare void
  @llvm.experimental.stackmap(i64 <id>, i32 <numShadowBytes>, ...)
```

Overview:

The `'llvm.experimental.stackmap'` intrinsic records the location of specified values in the stack map without generating any code.

Operands:

The first operand is an ID to be encoded within the stack map. The second operand is the number of shadow bytes following the intrinsic. The variable number of operands that follow are the `live` values for which locations will be recorded in the stack map.

To use this intrinsic as a bare-bones stack map, with no code patching support, the number of shadow bytes can be set to zero.

Semantics:

The stack map intrinsic generates no code in place, unless nops are needed to cover its shadow (see below). However, its offset from function entry is stored in the stack map. This is the relative instruction address immediately following the instructions that precede the stack map.

The stack map ID allows a runtime to locate the desired stack map record. LLVM passes this ID through directly to the stack map record without checking uniqueness.

LLVM guarantees a shadow of instructions following the stack map's instruction offset during which neither the end of the basic block nor another call to `llvm.experimental.stackmap` or `llvm.experimental.patchpoint` may occur. This allows the runtime to patch the code at this point in response to an event triggered from outside the code. The code for instructions following the stack map may be emitted in the stack map's shadow, and these instructions may be overwritten by destructive patching. Without shadow bytes, this destructive patching could overwrite program text or data outside the current function. We disallow overlapping stack map shadows so that the runtime does not need to consider this corner case.

For example, a stack map with 8 byte shadow:

```
call void @runtime()
call void (i64, i32, ...) * @llvm.experimental.stackmap(i64 77, i32 8,
                                                         i64* %ptr)
%val = load i64* %ptr
```

(continues on next page)

(continued from previous page)

```
%add = add i64 %val, 3
ret i64 %add
```

May require one byte of nop-padding:

```
0x00 callq _runtime
0x05 nop          <--- stack map address
0x06 movq (%rdi), %rax
0x07 addq $3, %rax
0x0a popq %rdx
0x0b ret          <---- end of 8-byte shadow
```

Now, if the runtime needs to invalidate the compiled code, it may patch 8 bytes of code at the stack map's address at follows:

```
0x00 callq _runtime
0x05 movl $0xffff, %rax <--- patched code at stack map address
0x0a callq *%rax          <---- end of 8-byte shadow
```

This way, after the normal call to the runtime returns, the code will execute a patched call to a special entry point that can rebuild a stack frame from the values located by the stack map.

'llvm.experimental.patchpoint.*' Intrinsic

Syntax:

```
declare void
  @llvm.experimental.patchpoint.void(i64 <id>, i32 <numBytes>,
                                     i8* <target>, i32 <numArgs>, ...)
declare i64
  @llvm.experimental.patchpoint.i64(i64 <id>, i32 <numBytes>,
                                     i8* <target>, i32 <numArgs>, ...)
```

Overview:

The 'llvm.experimental.patchpoint.*' intrinsics creates a function call to the specified <target> and records the location of specified values in the stack map.

Operands:

The first operand is an ID, the second operand is the number of bytes reserved for the patchable region, the third operand is the target address of a function (optionally null), and the fourth operand specifies how many of the following variable operands are considered function call arguments. The remaining variable number of operands are the live values for which locations will be recorded in the stack map.

Semantics:

The patch point intrinsic generates a stack map. It also emits a function call to the address specified by `<target>` if the address is not a constant null. The function call and its arguments are lowered according to the calling convention specified at the intrinsic's callsite. Variants of the intrinsic with non-void return type also return a value according to calling convention.

On PowerPC, note that `<target>` must be the ABI function pointer for the intended target of the indirect call. Specifically, when compiling for the ELF V1 ABI, `<target>` is the function-descriptor address normally used as the C/C++ function-pointer representation.

Requesting zero patch point arguments is valid. In this case, all variable operands are handled just like `llvm.experimental.stackmap.*`. The difference is that space will still be reserved for patching, a call will be emitted, and a return value is allowed.

The location of the arguments are not normally recorded in the stack map because they are already fixed by the calling convention. The remaining live values will have their location recorded, which could be a register, stack location, or constant. A special calling convention has been introduced for use with stack maps, `anyregcc`, which forces the arguments to be loaded into registers but allows those register to be dynamically allocated. These argument registers will have their register locations recorded in the stack map in addition to the remaining live values.

The patch point also emits nops to cover at least `<numBytes>` of instruction encoding space. Hence, the client must ensure that `<numBytes>` is enough to encode a call to the target address on the supported targets. If the call target is constant null, then there is no minimum requirement. A zero-byte null target patchpoint is valid.

The runtime may patch the code emitted for the patch point, including the call sequence and nops. However, the runtime may not assume anything about the code LLVM emits within the reserved space. Partial patching is not allowed. The runtime must patch all reserved bytes, padding with nops if necessary.

This example shows a patch point reserving 15 bytes, with one argument in `$rdi`, and a return value in `$rax` per native calling convention:

```
%target = inttoptr i64 -281474976710654 to i8*
%val = call i64 (i64, i32, ...) *
      @llvm.experimental.patchpoint.i64(i64 78, i32 15,
                                         i8* %target, i32 1, i64* %ptr)
%add = add i64 %val, 3
ret i64 %add
```

May generate:

```
0x00 movabsq $0xffff000000000002, %r11 <--- patch point address
0x0a callq   *%r11
0x0d nop
0x0e nop
0x0f addq    $0x3, %rax
0x10 movl    %rax, 8(%rsp)
<--- end of reserved 15-bytes
```

Note that no stack map locations will be recorded. If the patched code sequence does not need arguments fixed to specific calling convention registers, then the `anyregcc` convention may be used:

```
%val = call anyregcc @llvm.experimental.patchpoint(i64 78, i32 15,
                                                    i8* %target, i32 1,
                                                    i64* %ptr)
```

The stack map now indicates the location of the `%ptr` argument and return value:

```
Stack Map: ID=78, Loc0=%r9 Loc1=%r8
```

The patch code sequence may now use the argument that happened to be allocated in `%r8` and return a value allocated in `%r9`:

```
0x00 movslq 4(%r8) %r9          <--- patched code at patch point address
0x03 nop
...
0x0e nop                        <--- end of reserved 15-bytes
0x0f addq    $0x3, %r9
0x10 movl    %r9, 8(%rsp)
```

4.27.4 Stack Map Format

The existence of a stack map or patch point intrinsic within an LLVM Module forces code emission to create a *Stack Map Section*. The format of this section follows:

```
Header {
    uint8  : Stack Map Version (current version is 3)
    uint8  : Reserved (expected to be 0)
    uint16 : Reserved (expected to be 0)
}
uint32 : NumFunctions
uint32 : NumConstants
uint32 : NumRecords
StkSizeRecord[NumFunctions] {
    uint64 : Function Address
    uint64 : Stack Size
    uint64 : Record Count
}
Constants[NumConstants] {
    uint64 : LargeConstant
}
StkMapRecord[NumRecords] {
    uint64 : PatchPoint ID
    uint32 : Instruction Offset
    uint16 : Reserved (record flags)
    uint16 : NumLocations
    Location[NumLocations] {
        uint8  : Register | Direct | Indirect | Constant | ConstantIndex
        uint8  : Reserved (expected to be 0)
        uint16 : Location Size
        uint16 : Dwarf RegNum
        uint16 : Reserved (expected to be 0)
        int32  : Offset or SmallConstant
    }
    uint32 : Padding (only if required to align to 8 byte)
    uint16 : Padding
    uint16 : NumLiveOuts
    LiveOuts[NumLiveOuts]
        uint16 : Dwarf RegNum
        uint8  : Reserved
        uint8  : Size in Bytes
    }
    uint32 : Padding (only if required to align to 8 byte)
}
```

The first byte of each location encodes a type that indicates how to interpret the `RegNum` and `Offset` fields as follows:

Encoding	Type	Value	Description
0x1	Register	Reg	Value in a register
0x2	Direct	Reg + Offset	Frame index value
0x3	Indirect	[Reg + Offset]	Spilled value
0x4	Constant	Offset	Small constant
0x5	ConstIndex	Constants[Offset]	Large constant

In the common case, a value is available in a register, and the `Offset` field will be zero. Values spilled to the stack are encoded as `Indirect` locations. The runtime must load those values from a stack address, typically in the form `[BP + Offset]`. If an `alloca` value is passed directly to a stack map intrinsic, then LLVM may fold the frame index into the stack map as an optimization to avoid allocating a register or stack slot. These frame indices will be encoded as `Direct` locations in the form `BP + Offset`. LLVM may also optimize constants by emitting them directly in the stack map, either in the `Offset` of a `Constant` location or in the constant pool, referred to by `ConstIndex` locations.

At each callsite, a "liveout" register list is also recorded. These are the registers that are live across the stackmap and therefore must be saved by the runtime. This is an important optimization when the patchpoint intrinsic is used with a calling convention that by default preserves most registers as callee-save.

Each entry in the liveout register list contains a DWARF register number and size in bytes. The stackmap format deliberately omits specific subregister information. Instead the runtime must interpret this information conservatively. For example, if the stackmap reports one byte at `%rax`, then the value may be in either `%al` or `%ah`. It doesn't matter in practice, because the runtime will simply save `%rax`. However, if the stackmap reports 16 bytes at `%ymm0`, then the runtime can safely optimize by saving only `%xmm0`.

The stack map format is a contract between an LLVM SVN revision and the runtime. It is currently experimental and may change in the short term, but minimizing the need to update the runtime is important. Consequently, the stack map design is motivated by simplicity and extensibility. Compactness of the representation is secondary because the runtime is expected to parse the data immediately after compiling a module and encode the information in its own format. Since the runtime controls the allocation of sections, it can reuse the same stack map space for multiple modules.

Stackmap support is currently only implemented for 64-bit platforms. However, a 32-bit implementation should be able to use the same format with an insignificant amount of wasted space.

Stack Map Section

A JIT compiler can easily access this section by providing its own memory manager via the LLVM C API `LLVMCreateSimpleMCJITMemoryManager()`. When creating the memory manager, the JIT provides a callback: `LLVMMemoryManagerAllocateDataSectionCallback()`. When LLVM creates this section, it invokes the callback and passes the section name. The JIT can record the in-memory address of the section at this time and later parse it to recover the stack map data.

For MachO (e.g. on Darwin), the stack map section name is `"__llvm_stackmaps"`. The segment name is `"__LLVM_STACKMAPS"`.

For ELF (e.g. on Linux), the stack map section name is `".llvm_stackmaps"`. The segment name is `"__LLVM_STACKMAPS"`.

4.27.5 Stack Map Usage

The stack map support described in this document can be used to precisely determine the location of values at a specific position in the code. LLVM does not maintain any mapping between those values and any higher-level entity. The runtime must be able to interpret the stack map record given only the ID, offset, and the order of the locations, records, and functions, which LLVM preserves.

Note that this is quite different from the goal of debug information, which is a best-effort attempt to track the location of named variables at every instruction.

An important motivation for this design is to allow a runtime to commandeer a stack frame when execution reaches an instruction address associated with a stack map. The runtime must be able to rebuild a stack frame and resume program execution using the information provided by the stack map. For example, execution may resume in an interpreter or a recompiled version of the same function.

This usage restricts LLVM optimization. Clearly, LLVM must not move stores across a stack map. However, loads must also be handled conservatively. If the load may trigger an exception, hoisting it above a stack map could be invalid. For example, the runtime may determine that a load is safe to execute without a type check given the current state of the type system. If the type system changes while some activation of the load's function exists on the stack, the load becomes unsafe. The runtime can prevent subsequent execution of that load by immediately patching any stack map location that lies between the current call site and the load (typically, the runtime would simply patch all stack map locations to invalidate the function). If the compiler had hoisted the load above the stack map, then the program could crash before the runtime could take back control.

To enforce these semantics, stackmap and patchpoint intrinsics are considered to potentially read and write all memory. This may limit optimization more than some clients desire. This limitation may be avoided by marking the call site as "readonly". In the future we may also allow meta-data to be added to the intrinsic call to express aliasing, thereby allowing optimizations to hoist certain loads above stack maps.

Direct Stack Map Entries

As shown in [Stack Map Section](#), a Direct stack map location records the address of frame index. This address is itself the value that the runtime requested. This differs from Indirect locations, which refer to a stack locations from which the requested values must be loaded. Direct locations can communicate the address if an alloca, while Indirect locations handle register spills.

For example:

```
entry:
  %a = alloca i64...
  llvm.experimental.stackmap(i64 <ID>, i32 <shadowBytes>, i64* %a)
```

The runtime can determine this alloca's relative location on the stack immediately after compilation, or at any time thereafter. This differs from Register and Indirect locations, because the runtime can only read the values in those locations when execution reaches the instruction address of the stack map.

This functionality requires LLVM to treat entry-block allocas specially when they are directly consumed by an intrinsic. (This is the same requirement imposed by the `llvm.groot` intrinsic.) LLVM transformations must not substitute the alloca with any intervening value. This can be verified by the runtime simply by checking that the stack map's location is a Direct location type.

4.27.6 Supported Architectures

Support for StackMap generation and the related intrinsics requires some code for each backend. Today, only a subset of LLVM's backends are supported. The currently supported architectures are X86_64, PowerPC, and Aarch64.

4.28 Design and Usage of the InAlloca Attribute

4.28.1 Introduction

The *inalloca* attribute is designed to allow taking the address of an aggregate argument that is being passed by value through memory. Primarily, this feature is required for compatibility with the Microsoft C++ ABI. Under that ABI, class instances that are passed by value are constructed directly into argument stack memory. Prior to the addition of *inalloca*, calls in LLVM were indivisible instructions. There was no way to perform intermediate work, such as object construction, between the first stack adjustment and the final control transfer. With *inalloca*, all arguments passed in memory are modelled as a single alloca, which can be stored to prior to the call. Unfortunately, this complicated feature comes with a large set of restrictions designed to bound the lifetime of the argument memory around the call.

For now, it is recommended that frontends and optimizers avoid producing this construct, primarily because it forces the use of a base pointer. This feature may grow in the future to allow general mid-level optimization, but for now, it should be regarded as less efficient than passing by value with a copy.

4.28.2 Intended Usage

The example below is the intended LLVM IR lowering for some C++ code that passes two default-constructed `Foo` objects to `g` in the 32-bit Microsoft C++ ABI.

```
// Foo is non-trivial.
struct Foo { int a, b; Foo(); ~Foo(); Foo(const Foo &); };
void g(Foo a, Foo b);
void f() {
    g(Foo(), Foo());
}
```

```
%struct.Foo = type { i32, i32 }
declare void @Foo_ctor(%struct.Foo* %this)
declare void @Foo_dtor(%struct.Foo* %this)
declare void @g(<{ %struct.Foo, %struct.Foo }>* inalloca %memargs)

define void @f() {
entry:
    %base = call i8* @llvm.stacksave()
    %memargs = alloca <{ %struct.Foo, %struct.Foo }>
    %b = getelementptr <{ %struct.Foo, %struct.Foo }>* %memargs, i32 1
    call void @Foo_ctor(%struct.Foo* %b)

    ; If a's ctor throws, we must destruct b.
    %a = getelementptr <{ %struct.Foo, %struct.Foo }>* %memargs, i32 0
    invoke void @Foo_ctor(%struct.Foo* %a)
        to label %invoke.cont unwind %invoke.unwind

invoke.cont:
    call void @g(<{ %struct.Foo, %struct.Foo }>* inalloca %memargs)
    call void @llvm.stackrestore(i8* %base)
```

(continues on next page)

(continued from previous page)

```

...
invoke.unwind:
  call void @Foo_dtor(%struct.Foo* %b)
  call void @llvm.stackrestore(i8* %base)
  ...
}

```

To avoid stack leaks, the frontend saves the current stack pointer with a call to *llvm.stacksave*. Then, it allocates the argument stack space with *alloca* and calls the default constructor. The default constructor could throw an exception, so the frontend has to create a landing pad. The frontend has to destroy the already constructed argument *b* before restoring the stack pointer. If the constructor does not unwind, *g* is called. In the Microsoft C++ ABI, *g* will destroy its arguments, and then the stack is restored in *f*.

4.28.3 Design Considerations

Lifetime

The biggest design consideration for this feature is object lifetime. We cannot model the arguments as static allocas in the entry block, because all calls need to use the memory at the top of the stack to pass arguments. We cannot vend pointers to that memory at function entry because after code generation they will alias.

The rule against allocas between argument allocations and the call site avoids this problem, but it creates a cleanup problem. Cleanup and lifetime is handled explicitly with stack save and restore calls. In the future, we may want to introduce a new construct such as *freea* or *afree* to make it clear that this stack adjusting cleanup is less powerful than a full stack save and restore.

Nested Calls and Copy Elision

We also want to be able to support copy elision into these argument slots. This means we have to support multiple live argument allocations.

Consider the evaluation of:

```

// Foo is non-trivial.
struct Foo { int a; Foo(); Foo(const &Foo); ~Foo(); };
Foo bar(Foo b);
int main() {
  bar(bar(Foo()));
}

```

In this case, we want to be able to elide copies into *bar*'s argument slots. That means we need to have more than one set of argument frames active at the same time. First, we need to allocate the frame for the outer call so we can pass it in as the hidden struct return pointer to the middle call. Then we do the same for the middle call, allocating a frame and passing its address to *Foo*'s default constructor. By wrapping the evaluation of the inner *bar* with stack save and restore, we can have multiple overlapping active call frames.

Callee-cleanup Calling Conventions

Another wrinkle is the existence of callee-cleanup conventions. On Windows, all methods and many other functions adjust the stack to clear the memory used to pass their arguments. In some sense, this means that the allocas are automatically cleared by the call. However, LLVM instead models this as a write of undef to all of the inalloca values passed to the call instead of a stack adjustment. Frontends should still restore the stack pointer to avoid a stack leak.

Exceptions

There is also the possibility of an exception. If argument evaluation or copy construction throws an exception, the landing pad must do cleanup, which includes adjusting the stack pointer to avoid a stack leak. This means the cleanup of the stack memory cannot be tied to the call itself. There needs to be a separate IR-level instruction that can perform independent cleanup of arguments.

Efficiency

Eventually, it should be possible to generate efficient code for this construct. In particular, using inalloca should not require a base pointer. If the backend can prove that all points in the CFG only have one possible stack level, then it can address the stack directly from the stack pointer. While this is not yet implemented, the plan is that the inalloca attribute should not change much, but the frontend IR generation recommendations may change.

4.29 Using ARM NEON instructions in big endian mode

- *Introduction*
 - *Example: C-level intrinsics -> assembly*
- *Problem*
- *LDR and LD1*
- *Considerations*
 - *LLVM IR Lane ordering*
 - *AAPCS*
 - *Alignment*
 - *Summary*
- *Implementation*
 - *Bitconverts*

4.29.1 Introduction

Generating code for big endian ARM processors is for the most part straightforward. NEON loads and stores however have some interesting properties that make code generation decisions less obvious in big endian mode.

The aim of this document is to explain the problem with NEON loads and stores, and the solution that has been implemented in LLVM.

In this document the term "vector" refers to what the ARM ABI calls a "short vector", which is a sequence of items that can fit in a NEON register. This sequence can be 64 or 128 bits in length, and can constitute 8, 16, 32 or 64 bit items. This document refers to A64 instructions throughout, but is almost applicable to the A32/ARMv7 instruction sets also. The ABI format for passing vectors in A32 is slightly different to A64. Apart from that, the same concepts apply.

Example: C-level intrinsics -> assembly

It may be helpful first to illustrate how C-level ARM NEON intrinsics are lowered to instructions.

This trivial C function takes a vector of four ints and sets the zero'th lane to the value "42":

```
#include <arm_neon.h>
int32x4_t f(int32x4_t p) {
    return vsetq_lane_s32(42, p, 0);
}
```

arm_neon.h intrinsics generate "generic" IR where possible (that is, normal IR instructions not `llvm.arm.neon.*` intrinsic calls). The above generates:

```
define <4 x i32> @f(<4 x i32> %p) {
    %vset_lane = insertelement <4 x i32> %p, i32 42, i32 0
    ret <4 x i32> %vset_lane
}
```

Which then becomes the following trivial assembly:

```
f:
    movz    w8, #0x2a                // @f
    ins     v0.s[0], w8
    ret
```

4.29.2 Problem

The main problem is how vectors are represented in memory and in registers.

First, a recap. The "endianness" of an item affects its representation in memory only. In a register, a number is just a sequence of bits - 64 bits in the case of AArch64 general purpose registers. Memory, however, is a sequence of addressable units of 8 bits in size. Any number greater than 8 bits must therefore be split up into 8-bit chunks, and endianness describes the order in which these chunks are laid out in memory.

A "little endian" layout has the least significant byte first (lowest in memory address). A "big endian" layout has the *most* significant byte first. This means that when loading an item from big endian memory, the lowest 8-bits in memory must go in the most significant 8-bits, and so forth.

4.29.3 LDR and LD1

A vector is a consecutive sequence of items that are operated on simultaneously.

To load a 64-bit vector, 64 bits need to be read from memory. In little endian mode, we can do this by just performing a 64-bit load - `LDR q0, [x]`. However if we try this in big endian mode, because of the byte swapping the lane indices end up being swapped! The zero'th item as laid out in memory becomes the n'th lane in the vector.

Because of this, the instruction `LD1` performs a vector load but performs byte swapping

not on the entire 64 bits, but on the individual items within the vector. This means that the register content is the same as it would have been on a little endian system.

It may seem that `LD1` should suffice to perform vector loads on a big endian machine. However there are pros and cons to the two approaches that make it less than simple which register format to pick.

There are two options:

1. The content of a vector register is the same *as if* it had been loaded with an `LDR` instruction.

Fig. 1: Big endian vector load using `LDR`.

`LD1 v0.u32, [x]`

Fig. 2: Big endian vector load using `LD1`. Note that the lanes retain the correct ordering.

2. The content of a vector register is the same *as if* it had been loaded with an LD1 instruction.

Because LD1 == LDR + REV and similarly LDR == LD1 + REV (on a big endian system), we can simulate either type of load with the other type of load plus a REV instruction. So we're not deciding which instructions to use, but which format to use (which will then influence which instruction is best to use).

Note that throughout this section we only mention loads. Stores have exactly the same problems as their associated loads, so have been skipped for brevity.

4.29.4 Considerations

LLVM IR Lane ordering

LLVM IR has first class vector types. In LLVM IR, the zero'th element of a vector resides at the lowest memory address. The optimizer relies on this property in certain areas, for example when concatenating vectors together. The intention is for arrays and vectors to have identical memory layouts - `[4 x i8]` and `<4 x i8>` should be represented the same in memory. Without this property there would be many special cases that the optimizer would have to cleverly handle.

Use of LDR would break this lane ordering property. This doesn't preclude the use of LDR, but we would have to do one of two things:

1. Insert a REV instruction to reverse the lane order after every LDR.
2. Disable all optimizations that rely on lane layout, and for every access to an individual lane (`insertelement/extractelement/shufflevector`) reverse the lane index.

AAPCS

The ARM procedure call standard (AAPCS) defines the ABI for passing vectors between functions in registers. It states:

When a short vector is transferred between registers and memory it is treated as an opaque object. That is a short vector is stored in memory as if it were stored with a single STR of the entire register; a short vector is loaded from memory using the corresponding LDR instruction. On a little-endian system this means that element 0 will always contain the lowest addressed element of a short vector; on a big-endian system element 0 will contain the highest-addressed element of a short vector.

—Procedure Call Standard for the ARM 64-bit Architecture (AArch64), 4.1.2 Short Vectors

The use of LDR and STR as the ABI defines has at least one advantage over LD1 and ST1. LDR and STR are oblivious to the size of the individual lanes of a vector. LD1 and ST1 are not - the lane size is encoded within them. This is important across an ABI boundary, because it would become necessary to know the lane width the callee expects. Consider the following code:

```
<callee.c>
void callee(uint32x2_t v) {
    ...
}

<caller.c>
extern void callee(uint32x2_t);
void caller() {
    callee(...);
}
```

If `callee` changed its signature to `uint16x4_t`, which is equivalent in register content, if we passed as `LD1` we'd break this code until `caller` was updated and recompiled.

There is an argument that if the signatures of the two functions are different then the behaviour should be undefined. But there may be functions that are agnostic to the lane layout of the vector, and treating the vector as an opaque value (just loading it and storing it) would be impossible without a common format across ABI boundaries.

So to preserve ABI compatibility, we need to use the `LDR` lane layout across function calls.

Alignment

In strict alignment mode, `LDR qX` requires its address to be 128-bit aligned, whereas `LD1` only requires it to be as aligned as the lane size. If we canonicalised on using `LDR`, we'd still need to use `LD1` in some places to avoid alignment faults (the result of the `LD1` would then need to be reversed with `REV`).

Most operating systems however do not run with alignment faults enabled, so this is often not an issue.

Summary

The following table summarises the instructions that are required to be emitted for each property mentioned above for each of the two solutions.

	LDR layout	LD1 layout
Lane ordering	LDR + REV	LD1
AAPCS	LDR	LD1 + REV
Alignment for strict mode	LDR / LD1 + REV	LD1

Neither approach is perfect, and choosing one boils down to choosing the lesser of two evils. The issue with lane ordering, it was decided, would have to change target-agnostic compiler passes and would result in a strange IR in which lane indices were reversed. It was decided that this was worse than the changes that would have to be made to support `LD1`, so `LD1` was chosen as the canonical vector load instruction (and by inference, `ST1` for vector stores).

4.29.5 Implementation

There are 3 parts to the implementation:

1. Predicate `LDR` and `STR` instructions so that they are never allowed to be selected to generate vector loads and stores. The exception is one-lane vectors¹ - these by definition cannot have lane ordering problems so are fine to use `LDR/STR`.
2. Create code generation patterns for bitconverts that create `REV` instructions.
3. Make sure appropriate bitconverts are created so that vector values get passed over call boundaries as 1-element vectors (which is the same as if they were loaded with `LDR`).

¹ One lane vectors may seem useless as a concept but they serve to distinguish between values held in general purpose registers and values held in NEON/VFP registers. For example, an `i64` would live in an `x` register, but `<1 x i64>` would live in a `d` register.

Bitconverts

The main problem with the `LD1` solution is dealing with bitconverts (or bitcasts, or reinterpret casts). These are pseudo instructions that only change the compiler's interpretation of data, not the underlying data itself. A requirement is that if data is loaded and then saved again (called a "round trip"), the memory contents should be the same after the store as before the load. If a vector is loaded and is then bitconverted to a different vector type before storing, the round trip will currently be broken.

Take for example this code sequence:

```
%0 = load <4 x i32> %x
%1 = bitcast <4 x i32> %0 to <2 x i64>
store <2 x i64> %1, <2 x i64>* %y
```

This would produce a code sequence such as that in the figure on the right. The mismatched `LD1` and `ST1` cause the stored data to differ from the loaded data.

When we see a bitcast from type X to type Y , what we need to do is to change the in-register representation of the data to be *as if* it had just been loaded by a `LD1` of type Y .

Conceptually this is simple - we can insert a REV undoing the LD1 of type X (converting the in-register representation to the same as if it had been loaded by LDR) and then insert another REV to change the representation to be as if it had been loaded by an LD1 of type Y.

For the previous example, this would be:

```
LD1    v0.4s, [x]

REV64 v0.4s, v0.4s           // There is no REV128 instruction, so it must be
↪synthesized
EXT    v0.16b, v0.16b, v0.16b, #8 // with a REV64 then an EXT to swap the two 64-
↪bit elements.

REV64 v0.2d, v0.2d
EXT    v0.16b, v0.16b, v0.16b, #8

ST1    v0.2d, [y]
```

It turns out that these REV pairs can, in almost all cases, be squashed together into a single REV. For the example above, a REV128 4s + REV128 2d is actually a REV64 4s, as shown in the figure on the right.

4.30.1 Introduction

LLVM's code coverage mapping format is used to provide code coverage analysis using LLVM's and Clang's instrumentation based profiling (Clang's `-fprofile-instr-generate` option).

This document is aimed at those who use LLVM's code coverage mapping to provide code coverage analysis for their own programs, and for those who would like to know how it works under the hood. A prior knowledge of how Clang's profile guided optimization works is useful, but not required.

We start by showing how to use LLVM and Clang for code coverage analysis, then we briefly describe LLVM's code coverage mapping format and the way that Clang and LLVM's code coverage tool work with this format. After the basics are down, more advanced features of the coverage mapping format are discussed - such as the data structures, LLVM IR representation and the binary encoding.

4.30.2 Quick Start

Here's a short story that describes how to generate code coverage overview for a sample source file called *test.c*.

- First, compile an instrumented version of your program using Clang's `-fprofile-instr-generate` option with the additional `-fcoverage-mapping` option:

```
clang -o test -fprofile-instr-generate -fcoverage-mapping test.c
```

- Then, run the instrumented binary. The runtime will produce a file called *default.profraw* containing the raw profile instrumentation data:

```
./test
```

- After that, merge the profile data using the *llvm-profdata* tool:

```
llvm-profdata merge -o test.profdata default.profraw
```

- Finally, run LLVM's code coverage tool (*llvm-cov*) to produce the code coverage overview for the sample source file:

```
llvm-cov show ./test -instr-profile=test.profdata test.c
```

4.30.3 High Level Overview

LLVM's code coverage mapping format is designed to be a self contained data format, that can be embedded into the LLVM IR and object files. It's described in this document as a **mapping** format because its goal is to store the data that is required for a code coverage tool to map between the specific source ranges in a file and the execution counts obtained after running the instrumented version of the program.

The mapping data is used in two places in the code coverage process:

1. When clang compiles a source file with `-fcoverage-mapping`, it generates the mapping information that describes the mapping between the source ranges and the profiling instrumentation counters. This information gets embedded into the LLVM IR and conveniently ends up in the final executable file when the program is linked.
2. It is also used by *llvm-cov* - the mapping information is extracted from an object file and is used to associate the execution counts (the values of the profile instrumentation counters), and the source ranges in a file. After that, the tool is able to generate various code coverage reports for the program.

The coverage mapping format aims to be a "universal format" that would be suitable for usage by any frontend, and not just by Clang. It also aims to provide the frontend the possibility of generating the minimal coverage mapping data in order to reduce the size of the IR and object files - for example, instead of emitting mapping information for each

statement in a function, the frontend is allowed to group the statements with the same execution count into regions of code, and emit the mapping information only for those regions.

4.30.4 Advanced Concepts

The remainder of this guide is meant to give you insight into the way the coverage mapping format works.

The coverage mapping format operates on a per-function level as the profile instrumentation counters are associated with a specific function. For each function that requires code coverage, the frontend has to create coverage mapping data that can map between the source code ranges and the profile instrumentation counters for that function.

Mapping Region

The function's coverage mapping data contains an array of mapping regions. A mapping region stores the *source code range* that is covered by this region, the *file id*, the *coverage mapping counter* and the region's kind. There are several kinds of mapping regions:

- Code regions associate portions of source code and *coverage mapping counters*. They make up the majority of the mapping regions. They are used by the code coverage tool to compute the execution counts for lines, highlight the regions of code that were never executed, and to obtain the various code coverage statistics for a function. For example:
- Skipped regions are used to represent source ranges that were skipped by Clang's preprocessor. They don't associate with *coverage mapping counters*, as the frontend knows that they are never executed. They are used by the code coverage tool to mark the skipped lines inside a function as non-code lines that don't have execution counts. For example:
- Expansion regions are used to represent Clang's macro expansions. They have an additional property - *expanded file id*. This property can be used by the code coverage tool to find the mapping regions that are created as a result of this macro expansion, by checking if their file id matches the expanded file id. They don't associate with *coverage mapping counters*, as the code coverage tool can determine the execution count for this region by looking up the execution count of the first region with a corresponding file id. For example:

Source Range:

The source range record contains the starting and ending location of a certain mapping region. Both locations include the line and the column numbers.

File ID:

The file id an integer value that tells us in which source file or macro expansion is this region located. It enables Clang to produce mapping information for the code defined inside macros, like this example demonstrates:

Counter:

A coverage mapping counter can represent a reference to the profile instrumentation counter. The execution count for a region with such counter is determined by looking up the value of the corresponding profile instrumentation counter.

It can also represent a binary arithmetical expression that operates on coverage mapping counters or other expressions. The execution count for a region with an expression counter is determined by evaluating the expression's arguments and then adding them together or subtracting them from one another. In the example below, a subtraction expression is used to compute the execution count for the compound statement that follows the *else* keyword:

Finally, a coverage mapping counter can also represent an execution count of zero. The zero counter is used to provide coverage mapping for unreachable statements and expressions, like in the example below:

The zero counters allow the code coverage tool to display proper line execution counts for the unreachable lines and highlight the unreachable code. Without them, the tool would think that those lines and regions were still executed, as it doesn't possess the frontend's knowledge.

4.30.5 LLVM IR Representation

The coverage mapping data is stored in the LLVM IR using a single global constant structure variable called `__llvm_coverage_mapping` with the `__llvm_covmap` section specifier.

For example, let's consider a C file and how it gets compiled to LLVM:

```
int foo() {
    return 42;
}
int bar() {
    return 13;
}
```

The coverage mapping variable generated by Clang has 3 fields:

- Coverage mapping header.
- An array of function records.
- Coverage mapping data which is an array of bytes. Zero paddings are added at the end to force 8 byte alignment.

```
@__llvm_coverage_mapping = internal constant { { i32, i32, i32, i32 }, [2 x { i64, i32, i64 }], [40 x i8] }
{
  { i32, i32, i32, i32 } ; Coverage map header
  {
    i32 2, ; The number of function records
    i32 20, ; The length of the string that contains the encoded translation unit_
    ↪filenames
    i32 20, ; The length of the string that contains the encoded coverage mapping data
    i32 2, ; Coverage mapping format version
  },
  [2 x { i64, i32, i64 }] [ ; Function records
    { i64, i32, i64 } {
      i64 0x5cf8c24cdb18bdac, ; Function's name MD5
      i32 9, ; Function's encoded coverage mapping data string length
      i64 0 ; Function's structural hash
    },
    { i64, i32, i64 } {
      i64 0xe413754a191db537, ; Function's name MD5
    }
  ]
}
```

(continues on next page)

(continued from previous page)

```

    i32 9, ; Function's encoded coverage mapping data string length
    i64 0 ; Function's structural hash
  }],
  [40 x i8] c"..."; Encoded data (dissected later)
}, section "__llvm_covmap", align 8

```

The current version of the format is version 3. The only difference from version 2 is that a special encoding for column end locations was introduced to indicate gap regions.

The function record layout has evolved since version 1. In version 1, the function record for *foo* is defined as follows:

```

{ i8*, i32, i32, i64 } { i8* getelementptr inbounds ([3 x i8]* @__profn_foo, i32 0,
→ i32 0), ; Function's name
  i32 3, ; Function's name length
  i32 9, ; Function's encoded coverage mapping data string length
  i64 0 ; Function's structural hash
}

```

Coverage Mapping Header:

The coverage mapping header has the following fields:

- The number of function records.
- The length of the string in the third field of `__llvm_coverage_mapping` that contains the encoded translation unit filenames.
- The length of the string in the third field of `__llvm_coverage_mapping` that contains the encoded coverage mapping data.
- The format version. The current version is 3 (encoded as a 2).

Function record:

A function record is a structure of the following type:

```
{ i64, i32, i64 }
```

It contains function name's MD5, the length of the encoded mapping data for that function, and function's structural hash value.

Encoded data:

The encoded data is stored in a single string that contains the encoded filenames used by this translation unit and the encoded coverage mapping data for each function in this translation unit.

The encoded data has the following structure:

```
[filenames, coverageMappingDataForFunctionRecord0, coverageMappingDataForFunctionRecord1,
..., padding]
```

If necessary, the encoded data is padded with zeroes so that the size of the data string is rounded up to the nearest multiple of 8 bytes.

Dissecting the sample:

Here's an overview of the encoded data that was stored in the IR for the *coverage mapping sample* that was shown earlier:

- The IR contains the following string constant that represents the encoded coverage mapping data for the sample translation unit:

```
c"\01\12/Users/alex/test.c\01\00\00\01\01\01\0C\02\02\01\00\00\01\01\04\0C\02\02\
↪00\00"
```

- The string contains values that are encoded in the LEB128 format, which is used throughout for storing integers. It also contains a string value.
- The length of the substring that contains the encoded translation unit filenames is the value of the second field in the `__llvm_coverage_mapping` structure, which is 20, thus the filenames are encoded in this string:

```
c"\01\12/Users/alex/test.c"
```

This string contains the following data:

- Its first byte has a value of `0x01`. It stores the number of filenames contained in this string.
- Its second byte stores the length of the first filename in this string.
- The remaining 18 bytes are used to store the first filename.
- The length of the substring that contains the encoded coverage mapping data for the first function is the value of the third field in the first structure in an array of *function records* stored in the third field of the `__llvm_coverage_mapping` structure, which is the 9. Therefore, the coverage mapping for the first function record is encoded in this string:

```
c"\01\00\00\01\01\01\0C\02\02"
```

This string consists of the following bytes:

0x01	The number of file ids used by this function. There is only one file id used by the mapping data in this function.
0x00	An index into the filenames array which corresponds to the file <code>"/Users/alex/test.c"</code> .
0x00	The number of counter expressions used by this function. This function doesn't use any expressions.
0x01	The number of mapping regions that are stored in an array for the function's file id #0.
0x01	The coverage mapping counter for the first region in this function. The value of 1 tells us that it's a coverage mapping counter that is a reference to the profile instrumentation counter with an index of 0.
0x01	The starting line of the first mapping region in this function.
0x0C	The starting column of the first mapping region in this function.
0x02	The ending line of the first mapping region in this function.
0x02	The ending column of the first mapping region in this function.

- The length of the substring that contains the encoded coverage mapping data for the second function record is also 9. It's structured like the mapping data for the first function record.
- The two trailing bytes are zeroes and are used to pad the coverage mapping data to give it the 8 byte alignment.

4.30.6 Encoding

The per-function coverage mapping data is encoded as a stream of bytes, with a simple structure. The structure consists of the encoding *types* like variable-length unsigned integers, that are used to encode *File ID Mapping*, *Counter Expressions* and the *Mapping Regions*.

The format of the structure follows:

```
[file id mapping, counter expressions, mapping regions]
```

The translation unit filenames are encoded using the same encoding *types* as the per-function coverage mapping data, with the following structure:

```
[numFilenames : LEB128, filename0 : string, filename1 : string,
...]
```

Types

This section describes the basic types that are used by the encoding format and can appear after `:` in the `[foo : type]` description.

LEB128

LEB128 is an unsigned integer value that is encoded using DWARF's LEB128 encoding, optimizing for the case where values are small (1 byte for values less than 128).

Strings

```
[length : LEB128, characters...]
```

String values are encoded with a *LEB value* for the length of the string and a sequence of bytes for its characters.

File ID Mapping

```
[numIndices : LEB128, filenameIndex0 : LEB128, filenameIndex1 : LEB128,
...]
```

File id mapping in a function's coverage mapping stream contains the indices into the translation unit's filenames array.

Counter

```
[value : LEB128]
```

A *coverage mapping counter* is stored in a single *LEB value*. It is composed of two things --- the *tag* which is stored in the lowest 2 bits, and the *counter data* which is stored in the remaining bits.

Tag:

The counter's tag encodes the counter's kind and, if the counter is an expression, the expression's kind. The possible tag values are:

- 0 - The counter is zero.
- 1 - The counter is a reference to the profile instrumentation counter.
- 2 - The counter is a subtraction expression.
- 3 - The counter is an addition expression.

Data:

The counter's data is interpreted in the following manner:

- When the counter is a reference to the profile instrumentation counter, then the counter's data is the id of the profile counter.
- When the counter is an expression, then the counter's data is the index into the array of counter expressions.

Counter Expressions

```
[numExpressions : LEB128, expr0LHS : LEB128, expr0RHS : LEB128, expr1LHS :  
LEB128, expr1RHS : LEB128, ...]
```

Counter expressions consist of two counters as they represent binary arithmetic operations. The expression's kind is determined from the *tag* of the counter that references this expression.

Mapping Regions

```
[numRegionArrays : LEB128, regionsForFile0, regionsForFile1, ...]
```

The mapping regions are stored in an array of sub-arrays where every region in a particular sub-array has the same file id.

The file id for a sub-array of regions is the index of that sub-array in the main array e.g. The first sub-array will have the file id of 0.

Sub-Array of Regions

```
[numRegions : LEB128, region0, region1, ...]
```

The mapping regions for a specific file id are stored in an array that is sorted in an ascending order by the region's starting location.

Mapping Region

```
[header, source range]
```

The mapping region record contains two sub-records --- the *header*, which stores the counter and/or the region's kind, and the *source range* that contains the starting and ending location of this region.

Header

```
[counter]
```

or

```
[pseudo-counter]
```

The header encodes the region's counter and the region's kind.

The value of the counter's tag distinguishes between the counters and pseudo-counters --- if the tag is zero, then this header contains a pseudo-counter, otherwise this header contains an ordinary counter.

Counter:

A mapping region whose header has a counter with a non-zero tag is a code region.

Pseudo-Counter:

```
[value : LEB128]
```

A pseudo-counter is stored in a single *LEB value*, just like the ordinary counter. It has the following interpretation:

- bits 0-1: tag, which is always 0.
- bit 2: `expansionRegionTag`. If this bit is set, then this mapping region is an expansion region.
- remaining bits: data. If this region is an expansion region, then the data contains the expanded file id of that region.

Otherwise, the data contains the region's kind. The possible region kind values are:

- 0 - This mapping region is a code region with a counter of zero.
- 2 - This mapping region is a skipped region.

Source Range

```
[deltaLineStart : LEB128, columnStart : LEB128, numLines : LEB128,
columnEnd : LEB128]
```

The source range record contains the following fields:

- *deltaLineStart*: The difference between the starting line of the current mapping region and the starting line of the previous mapping region.

If the current mapping region is the first region in the current sub-array, then it stores the starting line of that region.

- *columnStart*: The starting column of the mapping region.

- *numLines*: The difference between the ending line and the starting line of the current mapping region.
- *columnEnd*: The ending column of the mapping region. If the high bit is set, the current mapping region is a gap area. A count for a gap area is only used as the line execution count if there are no other regions on a line.

4.31.1 Status

This document describes a set of extensions to LLVM to support garbage collection. By now, these mechanisms are well proven with commercial java implementation with a fully relocating collector having shipped using them. There are a couple places where bugs might still linger; these are called out below.

They are still listed as "experimental" to indicate that no forward or backward compatibility guarantees are offered across versions. If your use case is such that you need some form of forward compatibility guarantee, please raise the issue on the `llvm-dev` mailing list.

LLVM still supports an alternate mechanism for conservative garbage collection support using the `gcroot` intrinsic. The `gcroot` mechanism is mostly of historical interest at this point with one exception - its implementation of shadow stacks has been used successfully by a number of language frontends and is still supported.

4.31.2 Overview & Core Concepts

To collect dead objects, garbage collectors must be able to identify any references to objects contained within executing code, and, depending on the collector, potentially update them. The collector does not need this information at all points in code - that would make the problem much harder - but only at well-defined points in the execution known as 'safepoints'. For most collectors, it is sufficient to track at least one copy of each unique pointer value. However, for a collector which wishes to relocate objects directly reachable from running code, a higher standard is required.

One additional challenge is that the compiler may compute intermediate results ("derived pointers") which point outside of the allocation or even into the middle of another allocation. The eventual use of this intermediate value must yield an address within the bounds of the allocation, but such "exterior derived pointers" may be visible to the collector. Given this, a garbage collector can not safely rely on the runtime value of an address to indicate the object it is associated with. If the garbage collector wishes to move any object, the compiler must provide a mapping, for each pointer, to an indication of its allocation.

To simplify the interaction between a collector and the compiled code, most garbage collectors are organized in terms of three abstractions: load barriers, store barriers, and safepoints.

1. A load barrier is a bit of code executed immediately after the machine load instruction, but before any use of the value loaded. Depending on the collector, such a barrier may be needed for all loads, merely loads of a particular type (in the original source language), or none at all.
2. Analogously, a store barrier is a code fragment that runs immediately before the machine store instruction, but after the computation of the value stored. The most common use of a store barrier is to update a 'card table' in a generational garbage collector.
3. A safepoint is a location at which pointers visible to the compiled code (i.e. currently in registers or on the stack) are allowed to change. After the safepoint completes, the actual pointer value may differ, but the 'object' (as seen by the source language) pointed to will not.

Note that the term 'safepoint' is somewhat overloaded. It refers to both the location at which the machine state is parsable and the coordination protocol involved in bring application threads to a point at which the collector can safely use that information. The term "statepoint" as used in this document refers exclusively to the former.

This document focuses on the last item - compiler support for safepoints in generated code. We will assume that an outside mechanism has decided where to place safepoints. From our perspective, all safepoints will be function calls. To support relocation of objects directly reachable from values in compiled code, the collector must be able to:

1. identify every copy of a pointer (including copies introduced by the compiler itself) at the safepoint,
2. identify which object each pointer relates to, and
3. potentially update each of those copies.

This document describes the mechanism by which an LLVM based compiler can provide this information to a language runtime/collector, and ensure that all pointers can be read and updated if desired.

Abstract Machine Model

At a high level, LLVM has been extended to support compiling to an abstract machine which extends the actual target with a non-integral pointer type suitable for representing a garbage collected reference to an object. In particular, such non-integral pointer type have no defined mapping to an integer representation. This semantic quirk allows the runtime to pick a integer mapping for each point in the program allowing relocations of objects without visible effects.

This high level abstract machine model is used for most of the optimizer. As a result, transform passes do not need to be extended to look through explicit relocation sequence. Before starting code generation, we switch representations to an explicit form. The exact location chosen for lowering is an implementation detail.

Note that most of the value of the abstract machine model comes for collectors which need to model potentially relocatable objects. For a compiler which supports only a non-relocating collector, you may wish to consider starting with the fully explicit form.

Warning: There is one currently known semantic hole in the definition of non-integral pointers which has not been addressed upstream. To work around this, you need to disable speculation of loads unless the memory type (non-integral pointer vs anything else) is known to unchanged. That is, it is not safe to speculate a load if doing causes a non-integral pointer value to be loaded as any other type or vice versa. In practice, this restriction is well isolated to `isSafeToSpeculate` in `ValueTracking.cpp`.

Explicit Representation

A frontend could directly generate this low level explicit form, but doing so may inhibit optimization. Instead, it is recommended that compilers with relocating collectors target the abstract machine model just described.

The heart of the explicit approach is to construct (or rewrite) the IR in a manner where the possible updates performed by the garbage collector are explicitly visible in the IR. Doing so requires that we:

1. create a new SSA value for each potentially relocated pointer, and ensure that no uses of the original (non relocated) value is reachable after the safepoint,
2. specify the relocation in a way which is opaque to the compiler to ensure that the optimizer can not introduce new uses of an unrelocated value after a statepoint. This prevents the optimizer from performing unsound optimizations.
3. recording a mapping of live pointers (and the allocation they're associated with) for each statepoint.

At the most abstract level, inserting a safepoint can be thought of as replacing a call instruction with a call to a multiple return value function which both calls the original target of the call, returns its result, and returns updated values for any live pointers to garbage collected objects.

Note that the task of identifying all live pointers to garbage collected values, transforming the IR to expose a pointer giving the base object for every such live pointer, and inserting all the intrinsics correctly is explicitly out of scope for this document. The recommended approach is to use the *utility passes* described below.

This abstract function call is concretely represented by a sequence of intrinsic calls known collectively as a "statepoint relocation sequence".

Let's consider a simple call in LLVM IR:

```
define i8 @addrspace(1) * @test1(i8 @addrspace(1) * %obj)
    gc "statepoint-example" {
    call void () * @foo()
```

(continues on next page)

(continued from previous page)

```
ret i8 addrspace(1) * %obj
}
```

Depending on our language we may need to allow a safepoint during the execution of `foo`. If so, we need to let the collector update local values in the current frame. If we don't, we'll be accessing a potential invalid reference once we eventually return from the call.

In this example, we need to relocate the SSA value `%obj`. Since we can't actually change the value in the SSA value `%obj`, we need to introduce a new SSA value `%obj.relocated` which represents the potentially changed value of `%obj` after the safepoint and update any following uses appropriately. The resulting relocation sequence is:

```
define i8 addrspace(1) * @test1(i8 addrspace(1) * %obj)
  gc "statepoint-example" {
    %0 = call token (i64, i32, void ()*, i32, i32, ...) * @llvm.experimental.gc.
    ↪statepoint.p0f_isVoidf(i64 0, i32 0, void ()* @foo, i32 0, i32 0, i32 0, i32 0, i8_
    ↪addrspace(1) * %obj)
    %obj.relocated = call coldcc i8 addrspace(1) * @llvm.experimental.gc.relocate.
    ↪pl18(token %0, i32 7, i32 7)
    ret i8 addrspace(1) * %obj.relocated
  }
```

Ideally, this sequence would have been represented as a `M` argument, `N` return value function (where `M` is the number of values being relocated + the original call arguments and `N` is the original return value + each relocated value), but LLVM does not easily support such a representation.

Instead, the statepoint intrinsic marks the actual site of the safepoint or statepoint. The statepoint returns a token value (which exists only at compile time). To get back the original return value of the call, we use the `gc.result` intrinsic. To get the relocation of each pointer in turn, we use the `gc.relocate` intrinsic with the appropriate index. Note that both the `gc.relocate` and `gc.result` are tied to the statepoint. The combination forms a "statepoint relocation sequence" and represents the entirety of a parseable call or 'statepoint'.

When lowered, this example would generate the following x86 assembly:

```
.globl      test1
.align     16, 0x90
pushq %rax
callq foo
.Ltmp1:
movq  (%rsp), %rax  # This load is redundant (oops!)
popq  %rdx
retq
```

Each of the potentially relocated values has been spilled to the stack, and a record of that location has been recorded to the *Stack Map section*. If the garbage collector needs to update any of these pointers during the call, it knows exactly what to change.

The relevant parts of the StackMap section for our example are:

```
# This describes the call site
# Stack Maps: callsite 2882400000
    .quad 2882400000
    .long .Ltmp1-test1
    .short 0
# .. 8 entries skipped ..
# This entry describes the spill slot which is directly addressable
# off RSP with offset 0. Given the value was spilled with a pushq,
# that makes sense.
```

(continues on next page)

(continued from previous page)

```
# Stack Maps:   Loc 8: Direct RSP      [encoding: .byte 2, .byte 8, .short 7, .int 0]
               .byte 2
               .byte 8
               .short      7
               .long 0
```

This example was taken from the tests for the *RewriteStatepointsForGC* utility pass. As such, its full StackMap can be easily examined with the following command.

```
opt -rewrite-statepoints-for-gc test/Transforms/RewriteStatepointsForGC/basics.ll -S_
→ | llc -debug-only=stackmaps
```

Simplifications for Non-Relocating GCs

Some of the complexity in the previous example is unnecessary for a non-relocating collector. While a non-relocating collector still needs the information about which location contain live references, it doesn't need to represent explicit relocations. As such, the previously described explicit lowering can be simplified to remove all of the `gc.relocate` intrinsic calls and leave uses in terms of the original reference value.

Here's the explicit lowering for the previous example for a non-relocating collector:

```
define i8 @addrspace(1) * @test1(i8 @addrspace(1) * %obj)
{
  gc "statepoint-example" {
    call token (i64, i32, void ()*, i32, i32, ...) * @llvm.experimental.gc.statepoint.
→ p0f_isVoidf(i64 0, i32 0, void ()* @foo, i32 0, i32 0, i32 0, i32 0, i32 0, i8_
→ @addrspace(1) * %obj)
    ret i8 @addrspace(1) * %obj
  }
}
```

Recording On Stack Regions

In addition to the explicit relocation form previously described, the statepoint infrastructure also allows the listing of allocas within the gc pointer list. Allocas can be listed with or without additional explicit gc pointer values and relocations.

An alloca in the gc region of the statepoint operand list will cause the address of the stack region to be listed in the stackmap for the statepoint.

This mechanism can be used to describe explicit spill slots if desired. It then becomes the generator's responsibility to ensure that values are spill/filled to/from the alloca as needed on either side of the safepoint. Note that there is no way to indicate a corresponding base pointer for such an explicitly specified spill slot, so usage is restricted to values for which the associated collector can derive the object base from the pointer itself.

This mechanism can be used to describe on stack objects containing references provided that the collector can map from the location on the stack to a heap map describing the internal layout of the references the collector needs to process.

WARNING: At the moment, this alternate form is not well exercised. It is recommended to use this with caution and expect to have to fix a few bugs. In particular, the *RewriteStatepointsForGC* utility pass does not do anything for allocas today.

Base & Derived Pointers

A "base pointer" is one which points to the starting address of an allocation (object). A "derived pointer" is one which is offset from a base pointer by some amount. When relocating objects, a garbage collector needs to be able to relocate each derived pointer associated with an allocation to the same offset from the new address.

"Interior derived pointers" remain within the bounds of the allocation they're associated with. As a result, the base object can be found at runtime provided the bounds of allocations are known to the runtime system.

"Exterior derived pointers" are outside the bounds of the associated object; they may even fall within *another* allocations address range. As a result, there is no way for a garbage collector to determine which allocation they are associated with at runtime and compiler support is needed.

The `gc.relocate` intrinsic supports an explicit operand for describing the allocation associated with a derived pointer. This operand is frequently referred to as the base operand, but does not strictly speaking have to be a base pointer, but it does need to lie within the bounds of the associated allocation. Some collectors may require that the operand be an actual base pointer rather than merely an internal derived pointer. Note that during lowering both the base and derived pointer operands are required to be live over the associated call safepoint even if the base is otherwise unused afterwards.

If we extend our previous example to include a pointless derived pointer, we get:

```
define i8 @addrspace(1) * @test1(i8 @addrspace(1) * %obj)
    gc "statepoint-example" {
        %gep = getelementptr i8, i8 @addrspace(1) * %obj, i64 20000
        %token = call token (i64, i32, void ()*, i32, i32, ...) * @llvm.experimental.gc.
↳statepoint.p0f_isVoidf(i64 0, i32 0, void ()* @foo, i32 0, i32 0, i32 0, i32 0, i8
↳addrspace(1) * %obj, i8 @addrspace(1) * %gep)
        %obj.relocated = call i8 @addrspace(1) * @llvm.experimental.gc.relocate.pli8(token
↳%token, i32 7, i32 7)
        %gep.relocated = call i8 @addrspace(1) * @llvm.experimental.gc.relocate.pli8(token
↳%token, i32 7, i32 8)
        %p = getelementptr i8, i8 @addrspace(1) * %gep, i64 -20000
        ret i8 @addrspace(1) * %p
    }
}
```

Note that in this example `%p` and `%obj.relocate` are the same address and we could replace one with the other, potentially removing the derived pointer from the live set at the safepoint entirely.

GC Transitions

As a practical consideration, many garbage-collected systems allow code that is collector-aware ("managed code") to call code that is not collector-aware ("unmanaged code"). It is common that such calls must also be safepoints, since it is desirable to allow the collector to run during the execution of unmanaged code. Furthermore, it is common that coordinating the transition from managed to unmanaged code requires extra code generation at the call site to inform the collector of the transition. In order to support these needs, a statepoint may be marked as a GC transition, and data that is necessary to perform the transition (if any) may be provided as additional arguments to the statepoint.

Note that although in many cases statepoints may be inferred to be GC transitions based on the function symbols involved (e.g. a call from a function with GC strategy "foo" to a function with GC strategy "bar"), indirect calls that are also GC transitions must also be supported. This requirement is the driving force behind the decision to require that GC transitions are explicitly marked.

Let's revisit the sample given above, this time treating the call to `@f00` as a GC transition. Depending on our target, the transition code may need to access some extra state in order to inform the collector of the transition. Let's assume a hypothetical GC--somewhat unimaginatively named "hypothetical-gc"--that requires that a TLS variable must be written to before and after a call to unmanaged code. The resulting relocation sequence is:

```

@flag = thread_local global i32 0, align 4

define i8 @test1(i8 @addrspace(1) * %obj)
    gc "hypothetical-gc" {

        %0 = call token (i64, i32, void ()*, i32, i32, ...) * @llvm.experimental.gc.
        ↪statepoint.p0f_isVoidf(i64 0, i32 0, void ()* @foo, i32 0, i32 1, i32* @Flag, i32 0,
        ↪ i8 @addrspace(1) * %obj)
        %obj.relocated = call coldcc i8 @addrspace(1) * @llvm.experimental.gc.relocate.
        ↪pli8(token %0, i32 7, i32 7)
        ret i8 @addrspace(1) * %obj.relocated
    }

```

During lowering, this will result in a instruction selection DAG that looks something like:

```

CALLSEQ_START
...
GC_TRANSITION_START (lowered i32 *@Flag), SRCVALUE i32* Flag
STATEPOINT
GC_TRANSITION_END (lowered i32 *@Flag), SRCVALUE i32 *Flag
...
CALLSEQ_END

```

In order to generate the necessary transition code, the backend for each target supported by "hypothetical-gc" must be modified to lower GC_TRANSITION_START and GC_TRANSITION_END nodes appropriately when the "hypothetical-gc" strategy is in use for a particular function. Assuming that such lowering has been added for X86, the generated assembly would be:

```

    .globl      test1
    .align      16, 0x90
    pushq %rax
    movl $1, %fs:Flag@TPOFF
    callq foo
    movl $0, %fs:Flag@TPOFF
.Ltmp1:
    movq (%rsp), %rax # This load is redundant (oops!)
    popq %rdx
    retq

```

Note that the design as presented above is not fully implemented: in particular, strategy-specific lowering is not present, and all GC transitions are emitted as as single no-op before and after the call instruction. These no-ops are often removed by the backend during dead machine instruction elimination.

4.31.3 Intrinsics

'llvm.experimental.gc.statepoint' Intrinsic

Syntax:

```

declare token
    @llvm.experimental.gc.statepoint(i64 <id>, i32 <num patch bytes>,
                                     func_type <target>,
                                     i64 <#call args>, i64 <flags>,
                                     ... (call parameters),

```

(continues on next page)

(continued from previous page)

```
i64 <# transition args>, ... (transition parameters),
i64 <# deopt args>, ... (deopt parameters),
... (gc parameters))
```

Overview:

The statepoint intrinsic represents a call which is parse-able by the runtime.

Operands:

The 'id' operand is a constant integer that is reported as the ID field in the generated stackmap. LLVM does not interpret this parameter in any way and its meaning is up to the statepoint user to decide. Note that LLVM is free to duplicate code containing statepoint calls, and this may transform IR that had a unique 'id' per lexical call to statepoint to IR that does not.

If 'num patch bytes' is non-zero then the call instruction corresponding to the statepoint is not emitted and LLVM emits 'num patch bytes' bytes of nops in its place. LLVM will emit code to prepare the function arguments and retrieve the function return value in accordance to the calling convention; the former before the nop sequence and the latter after the nop sequence. It is expected that the user will patch over the 'num patch bytes' bytes of nops with a calling sequence specific to their runtime before executing the generated machine code. There are no guarantees with respect to the alignment of the nop sequence. Unlike *Stack maps and patch points in LLVM* statepoints do not have a concept of shadow bytes. Note that semantically the statepoint still represents a call or invoke to 'target', and the nop sequence after patching is expected to represent an operation equivalent to a call or invoke to 'target'.

The 'target' operand is the function actually being called. The target can be specified as either a symbolic LLVM function, or as an arbitrary Value of appropriate function type. Note that the function type must match the signature of the callee and the types of the 'call parameters' arguments.

The '#call args' operand is the number of arguments to the actual call. It must exactly match the number of arguments passed in the 'call parameters' variable length section.

The 'flags' operand is used to specify extra information about the statepoint. This is currently only used to mark certain statepoints as GC transitions. This operand is a 64-bit integer with the following layout, where bit 0 is the least significant bit:

Bit #	Usage
0	Set if the statepoint is a GC transition, cleared otherwise.
1-63	Reserved for future use; must be cleared.

The 'call parameters' arguments are simply the arguments which need to be passed to the call target. They will be lowered according to the specified calling convention and otherwise handled like a normal call instruction. The number of arguments must exactly match what is specified in '# call args'. The types must match the signature of 'target'.

The 'transition parameters' arguments contain an arbitrary list of Values which need to be passed to GC transition code. They will be lowered and passed as operands to the appropriate GC_TRANSITION nodes in the selection DAG. It is assumed that these arguments must be available before and after (but not necessarily during) the execution of the callee. The '# transition args' field indicates how many operands are to be interpreted as 'transition parameters'.

The 'deopt parameters' arguments contain an arbitrary list of Values which is meaningful to the runtime. The runtime may read any of these values, but is assumed not to modify them. If the garbage collector might need to modify one of these values, it must also be listed in the 'gc pointer' argument list. The '# deopt args' field indicates how many operands are to be interpreted as 'deopt parameters'.

The 'gc parameters' arguments contain every pointer to a garbage collector object which potentially needs to be updated by the garbage collector. Note that the argument list must explicitly contain a base pointer for every derived pointer listed. The order of arguments is unimportant. Unlike the other variable length parameter sets, this list is not length prefixed.

Semantics:

A statepoint is assumed to read and write all memory. As a result, memory operations can not be reordered past a statepoint. It is illegal to mark a statepoint as being either 'readonly' or 'readnone'.

Note that legal IR can not perform any memory operation on a 'gc pointer' argument of the statepoint in a location statically reachable from the statepoint. Instead, the explicitly relocated value (from a `gc.relocate`) must be used.

'llvm.experimental.gc.result' Intrinsic

Syntax:

```
declare type*
  @llvm.experimental.gc.result(token %statepoint_token)
```

Overview:

`gc.result` extracts the result of the original call instruction which was replaced by the `gc.statepoint`. The `gc.result` intrinsic is actually a family of three intrinsics due to an implementation limitation. Other than the type of the return value, the semantics are the same.

Operands:

The first and only argument is the `gc.statepoint` which starts the safepoint sequence of which this `gc.result` is a part. Despite the typing of this as a generic token, *only* the value defined by a `gc.statepoint` is legal here.

Semantics:

The `gc.result` represents the return value of the call target of the `statepoint`. The type of the `gc.result` must exactly match the type of the target. If the call target returns void, there will be no `gc.result`.

A `gc.result` is modeled as a 'readnone' pure function. It has no side effects since it is just a projection of the return value of the previous call represented by the `gc.statepoint`.

'llvm.experimental.gc.relocate' Intrinsic

Syntax:

```
declare <pointer type>
  @llvm.experimental.gc.relocate(token %statepoint_token,
                                i32 %base_offset,
                                i32 %pointer_offset)
```

Overview:

A `gc.relocate` returns the potentially relocated value of a pointer at the safepoint.

Operands:

The first argument is the `gc.statepoint` which starts the safepoint sequence of which this `gc.relocation` is a part. Despite the typing of this as a generic token, *only* the value defined by a `gc.statepoint` is legal here.

The second argument is an index into the statepoints list of arguments which specifies the allocation for the pointer being relocated. This index must land within the 'gc parameter' section of the statepoint's argument list. The associated value must be within the object with which the pointer being relocated is associated. The optimizer is free to change *which* interior derived pointer is reported, provided that it does not replace an actual base pointer with another interior derived pointer. Collectors are allowed to rely on the base pointer operand remaining an actual base pointer if so constructed.

The third argument is an index into the statepoint's list of arguments which specify the (potentially) derived pointer being relocated. It is legal for this index to be the same as the second argument if-and-only-if a base pointer is being relocated. This index must land within the 'gc parameter' section of the statepoint's argument list.

Semantics:

The return value of `gc.relocate` is the potentially relocated value of the pointer specified by its arguments. It is unspecified how the value of the returned pointer relates to the argument to the `gc.statepoint` other than that a) it points to the same source language object with the same offset, and b) the 'based-on' relationship of the newly relocated pointers is a projection of the unrelocated pointers. In particular, the integer value of the pointer returned is unspecified.

A `gc.relocate` is modeled as a `readonly` pure function. It has no side effects since it is just a way to extract information about work done during the actual call modeled by the `gc.statepoint`.

4.31.4 Stack Map Format

Locations for each pointer value which may need read and/or updated by the runtime or collector are provided in a separate section of the generated object file as specified in the PatchPoint documentation. This special section is encoded per the *Stack Map format*.

The general expectation is that a JIT compiler will parse and discard this format; it is not particularly memory efficient. If you need an alternate format (e.g. for an ahead of time compiler), see discussion under :ref: *open work items <OpenWork>* below.

Each statepoint generates the following Locations:

- Constant which describes the calling convention of the call target. This constant is a valid *calling convention identifier* for the version of LLVM used to generate the stackmap. No additional compatibility guarantees are made for this constant over what LLVM provides elsewhere w.r.t. these identifiers.
- Constant which describes the flags passed to the statepoint intrinsic
- Constant which describes number of following deopt *Locations* (not operands)
- Variable number of Locations, one for each deopt parameter listed in the IR statepoint (same number as described by previous Constant). At the moment, only deopt parameters with a bitwidth of 64 bits or less are supported. Values of a type larger than 64 bits can be specified and reported only if a) the value is constant at the

call site, and b) the constant can be represented with less than 64 bits (assuming zero extension to the original bitwidth).

- Variable number of relocation records, each of which consists of exactly two Locations. Relocation records are described in detail below.

Each relocation record provides sufficient information for a collector to relocate one or more derived pointers. Each record consists of a pair of Locations. The second element in the record represents the pointer (or pointers) which need updated. The first element in the record provides a pointer to the base of the object with which the pointer(s) being relocated is associated. This information is required for handling generalized derived pointers since a pointer may be outside the bounds of the original allocation, but still needs to be relocated with the allocation. Additionally:

- It is guaranteed that the base pointer must also appear explicitly as a relocation pair if used after the statepoint.
- There may be fewer relocation records than gc parameters in the IR statepoint. Each *unique* pair will occur at least once; duplicates are possible.
- The Locations within each record may either be of pointer size or a multiple of pointer size. In the later case, the record must be interpreted as describing a sequence of pointers and their corresponding base pointers. If the Location is of size $N \times \text{sizeof}(\text{pointer})$, then there will be N records of one pointer each contained within the Location. Both Locations in a pair can be assumed to be of the same size.

Note that the Locations used in each section may describe the same physical location. e.g. A stack slot may appear as a deopt location, a gc base pointer, and a gc derived pointer.

The LiveOut section of the StkMapRecord will be empty for a statepoint record.

4.31.5 Safepoint Semantics & Verification

The fundamental correctness property for the compiled code's correctness w.r.t. the garbage collector is a dynamic one. It must be the case that there is no dynamic trace such that a operation involving a potentially relocated pointer is observably-after a safepoint which could relocate it. 'observably-after' in this usage means that an outside observer could observe this sequence of events in a way which precludes the operation being performed before the safepoint.

To understand why this 'observable-after' property is required, consider a null comparison performed on the original copy of a relocated pointer. Assuming that control flow follows the safepoint, there is no way to observe externally whether the null comparison is performed before or after the safepoint. (Remember, the original Value is unmodified by the safepoint.) The compiler is free to make either scheduling choice.

The actual correctness property implemented is slightly stronger than this. We require that there be no *static path* on which a potentially relocated pointer is 'observably-after' it may have been relocated. This is slightly stronger than is strictly necessary (and thus may disallow some otherwise valid programs), but greatly simplifies reasoning about correctness of the compiled code.

By construction, this property will be upheld by the optimizer if correctly established in the source IR. This is a key invariant of the design.

The existing IR Verifier pass has been extended to check most of the local restrictions on the intrinsics mentioned in their respective documentation. The current implementation in LLVM does not check the key relocation invariant, but this is ongoing work on developing such a verifier. Please ask on `llvm-dev` if you're interested in experimenting with the current version.

4.31.6 Utility Passes for Safepoint Insertion

RewriteStatepointsForGC

The pass `RewriteStatepointsForGC` transforms a function's IR to lower from the abstract machine model described above to the explicit statepoint model of relocations. To do this, it replaces all calls or invokes of functions which might contain a safepoint poll with a `gc.statepoint` and associated full relocation sequence, including all required `gc.relocates`.

Note that by default, this pass only runs for the "statepoint-example" or "core-clr" gc strategies. You will need to add your custom strategy to this whitelist or use one of the predefined ones.

As an example, given this code:

```
define i8 @addrspace(1) * @test1(i8 @addrspace(1) * %obj)
    gc "statepoint-example" {
    call void @foo()
    ret i8 @addrspace(1) * %obj
    }
```

The pass would produce this IR:

```
define i8 @addrspace(1) * @test1(i8 @addrspace(1) * %obj)
    gc "statepoint-example" {
    %0 = call token (i64, i32, void ()*, i32, i32, ...) * @llvm.experimental.gc.
    ↪statepoint.p0f_isVoidf(i64 2882400000, i32 0, void ()* @foo, i32 0, i32 0, i32 0,
    ↪i32 5, i32 0, i32 -1, i32 0, i32 0, i32 0, i8 @addrspace(1) * %obj)
    %obj.relocated = call coldcc i8 @addrspace(1) * @llvm.experimental.gc.relocate.
    ↪pli8(token %0, i32 12, i32 12)
    ret i8 @addrspace(1) * %obj.relocated
    }
```

In the above examples, the `addrspace(1)` marker on the pointers is the mechanism that the `statepoint-example` GC strategy uses to distinguish references from non references. The pass assumes that all `addrspace(1)` pointers are non-integral pointer types. Address space 1 is not globally reserved for this purpose.

This pass can be used as a utility function by a language frontend that doesn't want to manually reason about liveness, base pointers, or relocation when constructing IR. As currently implemented, `RewriteStatepointsForGC` must be run after SSA construction (i.e. `mem2ref`).

`RewriteStatepointsForGC` will ensure that appropriate base pointers are listed for every relocation created. It will do so by duplicating code as needed to propagate the base pointer associated with each pointer being relocated to the appropriate safepoints. The implementation assumes that the following IR constructs produce base pointers: loads from the heap, addresses of global variables, function arguments, function return values. Constant pointers (such as null) are also assumed to be base pointers. In practice, this constraint can be relaxed to producing interior derived pointers provided the target collector can find the associated allocation from an arbitrary interior derived pointer.

By default `RewriteStatepointsForGC` passes in `0xABCDEF00` as the statepoint ID and 0 as the number of patchable bytes to the newly constructed `gc.statepoint`. These values can be configured on a per-callsite basis using the attributes "statepoint-id" and "statepoint-num-patch-bytes". If a call site is marked with a "statepoint-id" function attribute and its value is a positive integer (represented as a string), then that value is used as the ID of the newly constructed `gc.statepoint`. If a call site is marked with a "statepoint-num-patch-bytes" function attribute and its value is a positive integer, then that value is used as the 'num patch bytes' parameter of the newly constructed `gc.statepoint`. The "statepoint-id" and "statepoint-num-patch-bytes" attributes are not propagated to the `gc.statepoint` call or invoke if they could be successfully parsed.

In practice, `RewriteStatepointsForGC` should be run much later in the pass pipeline, after most optimization is already done. This helps to improve the quality of the generated code when compiled with garbage collection support.

PlaceSafepoints

The pass `PlaceSafepoints` inserts safepoint polls sufficient to ensure running code checks for a safepoint request on a timely manner. This pass is expected to be run before `RewriteStatepointsForGC` and thus does not produce full relocation sequences.

As an example, given input IR of the following:

```
define void @test() gc "statepoint-example" {  
    call void @foo()  
    ret void  
}  
  
declare void @do_safepoint()  
define void @gc.safepoint_poll() {  
    call void @do_safepoint()  
    ret void  
}
```

This pass would produce the following IR:

```
define void @test() gc "statepoint-example" {  
    call void @do_safepoint()  
    call void @foo()  
    ret void  
}
```

In this case, we've added an (unconditional) entry safepoint poll. Note that despite appearances, the entry poll is not necessarily redundant. We'd have to know that `foo` and `test` were not mutually recursive for the poll to be redundant. In practice, you'd probably want your poll definition to contain a conditional branch of some form.

At the moment, `PlaceSafepoints` can insert safepoint polls at method entry and loop backedges locations. Extending this to work with return polls would be straight forward if desired.

`PlaceSafepoints` includes a number of optimizations to avoid placing safepoint polls at particular sites unless needed to ensure timely execution of a poll under normal conditions. `PlaceSafepoints` does not attempt to ensure timely execution of a poll under worst case conditions such as heavy system paging.

The implementation of a safepoint poll action is specified by looking up a function of the name `gc.safepoint_poll` in the containing Module. The body of this function is inserted at each poll site desired. While calls or invokes inside this method are transformed to a `gc.statepoints`, recursive poll insertion is not performed.

This pass is useful for any language frontend which only has to support garbage collection semantics at safepoints. If you need other abstract frame information at safepoints (e.g. for deoptimization or introspection), you can insert safepoint polls in the frontend. If you have the later case, please ask on `llvm-dev` for suggestions. There's been a good amount of work done on making such a scheme work well in practice which is not yet documented here.

4.31.7 Supported Architectures

Support for statepoint generation requires some code for each backend. Today, only X86_64 is supported.

4.31.8 Limitations and Half Baked Ideas

Mixing References and Raw Pointers

Support for languages which allow unmanaged pointers to garbage collected objects (i.e. pass a pointer to an object to a C routine) in the abstract machine model. At the moment, the best idea on how to approach this involves an intrinsic or opaque function which hides the connection between the reference value and the raw pointer. The problem is that having a `ptrtoint` or `inttoptr` cast (which is common for such use cases) breaks the rules used for inferring base pointers for arbitrary references when lowering out of the abstract model to the explicit physical model. Note that a frontend which lowers directly to the physical model doesn't have any problems here.

Objects on the Stack

As noted above, the explicit lowering supports objects allocated on the stack provided the collector can find a heap map given the stack address.

The missing pieces are a) integration with rewriting (RS4GC) from the abstract machine model and b) support for optionally decomposing on stack objects so as not to require heap maps for them. The later is required for ease of integration with some collectors.

Lowering Quality and Representation Overhead

The current statepoint lowering is known to be somewhat poor. In the very long term, we'd like to integrate statepoints with the register allocator; in the near term this is unlikely to happen. We've found the quality of lowering to be relatively unimportant as hot-statepoints are almost always inliner bugs.

Concerns have been raised that the statepoint representation results in a large amount of IR being produced for some examples and that this contributes to higher than expected memory usage and compile times. There's no immediate plans to make changes due to this, but alternate models may be explored in the future.

Relocations Along Exceptional Edges

Relocations along exceptional paths are currently broken in ToT. In particular, there is current no way to represent a rethrow on a path which also has relocations. See [this llvm-dev discussion](#) for more detail.

Support for alternate stackmap formats

For some use cases, it is desirable to directly encode a final memory efficient stackmap format for use by the runtime. This is particularly relevant for ahead of time compilers which wish to directly link object files without the need for post processing of each individual object file. While not implemented today for statepoints, there is precedent for a GCStrategy to be able to select a customer GCMetadataPrinter for this purpose. Patches to enable this functionality upstream are welcome.

4.31.9 Bugs and Enhancements

Currently known bugs and enhancements under consideration can be tracked by performing a [bugzilla search](#) for [Statepoint] in the summary field. When filing new bugs, please use this tag so that interested parties see the newly filed bug. As with most LLVM features, design discussions take place on [llvm-dev](#), and patches should be sent to [llvm-commits](#) for review.

4.32 MergeFunctions pass, how it works

4.32.1 Introduction

Sometimes code contains equal functions, or functions that does exactly the same thing even though they are non-equal on the IR level (e.g.: multiplication on 2 and 'shl 1'). It could happen due to several reasons: mainly, the usage of templates and automatic code generators. Though, sometimes the user itself could write the same thing twice :-)

The main purpose of this pass is to recognize such functions and merge them.

This document is the extension to pass comments and describes the pass logic. It describes the algorithm that is used in order to compare functions and explains how we could combine equal functions correctly to keep the module valid.

Material is brought in a top-down form, so the reader could start to learn pass from high level ideas and end with low-level algorithm details, thus preparing him or her for reading the sources.

The main goal is to describe the algorithm and logic here and the concept. If you *don't want* to read the source code, but want to understand pass algorithms, this document is good for you. The author tries not to repeat the source-code and covers only common cases to avoid the cases of needing to update this document after any minor code changes.

What should I know to be able to follow along with this document?

The reader should be familiar with common compile-engineering principles and LLVM code fundamentals. In this article, we assume the reader is familiar with [Single Static Assignment](#) concept and has an understanding of [IR structure](#).

We will use terms such as "module", "function", "basic block", "user", "value", "instruction".

As a good starting point, the Kaleidoscope tutorial can be used:

[LLVM Tutorial: Table of Contents](#)

It's especially important to understand chapter 3 of tutorial:

[Kaleidoscope: Code generation to LLVM IR](#)

The reader should also know how passes work in LLVM. They could use this article as a reference and start point here:

[Writing an LLVM Pass](#)

What else? Well perhaps the reader should also have some experience in LLVM pass debugging and bug-fixing.

Narrative structure

The article consists of three parts. The first part explains pass functionality on the top-level. The second part describes the comparison procedure itself. The third part describes the merging process.

In every part, the author tries to put the contents in the top-down form. The top-level methods will first be described followed by the terminal ones at the end, in the tail of each part. If the reader sees the reference to the method that wasn't described yet, they will find its description a bit below.

4.32.2 Basics

How to do it?

Do we need to merge functions? The obvious answer is: Yes, that is quite a possible case. We usually *do* have duplicates and it would be good to get rid of them. But how do we detect duplicates? This is the idea: we split functions into smaller bricks or parts and compare the "bricks" amount. If equal, we compare the "bricks" themselves, and then do our conclusions about functions themselves.

What could the difference be? For example, on a machine with 64-bit pointers (let's assume we have only one address space), one function stores a 64-bit integer, while another one stores a pointer. If the target is the machine mentioned above, and if functions are identical, except the parameter type (we could consider it as a part of function type), then we can treat a `uint64_t` and a `void*` as equal.

This is just an example; more possible details are described a bit below.

As another example, the reader may imagine two more functions. The first function performs a multiplication on 2, while the second one performs an arithmetic right shift on 1.

Possible solutions

Let's briefly consider possible options about how and what we have to implement in order to create full-featured functions merging, and also what it would mean for us.

Equal function detection obviously supposes that a "detector" method to be implemented and latter should answer the question "whether functions are equal". This "detector" method consists of tiny "sub-detectors", which each answers exactly the same question, but for function parts.

As the second step, we should merge equal functions. So it should be a "merger" method. "Merger" accepts two functions *F1* and *F2*, and produces *F1F2* function, the result of merging.

Having such routines in our hands, we can process a whole module, and merge all equal functions.

In this case, we have to compare every function with every another function. As the reader may notice, this way seems to be quite expensive. Of course we could introduce hashing and other helpers, but it is still just an optimization, and thus the level of $O(N*N)$ complexity.

Can we reach another level? Could we introduce logarithmical search, or random access lookup? The answer is: "yes".

Random-access

How it could this be done? Just convert each function to a number, and gather all of them in a special hash-table. Functions with equal hashes are equal. Good hashing means, that every function part must be taken into account. That means we have to convert every function part into some number, and then add it into the hash. The lookup-up time would be small, but such a approach adds some delay due to the hashing routine.

Logarithmical search

We could introduce total ordering among the functions set, once ordered we could then implement a logarithmical search. Lookup time still depends on N , but adds a little of delay ($\log(N)$).

Present state

Both of the approaches (random-access and logarithmical) have been implemented and tested and both give a very good improvement. What was most surprising is that logarithmical search was faster; sometimes by up to 15%. The hashing method needs some extra CPU time, which is the main reason why it works slower; in most cases, total "hashing" time is greater than total "logarithmical-search" time.

So, preference has been granted to the "logarithmical search".

Though in the case of need, *logarithmical-search* (read "total-ordering") could be used as a milestone on our way to the *random-access* implementation.

Every comparison is based either on the numbers or on the flags comparison. In the *random-access* approach, we could use the same comparison algorithm. During comparison, we exit once we find the difference, but here we might have to scan the whole function body every time (note, it could be slower). Like in "total-ordering", we will track every number and flag, but instead of comparison, we should get the numbers sequence and then create the hash number. So, once again, *total-ordering* could be considered as a milestone for even faster (in theory) random-access approach.

MergeFunctions, main fields and runOnModule

There are two main important fields in the class:

`FnTree` – the set of all unique functions. It keeps items that couldn't be merged with each other. It is defined as:

```
std::set<FunctionNode> FnTree;
```

Here `FunctionNode` is a wrapper for `llvm::Function` class, with implemented "<" operator among the functions set (below we explain how it works exactly; this is a key point in fast functions comparison).

`Deferred` – merging process can affect bodies of functions that are in `FnTree` already. Obviously, such functions should be rechecked again. In this case, we remove them from `FnTree`, and mark them to be rescanned, namely put them into `Deferred` list.

runOnModule

The algorithm is pretty simple:

1. Put all module's functions into the *worklist*.
2. Scan *worklist*'s functions twice: first enumerate only strong functions and then only weak ones:
 - 2.1. Loop body: take a function from *worklist* (call it *FCur*) and try to insert it into *FnTree*: check whether *FCur* is equal to one of functions in *FnTree*. If there is an equal function in *FnTree* (call it *FExists*): merge function *FCur* with *FExists*. Otherwise add the function from the *worklist* to *FnTree*.
3. Once the *worklist* scanning and merging operations are complete, check the *Deferred* list. If it is not empty: refill the *worklist* contents with *Deferred* list and redo step 2, if the *Deferred* list is empty, then exit from method.

Comparison and logarithmical search

Let's recall our task: for every function F from module M , we have to find equal functions F' in the shortest time possible, and merge them into a single function.

Defining total ordering among the functions set allows us to organize functions into a binary tree. The lookup procedure complexity would be estimated as $O(\log(N))$ in this case. But how do we define *total-ordering*?

We have to introduce a single rule applicable to every pair of functions, and following this rule, then evaluate which of them is greater. What kind of rule could it be? Let's declare it as the "compare" method that returns one of 3 possible values:

- 1, left is *less* than right,
- 0, left and right are *equal*,
- 1, left is *greater* than right.

Of course it means, that we have to maintain *strict and non-strict order relation properties*:

- reflexivity ($a \leq a, a == a, a \geq a$),
- antisymmetry (if $a \leq b$ and $b \leq a$ then $a == b$),
- transitivity ($a \leq b$ and $b \leq c$, then $a \leq c$)
- asymmetry (if $a < b$, then $a > b$ or $a == b$).

As mentioned before, the comparison routine consists of "sub-comparison-routines", with each of them also consisting of "sub-comparison-routines", and so on. Finally, it ends up with primitive comparison.

Below, we will use the following operations:

1. `cmpNumbers(number1, number2)` is a method that returns -1 if left is less than right; 0, if left and right are equal; and 1 otherwise.
2. `cmpFlags(flag1, flag2)` is a hypothetical method that compares two flags. The logic is the same as in `cmpNumbers`, where `true` is 1, and `false` is 0.

The rest of the article is based on *MergeFunctions.cpp* source code (found in `<llvm_dir>/lib/Transforms/IPO/MergeFunctions.cpp`). We would like to ask reader to keep this file open, so we could use it as a reference for further explanations.

Now, we're ready to proceed to the next chapter and see how it works.

4.32.3 Functions comparison

At first, let's define how exactly we compare complex objects.

Complex object comparison (function, basic-block, etc) is mostly based on its sub-object comparison results. It is similar to the next "tree" objects comparison:

1. For two trees $T1$ and $T2$ we perform *depth-first-traversal* and have two sequences as a product: " $T1Items$ " and " $T2Items$ ".
2. We then compare chains " $T1Items$ " and " $T2Items$ " in the most-significant-item-first order. The result of items comparison would be the result of $T1$ and $T2$ comparison itself.

FunctionComparator::compare(void)

A brief look at the source code tells us that the comparison starts in the “`int FunctionComparator::compare(void)`” method.

1. The first parts to be compared are the function's attributes and some properties that is outside the “attributes” term, but still could make the function different without changing its body. This part of the comparison is usually done within simple *cmpNumbers* or *cmpFlags* operations (e.g. `cmpFlags(F1->hasGC(), F2->hasGC())`). Below is a full list of function's properties to be compared on this stage:

- *Attributes* (those are returned by `Function::getAttributes()` method).
- *GC*, for equivalence, *RHS* and *LHS* should be both either without *GC* or with the same one.
- *Section*, just like a *GC*: *RHS* and *LHS* should be defined in the same section.
- *Variable arguments*. *LHS* and *RHS* should be both either with or without *var-args*.
- *Calling convention* should be the same.

2. Function type. Checked by `FunctionComparator::cmpType(Type*, Type*)` method. It checks return type and parameters type; the method itself will be described later.

3. Associate function formal parameters with each other. Then comparing function bodies, if we see the usage of *LHS*'s *i*-th argument in *LHS*'s body, then, we want to see usage of *RHS*'s *i*-th argument at the same place in *RHS*'s body, otherwise functions are different. On this stage we grant the preference to those we met later in function body (value we met first would be *less*). This is done by “`FunctionComparator::cmpValues(const Value*, const Value*)`” method (will be described a bit later).

4. Function body comparison. As it written in method comments:

“We do a CFG-ordered walk since the actual ordering of the blocks in the linked list is immaterial. Our walk starts at the entry block for both functions, then takes each block from each terminator in order. As an artifact, this also means that unreachable blocks are ignored.”

So, using this walk we get BBs from *left* and *right* in the same order, and compare them by “`FunctionComparator::compare(const BasicBlock*, const BasicBlock*)`” method.

We also associate BBs with each other, like we did it with function formal arguments (see *cmpValues* method below).

FunctionComparator::cmpType

Consider how type comparison works.

1. Coerce pointer to integer. If left type is a pointer, try to coerce it to the integer type. It could be done if its address space is 0, or if address spaces are ignored at all. Do the same thing for the right type.
2. If left and right types are equal, return 0. Otherwise we need to give preference to one of them. So proceed to the next step.
3. If types are of different kind (different type IDs). Return result of type IDs comparison, treating them as numbers (use *cmpNumbers* operation).
4. If types are vectors or integers, return result of their pointers comparison, comparing them as numbers.
5. Check whether type ID belongs to the next group (call it equivalent-group):
 - Void
 - Float
 - Double

- X86_FP80
- FP128
- PPC_FP128
- Label
- Metadata.

If ID belongs to group above, return 0. Since it's enough to see that types has the same `TypeID`. No additional information is required.

6. Left and right are pointers. Return result of address space comparison (numbers comparison).

7. Complex types (structures, arrays, etc.). Follow complex objects comparison technique (see the very first paragraph of this chapter). Both *left* and *right* are to be expanded and their element types will be checked the same way. If we get -1 or 1 on some stage, return it. Otherwise return 0.

8. Steps 1-6 describe all the possible cases, if we passed steps 1-6 and didn't get any conclusions, then invoke `llvm_unreachable`, since it's quite an unexpected case.

cmpValues(const Value*, const Value*)

Method that compares local values.

This method gives us an answer to a very curious question: whether we could treat local values as equal, and which value is greater otherwise. It's better to start from example:

Consider the situation when we're looking at the same place in left function "*FL*" and in right function "*FR*". Every part of *left* place is equal to the corresponding part of *right* place, and (!) both parts use *Value* instances, for example:

```
instr0 i32 %LV      ; left side, function FL
instr0 i32 %RV      ; right side, function FR
```

So, now our conclusion depends on *Value* instances comparison.

The main purpose of this method is to determine relation between such values.

What can we expect from equal functions? At the same place, in functions "*FL*" and "*FR*" we expect to see *equal* values, or values *defined* at the same place in "*FL*" and "*FR*".

Consider a small example here:

```
define void %f(i32 %pf0, i32 %pf1) {
    instr0 i32 %pf0 instr1 i32 %pf1 instr2 i32 123
}
```

```
define void %g(i32 %pg0, i32 %pg1) {
    instr0 i32 %pg0 instr1 i32 %pg0 instr2 i32 123
}
```

In this example, *pf0* is associated with *pg0*, *pf1* is associated with *pg1*, and we also declare that *pf0* < *pf1*, and thus *pg0* < *pf1*.

Instructions with opcode "*instr0*" would be *equal*, since their types and opcodes are equal, and values are *associated*.

Instructions with opcode "*instr1*" from *f* is *greater* than instructions with opcode "*instr1*" from *g*; here we have equal types and opcodes, but "*pf1*" is greater than "*pg0*".

Instructions with opcode "*instr2*" are equal, because their opcodes and types are equal, and the same constant is used as a value.

What we associate in cmpValues?

- Function arguments. i -th argument from left function associated with i -th argument from right function.
- BasicBlock instances. In basic-block enumeration loop we associate i -th BasicBlock from the left function with i -th BasicBlock from the right function.
- Instructions.
- Instruction operands. Note, we can meet *Value* here we have never seen before. In this case it is not a function argument, nor *BasicBlock*, nor *Instruction*. It is a global value. It is a constant, since it's the only supposed global here. The method also compares: Constants that are of the same type and if right constant can be losslessly bit-casted to the left one, then we also compare them.

How to implement cmpValues?

Association is a case of equality for us. We just treat such values as equal, but, in general, we need to implement antisymmetric relation. As mentioned above, to understand what is *less*, we can use order in which we meet values. If both values have the same order in a function (met at the same time), we then treat values as *associated*. Otherwise – it depends on who was first.

Every time we run the top-level compare method, we initialize two identical maps (one for the left side, another one for the right side):

```
map<Value, int> sn_mapL, sn_mapR;
```

The key of the map is the *Value* itself, the *value* – is its order (call it *serial number*).

To add value V we need to perform the next procedure:

```
sn_map.insert(std::make_pair(V, sn_map.size()));
```

For the first *Value*, map will return 0 , for the second *Value* map will return 1 , and so on.

We can then check whether left and right values met at the same time with a simple comparison:

```
cmpNumbers(sn_mapL[Left], sn_mapR[Right]);
```

Of course, we can combine insertion and comparison:

```
std::pair<iterator, bool>
LeftRes = sn_mapL.insert(std::make_pair(Left, sn_mapL.size()));
RightRes = sn_mapR.insert(std::make_pair(Right, sn_mapR.size()));
return cmpNumbers(LeftRes.first->second, RightRes.first->second);
```

Let's look, how whole method could be implemented.

1. We have to start with the bad news. Consider function self and cross-referencing cases:

```
// self-reference unsigned fact0(unsigned n) { return n > 1 ? n
* fact0(n-1) : 1; } unsigned fact1(unsigned n) { return n > 1 ? n *
fact1(n-1) : 1; }

// cross-reference unsigned ping(unsigned n) { return n!= 0 ? pong(n-1) : 0;
} unsigned pong(unsigned n) { return n!= 0 ? ping(n-1) : 0; }
```

This comparison has been implemented in initial *MergeFunctions* pass version. But, unfortunately, it is not transitive. And this is the only case we can't convert to less-equal-greater comparison. It is a seldom case, 4-5 functions of 10000 (checked in test-suite), and, we hope, the reader would forgive us for such a sacrifice in order to get the $O(\log(N))$ pass time.

2. If left/right *Value* is a constant, we have to compare them. Return 0 if it is the same constant, or use `cmpConstants` method otherwise.
3. If left/right is *InlineAsm* instance. Return result of *Value* pointers comparison.
4. Explicit association of *L* (left value) and *R* (right value). We need to find out whether values met at the same time, and thus are *associated*. Or we need to put the rule: when we treat $L < R$. Now it is easy: we just return the result of numbers comparison:

```
std::pair<iterator, bool>
LeftRes = sn_mapL.insert(std::make_pair(Left, sn_mapL.size())),
RightRes = sn_mapR.insert(std::make_pair(Right, sn_mapR.size()));
if (LeftRes.first->second == RightRes.first->second) return 0;
if (LeftRes.first->second < RightRes.first->second) return -1;
return 1;
```

Now when *cmpValues* returns 0, we can proceed the comparison procedure. Otherwise, if we get (-1 or 1), we need to pass this result to the top level, and finish comparison procedure.

cmpConstants

Performs constants comparison as follows:

1. Compare constant types using `cmpType` method. If the result is -1 or 1, goto step 2, otherwise proceed to step 3.
2. If types are different, we still can check whether constants could be losslessly bitcasted to each other. The further explanation is modification of `canLosslesslyBitCastTo` method.
 - 2.1 Check whether constants are of the first class types (`isFirstClassType` check):
 - 2.1.1. If both constants are *not* of the first class type: return result of `cmpType`.
 - 2.1.2. Otherwise, if left type is not of the first class, return -1. If right type is not of the first class, return 1.
 - 2.1.3. If both types are of the first class type, proceed to the next step (2.1.3.1).
 - 2.1.3.1. If types are vectors, compare their bitwidth using the *cmpNumbers*. If result is not 0, return it.
 - 2.1.3.2. Different types, but not a vectors:
 - if both of them are pointers, good for us, we can proceed to step 3.
 - if one of types is pointer, return result of *isPointer* flags comparison (*cmpFlags* operation).
 - otherwise we have no methods to prove bitcastability, and thus return result of types comparison (-1 or 1).

Steps below are for the case when types are equal, or case when constants are bitcastable:

3. One of constants is a "null" value. Return the result of `cmpFlags(L->isNullValue, R->isNullValue)` comparison.
4. Compare value IDs, and return result if it is not 0:

```
if (int Res = cmpNumbers(L->getValueID(), R->getValueID()))
    return Res;
```

5. Compare the contents of constants. The comparison depends on the kind of constants, but on this stage it is just a lexicographical comparison. Just see how it was described in the beginning of "*Functions comparison*" paragraph. Mathematically, it is equal to the next case: we encode left constant and right constant (with similar way *bitcode-writer* does). Then compare left code sequence and right code sequence.

compare(const BasicBlock*, const BasicBlock*)

Compares two *BasicBlock* instances.

It enumerates instructions from left *BB* and right *BB*.

1. It assigns serial numbers to the left and right instructions, using `cmpValues` method.
2. If one of left or right is *GEP* (`GetElementPtr`), then treat *GEP* as greater than other instructions. If both instructions are *GEPs* use `cmpGEP` method for comparison. If result is -1 or 1, pass it to the top-level comparison (return it).
 - 3.1. Compare operations. Call `cmpOperation` method. If result is -1 or 1, return it.
 - 3.2. Compare number of operands, if result is -1 or 1, return it.
 - 3.3. Compare operands themselves, use `cmpValues` method. Return result if it is -1 or 1.
 - 3.4. Compare type of operands, using `cmpType` method. Return result if it is -1 or 1.
 - 3.5. Proceed to the next instruction.
4. We can finish instruction enumeration in 3 cases:
 - 4.1. We reached the end of both left and right basic-blocks. We didn't exit on steps 1-3, so contents are equal, return 0.
 - 4.2. We have reached the end of the left basic-block. Return -1.
 - 4.3. Return 1 (we reached the end of the right basic block).

cmpGEP

Compares two *GEPs* (`getelementptr` instructions).

It differs from regular operations comparison with the only thing: possibility to use `accumulateConstantOffset` method.

So, if we get constant offset for both left and right *GEPs*, then compare it as numbers, and return comparison result.

Otherwise treat it like a regular operation (see previous paragraph).

cmpOperation

Compares instruction opcodes and some important operation properties.

1. Compare opcodes, if it differs return the result.
2. Compare number of operands. If it differs – return the result.
3. Compare operation types, use `cmpType`. All the same – if types are different, return result.
4. Compare *subclassOptionalData*, get it with `getRawSubclassOptionalData` method, and compare it like a numbers.
5. Compare operand types.
6. For some particular instructions, check equivalence (relation in our case) of some significant attributes. For example, we have to compare alignment for `load` instructions.

O(log(N))

Methods described above implement order relationship. And latter, could be used for nodes comparison in a binary tree. So we can organize functions set into the binary tree and reduce the cost of lookup procedure from $O(N*N)$ to $O(\log(N))$.

4.32.4 Merging process, mergeTwoFunctions

Once *MergeFunctions* detected that current function (*G*) is equal to one that were analyzed before (function *F*) it calls `mergeTwoFunctions(Function*, Function*)`.

Operation affects `FnTree` contents with next way: *F* will stay in `FnTree`. *G* being equal to *F* will not be added to `FnTree`. Calls of *G* would be replaced with something else. It changes bodies of callers. So, functions that calls *G* would be put into `Deferred` set and removed from `FnTree`, and analyzed again.

The approach is next:

1. Most wished case: when we can use alias and both of *F* and *G* are weak. We make both of them with aliases to the third strong function *H*. Actually *H* is *F*. See below how it's made (but it's better to look straight into the source code). Well, this is a case when we can just replace *G* with *F* everywhere, we use `replaceAllUsesWith` operation here (*RAUW*).
2. *F* could not be overridden, while *G* could. It would be good to do the next: after merging the places where overridable function were used, still use overridable stub. So try to make *G* alias to *F*, or create overridable tail call wrapper around *F* and replace *G* with that call.
3. Neither *F* nor *G* could be overridden. We can't use *RAUW*. We can just change the callers: call *F* instead of *G*. That's what `replaceDirectCallers` does.

Below is a detailed body description.

If “F” may be overridden

As follows from `maybeOverridden` comments: “whether the definition of this global may be replaced by something non-equivalent at link time”. If so, that's ok: we can use alias to *F* instead of *G* or change call instructions itself.

HasGlobalAliases, removeUsers

First consider the case when we have global aliases of one function name to another. Our purpose is make both of them with aliases to the third strong function. Though if we keep *F* alive and without major changes we can leave it in `FnTree`. Try to combine these two goals.

Do stub replacement of *F* itself with an alias to *F*.

1. Create stub function *H*, with the same name and attributes like function *F*. It takes maximum alignment of *F* and *G*.
2. Replace all uses of function *F* with uses of function *H*. It is the two steps procedure instead. First of all, we must take into account, all functions from whom *F* is called would be changed: since we change the call argument (from *F* to *H*). If so we must to review these caller functions again after this procedure. We remove callers from `FnTree`, method with name `removeUsers(F)` does that (don't confuse with `replaceAllUsesWith`):
 - 2.1. Inside `removeUsers(Value* V)` we go through the all values that use value *V* (or *F* in our context). If value is instruction, we go to function that holds this instruction and mark it as to-be-analyzed-again (put to `Deferred` set), we also remove caller from `FnTree`.
 - 2.2. Now we can do the replacement: `call F->replaceAllUsesWith(H)`.

3. H (that now "officially" plays F 's role) is replaced with alias to F . Do the same with G : replace it with alias to F . So finally everywhere F was used, we use H and it is alias to F , and everywhere G was used we also have alias to F .

4. Set F linkage to private. Make it strong :-)

No global aliases, replaceDirectCallers

If global aliases are not supported. We call `replaceDirectCallers`. Just go through all calls of G and replace it with calls of F . If you look into the method you will see that it scans all uses of G too, and if use is callee (if user is call instruction and G is used as what to be called), we replace it with use of F .

If “F” could not be overridden, fix it!

We call `writeThunkOrAlias(Function *F, Function *G)`. Here we try to replace G with alias to F first. The next conditions are essential:

- target should support global aliases,
- the address itself of G should be not significant, not named and not referenced anywhere,
- function should come with external, local or weak linkage.

Otherwise we write thunk: some wrapper that has G 's interface and calls F , so G could be replaced with this wrapper.

writeAlias

As follows from *llvm* reference:

“Aliases act as *second name* for the aliasee value”. So we just want to create a second name for F and use it instead of G :

1. create global alias itself (GA),
2. adjust alignment of F so it must be maximum of current and G 's alignment;
3. replace uses of G :
 - 3.1. first mark all callers of G as to-be-analyzed-again, using `removeUsers` method (see chapter above),
 - 3.2. call `G->replaceAllUsesWith(GA)`.
4. Get rid of G .

writeThunk

As it written in method comments:

“Replace G with a simple tail call to `bitcast(F)`. Also replace direct uses of G with `bitcast(F)`. Deletes G .”

In general it does the same as usual when we want to replace callee, except the first point:

1. We generate tail call wrapper around F , but with interface that allows use it instead of G .
2. “As-usual”: `removeUsers` and `replaceAllUsesWith` then.
3. Get rid of G .

4.33 Type Metadata

Type metadata is a mechanism that allows IR modules to co-operatively build pointer sets corresponding to addresses within a given set of globals. LLVM's [control flow integrity](#) implementation uses this metadata to efficiently check (at each call site) that a given address corresponds to either a valid vtable or function pointer for a given class or function type, and its whole-program devirtualization pass uses the metadata to identify potential callees for a given virtual call.

To use the mechanism, a client creates metadata nodes with two elements:

1. a byte offset into the global (generally zero for functions)
2. a metadata object representing an identifier for the type

These metadata nodes are associated with globals by using global object metadata attachments with the `!type` metadata kind.

Each type identifier must exclusively identify either global variables or functions.

Limitation

The current implementation only supports attaching metadata to functions on the x86-32 and x86-64 architectures.

An intrinsic, `llvm.type.test`, is used to test whether a given pointer is associated with a type identifier.

4.33.1 Representing Type Information using Type Metadata

This section describes how Clang represents C++ type information associated with virtual tables using type metadata.

Consider the following inheritance hierarchy:

```
struct A {
    virtual void f();
};

struct B : A {
    virtual void f();
    virtual void g();
};

struct C {
    virtual void h();
};

struct D : A, C {
    virtual void f();
    virtual void h();
};
```

The virtual table objects for A, B, C and D look like this (under the Itanium ABI):

Table 82: Virtual Table Layout for A, B, C, D

Class	0	1	2	3	4	5	6
A	A::offset-to-top	&A::rtti	&A::f				
B	B::offset-to-top	&B::rtti	&B::f	&B::g			
C	C::offset-to-top	&C::rtti	&C::h				
D	D::offset-to-top	&D::rtti	&D::f	&D::h	D::offset-to-top	&D::rtti	thunk for &D::h

When an object of type A is constructed, the address of `&A::f` in A's virtual table object is stored in the object's vtable pointer. In ABI parlance this address is known as an [address point](#). Similarly, when an object of type B is constructed, the address of `&B::f` is stored in the vtable pointer. In this way, the vtable in B's virtual table object is compatible with A's vtable.

D is a little more complicated, due to the use of multiple inheritance. Its virtual table object contains two vtables, one compatible with A's vtable and the other compatible with C's vtable. Objects of type D contain two virtual pointers, one belonging to the A subobject and containing the address of the vtable compatible with A's vtable, and the other belonging to the C subobject and containing the address of the vtable compatible with C's vtable.

The full set of compatibility information for the above class hierarchy is shown below. The following table shows the name of a class, the offset of an address point within that class's vtable and the name of one of the classes with which that address point is compatible.

Table 83: Type Offsets for A, B, C, D

VTable for	Offset	Compatible Class
A	16	A
B	16	A
		B
C	16	C
D	16	A
		D
	48	C

The next step is to encode this compatibility information into the IR. The way this is done is to create type metadata named after each of the compatible classes, with which we associate each of the compatible address points in each vtable. For example, these type metadata entries encode the compatibility information for the above hierarchy:

```
@_ZTV1A = constant [...], !type !0
@_ZTV1B = constant [...], !type !0, !type !1
@_ZTV1C = constant [...], !type !2
@_ZTV1D = constant [...], !type !0, !type !3, !type !4

!0 = !{i64 16, !"_ZTS1A"}
!1 = !{i64 16, !"_ZTS1B"}
!2 = !{i64 16, !"_ZTS1C"}
!3 = !{i64 16, !"_ZTS1D"}
!4 = !{i64 48, !"_ZTS1C"}
```

With this type metadata, we can now use the `llvm.type.test` intrinsic to test whether a given pointer is compatible with a type identifier. Working backwards, if `llvm.type.test` returns true for a particular pointer, we can also statically determine the identities of the virtual functions that a particular virtual call may call. For example, if a program assumes a pointer to be a member of `!"_ZTS1A"`, we know that the address can be only be one of `_ZTV1A+16`, `_ZTV1B+16` or `_ZTV1D+16` (i.e. the address points of the vtables of A, B and D respectively). If we then load an address from that pointer, we know that the address can only be one of `&A::f`, `&B::f` or `&D::f`.

4.33.2 Testing Addresses For Type Membership

If a program tests an address using `llvm.type.test`, this will cause a link-time optimization pass, `LowerTypeTests`, to replace calls to this intrinsic with efficient code to perform type member tests. At a high level, the pass will lay out referenced globals in a consecutive memory region in the object file, construct bit vectors that map onto that memory region, and generate code at each of the `llvm.type.test` call sites to test pointers against those bit vectors. Because of the layout manipulation, the globals' definitions must be available at LTO time. For more information, see the [control flow integrity design document](#).

A type identifier that identifies functions is transformed into a jump table, which is a block of code consisting of one branch instruction for each of the functions associated with the type identifier that branches to the target function. The pass will redirect any taken function addresses to the corresponding jump table entry. In the object file's symbol table, the jump table entries take the identities of the original functions, so that addresses taken outside the module will pass any verification done inside the module.

Jump tables may call external functions, so their definitions need not be available at LTO time. Note that if an externally defined function is associated with a type identifier, there is no guarantee that its identity within the module will be the same as its identity outside of the module, as the former will be the jump table entry if a jump table is necessary.

The `GlobalLayoutBuilder` class is responsible for laying out the globals efficiently to minimize the sizes of the underlying bitsets.

Example

```
target datalayout = "e-p:32:32"

@a = internal global i32 0, !type !0
@b = internal global i32 0, !type !0, !type !1
@c = internal global i32 0, !type !1
@d = internal global [2 x i32] [i32 0, i32 0], !type !2

define void @e() !type !3 {
    ret void
}

define void @f() {
    ret void
}

declare void @g() !type !3

!0 = !{i32 0, !"typeid1"}
!1 = !{i32 0, !"typeid2"}
!2 = !{i32 4, !"typeid2"}
!3 = !{i32 0, !"typeid3"}

declare i1 @llvm.type.test(i8* %ptr, metadata %typeid) nounwind readnone

define i1 @foo(i32* %p) {
    %pi8 = bitcast i32* %p to i8*
    %x = call i1 @llvm.type.test(i8* %pi8, metadata !"typeid1")
    ret i1 %x
}

define i1 @bar(i32* %p) {
    %pi8 = bitcast i32* %p to i8*
    %x = call i1 @llvm.type.test(i8* %pi8, metadata !"typeid2")
    ret i1 %x
}
```

(continues on next page)

(continued from previous page)

```

}

define i1 @baz(void ()* %p) {
    %pi8 = bitcast void ()* %p to i8*
    %x = call i1 @llvm.type.test(i8* %pi8, metadata !"typeid3")
    ret i1 %x
}

define void @main() {
    %a1 = call i1 @foo(i32* @a) ; returns 1
    %b1 = call i1 @foo(i32* @b) ; returns 1
    %c1 = call i1 @foo(i32* @c) ; returns 0
    %a2 = call i1 @bar(i32* @a) ; returns 0
    %b2 = call i1 @bar(i32* @b) ; returns 1
    %c2 = call i1 @bar(i32* @c) ; returns 1
    %d02 = call i1 @bar(i32* getelementptr ([2 x i32]* @d, i32 0, i32 0)) ; returns 0
    %d12 = call i1 @bar(i32* getelementptr ([2 x i32]* @d, i32 0, i32 1)) ; returns 1
    %e = call i1 @baz(void ()* @e) ; returns 1
    %f = call i1 @baz(void ()* @f) ; returns 0
    %g = call i1 @baz(void ()* @g) ; returns 1
    ret void
}

```

4.34 Code Transformation Metadata

- *Overview*
- *Metadata on Loops*
- *Transformation Metadata Structure*
- *Pass-Specific Transformation Metadata*
 - *Loop Vectorization and Interleaving*
 - *Loop Unrolling*
 - *Unroll-And-Jam*
 - *Loop Distribution*
 - *Versioning LICM*
 - *Loop Interchange*
- *Ambiguous Transformation Order*
- *Leftover Transformations*

4.34.1 Overview

LLVM transformation passes can be controlled by attaching metadata to the code to transform. By default, transformation passes use heuristics to determine whether or not to perform transformations, and when doing so, other details of how the transformations are applied (e.g., which vectorization factor to select). Unless the optimizer is otherwise directed, transformations are applied conservatively. This conservatism generally allows the optimizer to avoid unprofitable transformations, but in practice, this results in the optimizer not applying transformations that would be highly profitable.

Frontends can give additional hints to LLVM passes on which transformations they should apply. This can be additional knowledge that cannot be derived from the emitted IR, or directives passed from the user/programmer. OpenMP pragmas are an example of the latter.

If any such metadata is dropped from the program, the code's semantics must not change.

4.34.2 Metadata on Loops

Attributes can be attached to loops as described in *'llvm.loop'*. Attributes can describe properties of the loop, disable transformations, force specific transformations and set transformation options.

Because metadata nodes are immutable (with the exception of `MDNode::replaceOperandWith` which is dangerous to use on unique metadata), in order to add or remove a loop attributes, a new `MDNode` must be created and assigned as the new `llvm.loop` metadata. Any connection between the old `MDNode` and the loop is lost. The `llvm.loop` node is also used as `LoopID` (`Loop::getLoopID()`), i.e. the loop effectively gets a new identifier. For instance, `llvm.mem.parallel_loop_access` references the `LoopID`. Therefore, if the parallel access property is to be preserved after adding/removing loop attributes, any `llvm.mem.parallel_loop_access` reference must be updated to the new `LoopID`.

4.34.3 Transformation Metadata Structure

Some attributes describe code transformations (unrolling, vectorizing, loop distribution, etc.). They can either be a hint to the optimizer that a transformation might be beneficial, instruction to use a specific option, or convey a specific request from the user (such as `#pragma clang loop or #pragma omp simd`).

If a transformation is forced but cannot be carried-out for any reason, an optimization-missed warning must be emitted. Semantic information such as a transformation being safe (e.g. `llvm.mem.parallel_loop_access`) can be unused by the optimizer without generating a warning.

Unless explicitly disabled, any optimization pass may heuristically determine whether a transformation is beneficial and apply it. If metadata for another transformation was specified, applying a different transformation before it might be inadvertent due to being applied on a different loop or the loop not existing anymore. To avoid having to explicitly disable an unknown number of passes, the attribute `llvm.loop.disable_nonforced` disables all optional, high-level, restructuring transformations.

The following example avoids the loop being altered before being vectorized, for instance being unrolled.

```
br i1 %exitcond, label %for.exit, label %for.header, !llvm.loop !0
...
!0 = distinct !{!0, !1, !2}
!1 = !{"llvm.loop.vectorize.enable", i1 true}
!2 = !{"llvm.loop.disable_nonforced"}
```

After a transformation is applied, follow-up attributes are set on the transformed and/or new loop(s). This allows additional attributes including followup-transformations to be specified. Specifying multiple transformations in the same

metadata node is possible for compatibility reasons, but their execution order is undefined. For instance, when `llvm.loop.vectorize.enable` and `llvm.loop.unroll.enable` are specified at the same time, unrolling may occur either before or after vectorization.

As an example, the following instructs a loop to be vectorized and only then unrolled.

```
!0 = distinct !{!0, !1, !2, !3}
!1 = !{"llvm.loop.vectorize.enable", i1 true}
!2 = !{"llvm.loop.disable_nonforced"}
!3 = !{"llvm.loop.vectorize.followup_vectorized", !{"llvm.loop.unroll.enable"}}
```

If, and only if, no followup is specified, the pass may add attributes itself. For instance, the vectorizer adds a `llvm.loop.isvectorized` attribute and all attributes from the original loop excluding its loop vectorizer attributes. To avoid this, an empty followup attribute can be used, e.g.

```
!3 = !{"llvm.loop.vectorize.followup_vectorized"}
```

The followup attributes of a transformation that cannot be applied will never be added to a loop and are therefore effectively ignored. This means that any followup-transformation in such attributes requires that its prior transformations are applied before the followup-transformation. The user should receive a warning about the first transformation in the transformation chain that could not be applied if it a forced transformation. All following transformations are skipped.

4.34.4 Pass-Specific Transformation Metadata

Transformation options are specific to each transformation. In the following, we present the model for each LLVM loop optimization pass and the metadata to influence them.

Loop Vectorization and Interleaving

Loop vectorization and interleaving is interpreted as a single transformation. It is interpreted as forced if `!{"llvm.loop.vectorize.enable", i1 true}` is set.

Assuming the pre-vectorization loop is

```
for (int i = 0; i < n; i+=1) // original loop
    Stmt(i);
```

then the code after vectorization will be approximately (assuming an SIMD width of 4):

```
int i = 0;
if (rtc) {
    for (; i + 3 < n; i+=4) // vectorized/interleaved loop
        Stmt(i:i+3);
}
for (; i < n; i+=1) // epilogue loop
    Stmt(i);
```

where `rtc` is a generated runtime check.

`llvm.loop.vectorize.followup_vectorized` will set the attributes for the vectorized loop. If not specified, `llvm.loop.isvectorized` is combined with the original loop's attributes to avoid it being vectorized multiple times.

`llvm.loop.vectorize.followup_epilogue` will set the attributes for the remainder loop. If not specified, it will have the original loop's attributes combined with `llvm.loop.isvectorized` and `llvm.loop.unroll.runtime.disable` (unless the original loop already has unroll metadata).

The attributes specified by `llvm.loop.vectorize.followup_all` are added to both loops.

When using a follow-up attribute, it replaces any automatically deduced attributes for the generated loop in question. Therefore it is recommended to add `llvm.loop.isvectorized` to `llvm.loop.vectorize.followup_all` which avoids that the loop vectorizer tries to optimize the loops again.

Loop Unrolling

Unrolling is interpreted as forced any `!{"llvm.loop.unroll.enable"}` metadata or option (`llvm.loop.unroll.count`, `llvm.loop.unroll.full`) is present. Unrolling can be full unrolling, partial unrolling of a loop with constant trip count or runtime unrolling of a loop with a trip count unknown at compile-time.

If the loop has been unrolled fully, there is no followup-loop. For partial/runtime unrolling, the original loop of

```
for (int i = 0; i < n; i+=1) // original loop
    Stmt(i);
```

is transformed into (using an unroll factor of 4):

```
int i = 0;
for (; i + 3 < n; i+=4) // unrolled loop
    Stmt(i);
    Stmt(i+1);
    Stmt(i+2);
    Stmt(i+3);
}
for (; i < n; i+=1) // remainder loop
    Stmt(i);
```

`llvm.loop.unroll.followup_unrolled` will set the loop attributes of the unrolled loop. If not specified, the attributes of the original loop without the `llvm.loop.unroll.*` attributes are copied and `llvm.loop.unroll.disable` added to it.

`llvm.loop.unroll.followup_remainder` defines the attributes of the remainder loop. If not specified the remainder loop will have no attributes. The remainder loop might not be present due to being fully unrolled in which case this attribute has no effect.

Attributes defined in `llvm.loop.unroll.followup_all` are added to the unrolled and remainder loops.

To avoid that the partially unrolled loop is unrolled again, it is recommended to add `llvm.loop.unroll.disable` to `llvm.loop.unroll.followup_all`. If no follow-up attribute specified for a generated loop, it is added automatically.

Unroll-And-Jam

Unroll-and-jam uses the following transformation model (here with an unroll factor if 2). Currently, it does not support a fallback version when the transformation is unsafe.

```
for (int i = 0; i < n; i+=1) { // original outer loop
    Fore(i);
    for (int j = 0; j < m; j+=1) // original inner loop
        SubLoop(i, j);
    Aft(i);
}
```

```

int i = 0;
for (; i + 1 < n; i+=2) { // unrolled outer loop
  Fore(i);
  Fore(i+1);
  for (int j = 0; j < m; j+=1) { // unrolled inner loop
    SubLoop(i, j);
    SubLoop(i+1, j);
  }
  Aft(i);
  Aft(i+1);
}
for (; i < n; i+=1) { // remainder outer loop
  Fore(i);
  for (int j = 0; j < m; j+=1) // remainder inner loop
    SubLoop(i, j);
  Aft(i);
}

```

`llvm.loop.unroll_and_jam.followup_outer` will set the loop attributes of the unrolled outer loop. If not specified, the attributes of the original outer loop without the `llvm.loop.unroll.*` attributes are copied and `llvm.loop.unroll.disable` added to it.

`llvm.loop.unroll_and_jam.followup_inner` will set the loop attributes of the unrolled inner loop. If not specified, the attributes of the original inner loop are used unchanged.

`llvm.loop.unroll_and_jam.followup_remainder_outer` sets the loop attributes of the outer remainder loop. If not specified it will not have any attributes. The remainder loop might not be present due to being fully unrolled.

`llvm.loop.unroll_and_jam.followup_remainder_inner` sets the loop attributes of the inner remainder loop. If not specified it will have the attributes of the original inner loop. If the outer remainder loop is unrolled, the inner remainder loop might be present multiple times.

Attributes defined in `llvm.loop.unroll_and_jam.followup_all` are added to all of the aforementioned output loops.

To avoid that the unrolled loop is unrolled again, it is recommended to add `llvm.loop.unroll.disable` to `llvm.loop.unroll_and_jam.followup_all`. It suppresses unroll-and-jam as well as an additional inner loop unrolling. If no follow-up attribute specified for a generated loop, it is added automatically.

Loop Distribution

The `LoopDistribution` pass tries to separate vectorizable parts of a loop from the non-vectorizable part (which otherwise would make the entire loop non-vectorizable). Conceptually, it transforms a loop such as

```

for (int i = 1; i < n; i+=1) { // original loop
  A[i] = i;
  B[i] = 2 + B[i];
  C[i] = 3 + C[i - 1];
}

```

into the following code:

```

if (rtc) {
  for (int i = 1; i < n; i+=1) // coincident loop
    A[i] = i;
  for (int i = 1; i < n; i+=1) // coincident loop

```

(continues on next page)

(continued from previous page)

```

    B[i] = 2 + B[i];
    for (int i = 1; i < n; i+=1) // sequential loop
        C[i] = 3 + C[i - 1];
} else {
    for (int i = 1; i < n; i+=1) { // fallback loop
        A[i] = i;
        B[i] = 2 + B[i];
        C[i] = 3 + C[i - 1];
    }
}

```

where `rtc` is a generated runtime check.

`llvm.loop.distribute.followup_coincident` sets the loop attributes of all loops without loop-carried dependencies (i.e. vectorizable loops). There might be more than one such loops. If not defined, the loops will inherit the original loop's attributes.

`llvm.loop.distribute.followup_sequential` sets the loop attributes of the loop with potentially unsafe dependencies. There should be at most one such loop. If not defined, the loop will inherit the original loop's attributes.

`llvm.loop.distribute.followup_fallback` defines the loop attributes for the fallback loop, which is a copy of the original loop for when loop versioning is required. If undefined, the fallback loop inherits all attributes from the original loop.

Attributes defined in `llvm.loop.distribute.followup_all` are added to all of the aforementioned output loops.

It is recommended to add `llvm.loop.disable_nonforced` to `llvm.loop.distribute.followup_fallback`. This avoids that the fallback version (which is likely never executed) is further optimized which would increase the code size.

Versioning LICM

The pass hoists code out of loops that are only loop-invariant when dynamic conditions apply. For instance, it transforms the loop

```

for (int i = 0; i < n; i+=1) // original loop
    A[i] = B[0];

```

into:

```

if (rtc) {
    auto b = B[0];
    for (int i = 0; i < n; i+=1) // versioned loop
        A[i] = b;
} else {
    for (int i = 0; i < n; i+=1) // unversioned loop
        A[i] = B[0];
}

```

The runtime condition (`rtc`) checks that the array `A` and the element `B[0]` do not alias.

Currently, this transformation does not support followup-attributes.

Loop Interchange

Currently, the `LoopInterchange` pass does not use any metadata.

4.34.5 Ambiguous Transformation Order

If there multiple transformations defined, the order in which they are executed depends on the order in LLVM's pass pipeline, which is subject to change. The default optimization pipeline (anything higher than `-O0`) has the following order.

When using the legacy pass manager:

- `LoopInterchange` (if enabled)
- `SimpleLoopUnroll/LoopFullUnroll` (only performs full unrolling)
- `VersioningLICM` (if enabled)
- `LoopDistribute`
- `LoopVectorizer`
- `LoopUnrollAndJam` (if enabled)
- `LoopUnroll` (partial and runtime unrolling)

When using the legacy pass manager with LTO:

- `LoopInterchange` (if enabled)
- `SimpleLoopUnroll/LoopFullUnroll` (only performs full unrolling)
- `LoopVectorizer`
- `LoopUnroll` (partial and runtime unrolling)

When using the new pass manager:

- `SimpleLoopUnroll/LoopFullUnroll` (only performs full unrolling)
- `LoopDistribute`
- `LoopVectorizer`
- `LoopUnrollAndJam` (if enabled)
- `LoopUnroll` (partial and runtime unrolling)

4.34.6 Leftover Transformations

Forced transformations that have not been applied after the last transformation pass should be reported to the user. The transformation passes themselves cannot be responsible for this reporting because they might not be in the pipeline, there might be multiple passes able to apply a transformation (e.g. `LoopInterchange` and `Polly`) or a transformation attribute may be 'hidden' inside another passes' `followup` attribute.

The pass `-transform-warning` (`WarnMissedTransformationsPass`) emits such warnings. It should be placed after the last transformation pass.

The current pass pipeline has a fixed order in which transformations passes are executed. A transformation can be in the followup of a pass that is executed later and thus leftover. For instance, a loop nest cannot be distributed and then interchanged with the current pass pipeline. The loop distribution will execute, but there is no loop interchange pass following such that any loop interchange metadata will be ignored. The `-transform-warning` should emit a warning in this case.

Future versions of LLVM may fix this by executing transformations using a dynamic ordering.

4.35 FaultMaps and implicit checks

- *Motivation*
- *The Fault Map Section*
- *The ImplicitNullChecks pass*
 - *make.implicit.metadata*

4.35.1 Motivation

Code generated by managed language runtimes tend to have checks that are required for safety but never fail in practice. In such cases, it is profitable to make the non-failing case cheaper even if it makes the failing case significantly more expensive. This asymmetry can be exploited by folding such safety checks into operations that can be made to fault reliably if the check would have failed, and recovering from such a fault by using a signal handler.

For example, Java requires null checks on objects before they are read from or written to. If the object is `null` then a `NullPointerException` has to be thrown, interrupting normal execution. In practice, however, dereferencing a null pointer is extremely rare in well-behaved Java programs, and typically the null check can be folded into a nearby memory operation that operates on the same memory location.

4.35.2 The Fault Map Section

Information about implicit checks generated by LLVM are put in a special "fault map" section. On Darwin this section is named `__llvm_faultmaps`.

The format of this section is

```
Header {
  uint8  : Fault Map Version (current version is 1)
  uint8  : Reserved (expected to be 0)
  uint16 : Reserved (expected to be 0)
}
uint32 : NumFunctions
FunctionInfo[NumFunctions] {
  uint64 : FunctionAddress
  uint32 : NumFaultingPCs
  uint32 : Reserved (expected to be 0)
  FunctionFaultInfo[NumFaultingPCs] {
    uint32 : FaultKind
    uint32 : FaultingPCOffset
    uint32 : HandlerPCOffset
  }
}
```

`FaultKind` describes the reason of expected fault. Currently three kind of faults are supported:

1. `FaultMaps::FaultingLoad` - fault due to load from memory.
2. `FaultMaps::FaultingLoadStore` - fault due to instruction load and store.

3. `FaultMaps::FaultingStore` - fault due to store to memory.

4.35.3 The `ImplicitNullChecks` pass

The `ImplicitNullChecks` pass transforms explicit control flow for checking if a pointer is null, like:

```
%ptr = call i32* @get_ptr()
%ptr_is_null = icmp i32* %ptr, null
br i1 %ptr_is_null, label %is_null, label %not_null, !make.implicit !0

not_null:
  %t = load i32, i32* %ptr
  br label %do_something_with_t

is_null:
  call void @HFC()
  unreachable

!0 = !{}
```

to control flow implicit in the instruction loading or storing through the pointer being null checked:

```
%ptr = call i32* @get_ptr()
%t = load i32, i32* %ptr ;; handler-pc = label %is_null
br label %do_something_with_t

is_null:
  call void @HFC()
  unreachable
```

This transform happens at the `MachineInstr` level, not the LLVM IR level (so the above example is only representative, not literal). The `ImplicitNullChecks` pass runs during codegen, if `-enable-implicit-null-checks` is passed to `llc`.

The `ImplicitNullChecks` pass adds entries to the `__llvm_faultmaps` section described above as needed.

`make.implicit` metadata

Making null checks implicit is an aggressive optimization, and it can be a net performance pessimization if too many memory operations end up faulting because of it. A language runtime typically needs to ensure that only a negligible number of implicit null checks actually fault once the application has reached a steady state. A standard way of doing this is by healing failed implicit null checks into explicit null checks via code patching or recompilation. It follows that there are two requirements an explicit null check needs to satisfy for it to be profitable to convert it to an implicit null check:

1. The case where the pointer is actually null (i.e. the "failing" case) is extremely rare.
2. The failing path heals the implicit null check into an explicit null check so that the application does not repeatedly page fault.

The frontend is expected to mark branches that satisfy (1) and (2) using a `!make.implicit` metadata node (the actual content of the metadata node is ignored). Only branches that are marked with `!make.implicit` metadata are considered as candidates for conversion into implicit null checks.

(Note that while we could deal with (1) using profiling data, dealing with (2) requires some information not present in branch profiles.)

4.36.1 Introduction

This document is a reference manual for the Machine IR (MIR) serialization format. MIR is a human readable serialization format that is used to represent LLVM's *machine specific intermediate representation*.

The MIR serialization format is designed to be used for testing the code generation passes in LLVM.

4.36.2 Overview

The MIR serialization format uses a YAML container. YAML is a standard data serialization language, and the full YAML language spec can be read at yaml.org.

A MIR file is split up into a series of [YAML documents](#). The first document can contain an optional embedded LLVM IR module, and the rest of the documents contain the serialized machine functions.

4.36.3 MIR Testing Guide

You can use the MIR format for testing in two different ways:

- You can write MIR tests that invoke a single code generation pass using the `-run-pass` option in `llc`.
- You can use `llc`'s `-stop-after` option with existing or new LLVM assembly tests and check the MIR output of a specific code generation pass.

Testing Individual Code Generation Passes

The `-run-pass` option in `llc` allows you to create MIR tests that invoke just a single code generation pass. When this option is used, `llc` will parse an input MIR file, run the specified code generation pass(es), and output the resulting MIR code.

You can generate an input MIR file for the test by using the `-stop-after` or `-stop-before` option in `llc`. For example, if you would like to write a test for the post register allocation pseudo instruction expansion pass, you can specify the machine copy propagation pass in the `-stop-after` option, as it runs just before the pass that we are trying to test:

```
llc -stop-after=machine-cp bug-trigger.ll > test.mir
```

If the same pass is run multiple times, a run index can be included after the name with a comma.

```
llc -stop-after=dead-mi-elimination,1 bug-trigger.ll > test.mir
```

After generating the input MIR file, you'll have to add a run line that uses the `-run-pass` option to it. In order to test the post register allocation pseudo instruction expansion pass on X86-64, a run line like the one shown below can be used:

```
# RUN: llc -o - %s -mtriple=x86_64-- -run-pass=postrapseudos |
FileCheck %s
```

The MIR files are target dependent, so they have to be placed in the target specific test directories (`lib/CodeGen/TARGETNAME`). They also need to specify a target triple or a target architecture either in the run line or in the embedded LLVM IR module.

Simplifying MIR files

The MIR code coming out of `-stop-after/-stop-before` is very verbose; Tests are more accessible and future proof when simplified:

- Use the `-simplify-mir` option with `llc`.
- Machine function attributes often have default values or the test works just as well with default values. Typical candidates for this are: *alignment:*, *exposesReturnsTwice*, *legalized*, *regBankSelected*, *selected*. The whole *frameInfo* section is often unnecessary if there is no special frame usage in the function. *tracksRegLiveness* on the other hand is often necessary for some passes that care about block livein lists.
- The (global) *liveins:* list is typically only interesting for early instruction selection passes and can be removed when testing later passes. The per-block *liveins:* on the other hand are necessary if *tracksRegLiveness* is true.
- Branch probability data in block *successors:* lists can be dropped if the test doesn't depend on it. Example: *successors: %bb.1(0x40000000), %bb.2(0x40000000)* can be replaced with *successors: %bb.1, %bb.2*.
- MIR code contains a whole IR module. This is necessary because there are no equivalents in MIR for global variables, references to external functions, function attributes, metadata, debug info. Instead some MIR data references the IR constructs. You can often remove them if the test doesn't depend on them.
- Alias Analysis is performed on IR values. These are referenced by memory operands in MIR. Example: `:: (load 8 from %ir:foobar, !alias.scope !9)`. If the test doesn't depend on (good) alias analysis the references can be dropped: `:: (load 8)`
- MIR blocks can reference IR blocks for debug printing, profile information or debug locations. Example: *bb.42.myblock* in MIR references the IR block *myblock*. It is usually possible to drop the *.myblock* reference and simply use *bb.42*.
- If there are no memory operands or blocks referencing the IR then the IR function can be replaced by a parameterless dummy function like `define @func() { ret void }`.
- It is possible to drop the whole IR section of the MIR file if it only contains dummy functions (see above). The `.mir` loader will create the IR functions automatically in this case.

Limitations

Currently the MIR format has several limitations in terms of which state it can serialize:

- The target-specific state in the target-specific `MachineFunctionInfo` subclasses isn't serialized at the moment.
- The target-specific `MachineConstantPoolValue` subclasses (in the ARM and SystemZ backends) aren't serialized at the moment.
- The `MCSymbol` machine operands don't support temporary or local symbols.
- A lot of the state in `MachineModuleInfo` isn't serialized - only the CFI instructions and the variable debug information from MMI is serialized right now.

These limitations impose restrictions on what you can test with the MIR format. For now, tests that would like to test some behaviour that depends on the state of temporary or local `MCSymbol` operands or the exception handling state in MMI, can't use the MIR format. As well as that, tests that test some behaviour that depends on the state of the target specific `MachineFunctionInfo` or `MachineConstantPoolValue` subclasses can't use the MIR format at the moment.

4.36.4 High Level Structure

Embedded Module

When the first YAML document contains a [YAML block literal string](#), the MIR parser will treat this string as an LLVM assembly language string that represents an embedded LLVM IR module. Here is an example of a YAML document that contains an LLVM module:

```
define i32 @inc(i32* %x) {
entry:
  %0 = load i32, i32* %x
  %1 = add i32 %0, 1
  store i32 %1, i32* %x
  ret i32 %1
}
```

Machine Functions

The remaining YAML documents contain the machine functions. This is an example of such YAML document:

```
---
name:                inc
tracksRegLiveness: true
liveins:
- { reg: '$rdi' }
callSites:
- { bb: 0, offset: 3, fwdArgRegs:
  - { arg: 0, reg: '$edi' } }
body: |
  bb.0.entry:
    liveins: $rdi

    $eax = MOV32rm $rdi, 1, __, 0, _
    $eax = INC32r killed $eax, implicit-def dead $eflags
    MOV32mr killed $rdi, 1, __, 0, __, $eax
    CALL64pcrel32 @foo <regmask...>
    RETQ $eax
...
```

The document above consists of attributes that represent the various properties and data structures in a machine function.

The attribute `name` is required, and its value should be identical to the name of a function that this machine function is based on.

The attribute `body` is a [YAML block literal string](#). Its value represents the function's machine basic blocks and their machine instructions.

The attribute `callSites` is a representation of call site information which keeps track of call instructions and registers used to transfer call arguments.

4.36.5 Machine Instructions Format Reference

The machine basic blocks and their instructions are represented using a custom, human readable serialization language. This language is used in the [YAML block literal string](#) that corresponds to the machine function's body.

A source string that uses this language contains a list of machine basic blocks, which are described in the section below.

Machine Basic Blocks

A machine basic block is defined in a single block definition source construct that contains the block's ID. The example below defines two blocks that have an ID of zero and one:

```
bb.0:
  <instructions>
bb.1:
  <instructions>
```

A machine basic block can also have a name. It should be specified after the ID in the block's definition:

```
bb.0.entry:      ; This block's name is "entry"
  <instructions>
```

The block's name should be identical to the name of the IR block that this machine block is based on.

Block References

The machine basic blocks are identified by their ID numbers. Individual blocks are referenced using the following syntax:

```
%bb.<id>
```

Example:

```
%bb.0
```

The following syntax is also supported, but the former syntax is preferred for block references:

```
%bb.<id>[.<name>]
```

Example:

```
%bb.1.then
```

Successors

The machine basic block's successors have to be specified before any of the instructions:

```
bb.0.entry:
  successors: %bb.1.then, %bb.2.else
  <instructions>
bb.1.then:
  <instructions>
```

(continues on next page)

(continued from previous page)

```
bb.2.else:
  <instructions>
```

The branch weights can be specified in brackets after the successor blocks. The example below defines a block that has two successors with branch weights of 32 and 16:

```
bb.0.entry:
  successors: %bb.1.then(32), %bb.2.else(16)
```

Live In Registers

The machine basic block's live in registers have to be specified before any of the instructions:

```
bb.0.entry:
  liveins: $edi, $esi
```

The list of live in registers and successors can be empty. The language also allows multiple live in register and successor lists - they are combined into one list by the parser.

Miscellaneous Attributes

The attributes `IsAddressTaken`, `IsLandingPad` and `Alignment` can be specified in brackets after the block's definition:

```
bb.0.entry (address-taken):
  <instructions>
bb.2.else (align 4):
  <instructions>
bb.3(landing-pad, align 4):
  <instructions>
```

Machine Instructions

A machine instruction is composed of a name, *machine operands*, *instruction flags*, and machine memory operands.

The instruction's name is usually specified before the operands. The example below shows an instance of the X86 `RETQ` instruction with a single machine operand:

```
RETQ $eax
```

However, if the machine instruction has one or more explicitly defined register operands, the instruction's name has to be specified after them. The example below shows an instance of the AArch64 `LDPXpost` instruction with three defined register operands:

```
$sp, $fp, $lr = LDPXpost $sp, 2
```

The instruction names are serialized using the exact definitions from the target's `*InstrInfo.td` files, and they are case sensitive. This means that similar instruction names like `TSTri` and `tSTri` represent different machine instructions.

Instruction Flags

The flag `frame-setup` or `frame-destroy` can be specified before the instruction's name:

```
$fp = frame-setup ADDXri $sp, 0, 0
```

```
$x21, $x20 = frame-destroy LDPXi $sp
```

Bundled Instructions

The syntax for bundled instructions is the following:

```
BUNDLE implicit-def $r0, implicit-def $r1, implicit $r2 {  
  $r0 = SOME_OP $r2  
  $r1 = ANOTHER_OP internal $r0  
}
```

The first instruction is often a bundle header. The instructions between `{` and `}` are bundled with the first instruction.

Registers

Registers are one of the key primitives in the machine instructions serialization language. They are primarily used in the *register machine operands*, but they can also be used in a number of other places, like the *basic block's live in list*.

The physical registers are identified by their name and by the '\$' prefix sigil. They use the following syntax:

```
$<name>
```

The example below shows three X86 physical registers:

```
$eax  
$r15  
$eflags
```

The virtual registers are identified by their ID number and by the '%' sigil. They use the following syntax:

```
%<id>
```

Example:

```
%0
```

The null registers are represented using an underscore ('_'). They can also be represented using a '\$noreg' named register, although the former syntax is preferred.

Machine Operands

There are seventeen different kinds of machine operands, and all of them can be serialized.

Immediate Operands

The immediate machine operands are untyped, 64-bit signed integers. The example below shows an instance of the X86 `MOV32ri` instruction that has an immediate machine operand `-42`:

```
$eax = MOV32ri -42
```

An immediate operand is also used to represent a subregister index when the machine instruction has one of the following opcodes:

- `EXTRACT_SUBREG`
- `INSERT_SUBREG`
- `REG_SEQUENCE`
- `SUBREG_TO_REG`

In case this is true, the Machine Operand is printed according to the target.

For example:

In `AArch64RegisterInfo.td`:

```
def sub_32 : SubRegIndex<32>;
```

If the third operand is an immediate with the value 15 (target-dependent value), based on the instruction's opcode and the operand's index the operand will be printed as `%subreg.sub_32`:

```
%1:gpr64 = SUBREG_TO_REG 0, %0, %subreg.sub_32
```

For integers > 64bit, we use a special machine operand, `MO_CImmediate`, which stores the immediate in a `ConstantInt` using an `APInt` (LLVM's arbitrary precision integers).

Register Operands

The *register* primitive is used to represent the register machine operands. The register operands can also have optional *register flags*, a *subregister index*, and a reference to the tied register operand. The full syntax of a register operand is shown below:

```
[<flags>] <register> [ :<subregister-idx-name> ] [ (tied-def <tied-op>) ]
```

This example shows an instance of the X86 `XOR32rr` instruction that has 5 register operands with different register flags:

```
dead $eax = XOR32rr undef $eax, undef $eax, implicit-def dead $eflags, implicit-def
↳ $al
```

Register Flags

The table below shows all of the possible register flags along with the corresponding internal `llvm::RegState` representation:

Flag	Internal Value
<code>implicit</code>	<code>RegState::Implicit</code>
<code>implicit-def</code>	<code>RegState::ImplicitDefine</code>
<code>def</code>	<code>RegState::Define</code>
<code>dead</code>	<code>RegState::Dead</code>
<code>killed</code>	<code>RegState::Kill</code>
<code>undef</code>	<code>RegState::Undef</code>
<code>internal</code>	<code>RegState::InternalRead</code>
<code>early-clobber</code>	<code>RegState::EarlyClobber</code>
<code>debug-use</code>	<code>RegState::Debug</code>
<code>renamable</code>	<code>RegState::Renamable</code>

Subregister Indices

The register machine operands can reference a portion of a register by using the subregister indices. The example below shows an instance of the `COPY` pseudo instruction that uses the `X86_sub_8bit` subregister index to copy 8 lower bits from the 32-bit virtual register 0 to the 8-bit virtual register 1:

```
%1 = COPY %0:sub_8bit
```

The names of the subregister indices are target specific, and are typically defined in the target's `*RegisterInfo.td` file.

Constant Pool Indices

A constant pool index (CPI) operand is printed using its index in the function's `MachineConstantPool` and an offset.

For example, a CPI with the index 1 and offset 8:

```
%1:gr64 = MOV64ri %const.1 + 8
```

For a CPI with the index 0 and offset -12:

```
%1:gr64 = MOV64ri %const.0 - 12
```

A constant pool entry is bound to a LLVM IR `Constant` or a target-specific `MachineConstantPoolValue`. When serializing all the function's constants the following format is used:

```
constants:
- id:          <index>
  value:       <value>
  alignment:   <alignment>
  isTargetSpecific: <target-specific>
```

where `<index>` is a 32-bit unsigned integer, `<value>` is a [LLVM IR Constant](#), alignment is a 32-bit unsigned integer, and `<target-specific>` is either true or false.

Example:

```
constants:
- id:          0
  value:       'double 3.250000e+00'
  alignment:   8
- id:          1
  value:       'g-(LPC0+8) '
  alignment:   4
  isTargetSpecific: true
```

Global Value Operands

The global value machine operands reference the global values from the *embedded LLVM IR module*. The example below shows an instance of the X86 MOV64rm instruction that has a global value operand named G:

```
$rax = MOV64rm $rip, 1, __, @G, __
```

The named global values are represented using an identifier with the '@' prefix. If the identifier doesn't match the regular expression `[-a-zA-Z$_][_-a-zA-Z$_0-9]*`, then this identifier must be quoted.

The unnamed global values are represented using an unsigned numeric value with the '@' prefix, like in the following examples: @0, @989.

Target-dependent Index Operands

A target index operand is a target-specific index and an offset. The target-specific index is printed using target-specific names and a positive or negative offset.

For example, the `amdgpu-constdata-start` is associated with the index 0 in the AMDGPU backend. So if we have a target index operand with the index 0 and the offset 8:

```
$sgpr2 = S_ADD_U32 __, target-index(amdgpu-constdata-start) + 8, implicit-def __,
↳ implicit-def __
```

Jump-table Index Operands

A jump-table index operand with the index 0 is printed as following:

```
tBR_JTr killed $r0, %jump-table.0
```

A machine jump-table entry contains a list of `MachineBasicBlocks`. When serializing all the function's jump-table entries, the following format is used:

```
jumpTable:
  kind:          <kind>
  entries:
    - id:         <index>
      blocks:     [ <breference>, <breference>, ... ]
```

where `<kind>` is describing how the jump table is represented and emitted (plain address, relocations, PIC, etc.), and each `<index>` is a 32-bit unsigned integer and `blocks` contains a list of *machine basic block references*.

Example:

```
jumpTable:
  kind:          inline
  entries:
    - id:        0
      blocks:    [ '%bb.3', '%bb.9', '%bb.4.d3' ]
    - id:        1
      blocks:    [ '%bb.7', '%bb.7', '%bb.4.d3', '%bb.5' ]
```

External Symbol Operands

An external symbol operand is represented using an identifier with the `&` prefix. The identifier is surrounded with `""`s and escaped if it has any special non-printable characters in it.

Example:

```
CALL64pcrel32 &__stack_chk_fail, csr_64, implicit $rsp, implicit-def $rsp
```

MCSymbol Operands

A MCSymbol operand is holding a pointer to a MCSymbol. For the limitations of this operand in MIR, see [limitations](#).

The syntax is:

```
EH_LABEL <mcsymbol Ltmpl>
```

CFIIndex Operands

A CFI Index operand is holding an index into a per-function side-table, `MachineFunction::getFrameInstructions()`, which references all the frame instructions in a `MachineFunction`. A CFI_INSTRUCTION may look like it contains multiple operands, but the only operand it contains is the CFI Index. The other operands are tracked by the `MCCFIInstruction` object.

The syntax is:

```
CFI_INSTRUCTION offset $w30, -16
```

which may be emitted later in the MC layer as:

```
.cfi_offset w30, -16
```

IntrinsicID Operands

An Intrinsic ID operand contains a generic intrinsic ID or a target-specific ID.

The syntax for the `returnaddress` intrinsic is:

```
$x0 = COPY intrinsic(@llvm.returnaddress)
```

Predicate Operands

A Predicate operand contains an IR predicate from `CmpInst::Predicate`, like `ICMP_EQ`, etc.

For an int eq predicate `ICMP_EQ`, the syntax is:

```
%2:gpr(s32) = G_ICMP intpred(eq), %0, %1
```

4.37.1 Introduction

LLVM coroutines are functions that have one or more *suspend points*. When a suspend point is reached, the execution of a coroutine is suspended and control is returned back to its caller. A suspended coroutine can be resumed to continue execution from the last suspend point or it can be destroyed.

In the following example, we call function *f* (which may or may not be a coroutine itself) that returns a handle to a suspended coroutine (**coroutine handle**) that is used by *main* to resume the coroutine twice and then destroy it:

```
define i32 @main() {  
entry:  
  %hdl = call i8* @f(i32 4)  
  call void @llvm.coro.resume(i8* %hdl)  
  call void @llvm.coro.resume(i8* %hdl)  
  call void @llvm.coro.destroy(i8* %hdl)  
  ret i32 0  
}
```

In addition to the function stack frame which exists when a coroutine is executing, there is an additional region of storage that contains objects that keep the coroutine state when a coroutine is suspended. This region of storage is called **coroutine frame**. It is created when a coroutine is called and destroyed when a coroutine runs to completion or destroyed by a call to the *coro.destroy* intrinsic.

An LLVM coroutine is represented as an LLVM function that has calls to *coroutine intrinsics* defining the structure of the coroutine. After lowering, a coroutine is split into several functions that represent three different ways of how control can enter the coroutine:

1. a ramp function, which represents an initial invocation of the coroutine that creates the coroutine frame and executes the coroutine code until it encounters a suspend point or reaches the end of the function;
2. a coroutine resume function that is invoked when the coroutine is resumed;
3. a coroutine destroy function that is invoked when the coroutine is destroyed.

Note: Splitting out resume and destroy functions are just one of the possible ways of lowering the coroutine. We chose it for initial implementation as it matches closely the mental model and results in reasonably nice code.

4.37.2 Coroutines by Example

Coroutine Representation

Let's look at an example of an LLVM coroutine with the behavior sketched by the following pseudo-code.

```
void *f(int n) {
    for(;;) {
        print(n++);
        <suspend> // returns a coroutine handle on first suspend
    }
}
```

This coroutine calls some function *print* with value *n* as an argument and suspends execution. Every time this coroutine resumes, it calls *print* again with an argument one bigger than the last time. This coroutine never completes by itself and must be destroyed explicitly. If we use this coroutine with a *main* shown in the previous section. It will call *print* with values 4, 5 and 6 after which the coroutine will be destroyed.

The LLVM IR for this coroutine looks like this:

```
define i8* @f(i32 %n) {
entry:
    %id = call token @llvm.coro.id(i32 0, i8* null, i8* null, i8* null)
    %size = call i32 @llvm.coro.size.i32()
    %alloc = call i8* @malloc(i32 %size)
    %hdl = call noalias i8* @llvm.coro.begin(token %id, i8* %alloc)
    br label %loop
loop:
    %n.val = phi i32 [ %n, %entry ], [ %inc, %loop ]
    %inc = add nsw i32 %n.val, 1
    call void @print(i32 %n.val)
    %0 = call i8 @llvm.coro.suspend(token none, i1 false)
    switch i8 %0, label %suspend [i8 0, label %loop
                                i8 1, label %cleanup]
cleanup:
    %mem = call i8* @llvm.coro.free(token %id, i8* %hdl)
    call void @free(i8* %mem)
    br label %suspend
suspend:
    %unused = call i1 @llvm.coro.end(i8* %hdl, i1 false)
    ret i8* %hdl
}
```

The *entry* block establishes the coroutine frame. The *coro.size* intrinsic is lowered to a constant representing the size required for the coroutine frame. The *coro.begin* intrinsic initializes the coroutine frame and returns the coroutine handle. The second parameter of *coro.begin* is given a block of memory to be used if the coroutine frame needs to be allocated dynamically. The *coro.id* intrinsic serves as coroutine identity useful in cases when the *coro.begin* intrinsic get duplicated by optimization passes such as jump-threading.

The *cleanup* block destroys the coroutine frame. The *coro.free* intrinsic, given the coroutine handle, returns a pointer of the memory block to be freed or *null* if the coroutine frame was not allocated dynamically. The *cleanup* block is entered when coroutine runs to completion by itself or destroyed via call to the *coro.destroy* intrinsic.

The *suspend* block contains code to be executed when coroutine runs to completion or suspended. The *coro.end* intrinsic marks the point where a coroutine needs to return control back to the caller if it is not an initial invocation of the coroutine.

The *loop* blocks represents the body of the coroutine. The *coro.suspend* intrinsic in combination with the following

switch indicates what happens to control flow when a coroutine is suspended (default case), resumed (case 0) or destroyed (case 1).

Coroutine Transformation

One of the steps of coroutine lowering is building the coroutine frame. The def-use chains are analyzed to determine which objects need be kept alive across suspend points. In the coroutine shown in the previous section, use of virtual register `%n.val` is separated from the definition by a suspend point, therefore, it cannot reside on the stack frame since the latter goes away once the coroutine is suspended and control is returned back to the caller. An i32 slot is allocated in the coroutine frame and `%n.val` is spilled and reloaded from that slot as needed.

We also store addresses of the resume and destroy functions so that the `coro.resume` and `coro.destroy` intrinsics can resume and destroy the coroutine when its identity cannot be determined statically at compile time. For our example, the coroutine frame will be:

```
%f.frame = type { void (%f.frame*)*, void (%f.frame*)*, i32 }
```

After resume and destroy parts are outlined, function `f` will contain only the code responsible for creation and initialization of the coroutine frame and execution of the coroutine until a suspend point is reached:

```
define i8* @f(i32 %n) {
entry:
  %id = call token @llvm.coro.id(i32 0, i8* null, i8* null, i8* null)
  %alloc = call noalias i8* @malloc(i32 24)
  %0 = call noalias i8* @llvm.coro.begin(token %id, i8* %alloc)
  %frame = bitcast i8* %0 to %f.frame*
  %1 = getelementptr %f.frame, %f.frame* %frame, i32 0, i32 0
  store void (%f.frame*)* @f.resume, void (%f.frame*)** %1
  %2 = getelementptr %f.frame, %f.frame* %frame, i32 0, i32 1
  store void (%f.frame*)* @f.destroy, void (%f.frame*)** %2

  %inc = add nsw i32 %n, 1
  %inc.spill.addr = getelementptr inbounds %f.Frame, %f.Frame* %FramePtr, i32 0, i32 2
  store i32 %inc, i32* %inc.spill.addr
  call void @print(i32 %n)

  ret i8* %frame
}
```

Outlined resume part of the coroutine will reside in function `f.resume`:

```
define internal fastcc void @f.resume(%f.frame* %frame.ptr.resume) {
entry:
  %inc.spill.addr = getelementptr %f.frame, %f.frame* %frame.ptr.resume, i64 0, i32 2
  %inc.spill = load i32, i32* %inc.spill.addr, align 4
  %inc = add i32 %n.val, 1
  store i32 %inc, i32* %inc.spill.addr, align 4
  tail call void @print(i32 %inc)
  ret void
}
```

Whereas function `f.destroy` will contain the cleanup code for the coroutine:

```
define internal fastcc void @f.destroy(%f.frame* %frame.ptr.destroy) {
entry:
  %0 = bitcast %f.frame* %frame.ptr.destroy to i8*
```

(continues on next page)

(continued from previous page)

```

tail call void @free(i8* %0)
ret void
}

```

Avoiding Heap Allocations

A particular coroutine usage pattern, which is illustrated by the *main* function in the overview section, where a coroutine is created, manipulated and destroyed by the same calling function, is common for coroutines implementing RAII idiom and is suitable for allocation elision optimization which avoid dynamic allocation by storing the coroutine frame as a static *alloca* in its caller.

In the entry block, we will call *coro.alloc* intrinsic that will return *true* when dynamic allocation is required, and *false* if dynamic allocation is elided.

```

entry:
  %id = call token @llvm.coro.id(i32 0, i8* null, i8* null, i8* null)
  %need.dyn.alloc = call i1 @llvm.coro.alloc(token %id)
  br i1 %need.dyn.alloc, label %dyn.alloc, label %coro.begin
dyn.alloc:
  %size = call i32 @llvm.coro.size.i32()
  %alloc = call i8* @CustomAlloc(i32 %size)
  br label %coro.begin
coro.begin:
  %phi = phi i8* [ null, %entry ], [ %alloc, %dyn.alloc ]
  %hdl = call noalias i8* @llvm.coro.begin(token %id, i8* %phi)

```

In the cleanup block, we will make freeing the coroutine frame conditional on *coro.free* intrinsic. If allocation is elided, *coro.free* returns *null* thus skipping the deallocation code:

```

cleanup:
  %mem = call i8* @llvm.coro.free(token %id, i8* %hdl)
  %need.dyn.free = icmp ne i8* %mem, null
  br i1 %need.dyn.free, label %dyn.free, label %if.end
dyn.free:
  call void @CustomFree(i8* %mem)
  br label %if.end
if.end:
  ...

```

With allocations and deallocations represented as described as above, after coroutine heap allocation elision optimization, the resulting main will be:

```

define i32 @main() {
entry:
  call void @print(i32 4)
  call void @print(i32 5)
  call void @print(i32 6)
  ret i32 0
}

```

Multiple Suspend Points

Let's consider the coroutine that has more than one suspend point:

```
void *f(int n) {
    for(;;) {
        print(n++);
        <suspend>
        print(-n);
        <suspend>
    }
}
```

Matching LLVM code would look like (with the rest of the code remaining the same as the code in the previous section):

```
loop:
    %n.addr = phi i32 [ %n, %entry ], [ %inc, %loop.resume ]
    call void @print(i32 %n.addr) #4
    %2 = call i8 @llvm.coro.suspend(token none, i1 false)
    switch i8 %2, label %suspend [i8 0, label %loop.resume
                                i8 1, label %cleanup]

loop.resume:
    %inc = add nsw i32 %n.addr, 1
    %sub = xor i32 %n.addr, -1
    call void @print(i32 %sub)
    %3 = call i8 @llvm.coro.suspend(token none, i1 false)
    switch i8 %3, label %suspend [i8 0, label %loop
                                i8 1, label %cleanup]
```

In this case, the coroutine frame would include a suspend index that will indicate at which suspend point the coroutine needs to resume. The resume function will use an index to jump to an appropriate basic block and will look as follows:

```
define internal fastcc void @f.Resume(%f.Frame* %FramePtr) {
entry.Resume:
    %index.addr = getelementptr inbounds %f.Frame, %f.Frame* %FramePtr, i64 0, i32 2
    %index = load i8, i8* %index.addr, align 1
    %switch = icmp eq i8 %index, 0
    %n.addr = getelementptr inbounds %f.Frame, %f.Frame* %FramePtr, i64 0, i32 3
    %n = load i32, i32* %n.addr, align 4
    br i1 %switch, label %loop.resume, label %loop

loop.resume:
    %sub = xor i32 %n, -1
    call void @print(i32 %sub)
    br label %suspend

loop:
    %inc = add nsw i32 %n, 1
    store i32 %inc, i32* %n.addr, align 4
    tail call void @print(i32 %inc)
    br label %suspend

suspend:
    %storemerge = phi i8 [ 0, %loop ], [ 1, %loop.resume ]
    store i8 %storemerge, i8* %index.addr, align 1
    ret void
}
```

If different cleanup code needs to get executed for different suspend points, a similar switch will be in the *f.destroy* function.

Note: Using suspend index in a coroutine state and having a switch in *f.resume* and *f.destroy* is one of the possible implementation strategies. We explored another option where a distinct *f.resume1*, *f.resume2*, etc. are created for every suspend point, and instead of storing an index, the resume and destroy function pointers are updated at every suspend. Early testing showed that the current approach is easier on the optimizer than the latter so it is a lowering strategy implemented at the moment.

Distinct Save and Suspend

In the previous example, setting a resume index (or some other state change that needs to happen to prepare a coroutine for resumption) happens at the same time as a suspension of a coroutine. However, in certain cases, it is necessary to control when coroutine is prepared for resumption and when it is suspended.

In the following example, a coroutine represents some activity that is driven by completions of asynchronous operations *async_op1* and *async_op2* which get a coroutine handle as a parameter and resume the coroutine once async operation is finished.

```
void g() {
    for (;;) {
        if (cond()) {
            async_op1(<coroutine-handle>); // will resume once async_op1 completes
            <suspend>
            do_one();
        }
        else {
            async_op2(<coroutine-handle>); // will resume once async_op2 completes
            <suspend>
            do_two();
        }
    }
}
```

In this case, coroutine should be ready for resumption prior to a call to *async_op1* and *async_op2*. The *coro.save* intrinsic is used to indicate a point when coroutine should be ready for resumption (namely, when a resume index should be stored in the coroutine frame, so that it can be resumed at the correct resume point):

```
if.true:
    %save1 = call token @llvm.coro.save(i8* %hdl)
    call void @async_op1(i8* %hdl)
    %suspend1 = call i1 @llvm.coro.suspend(token %save1, i1 false)
    switch i8 %suspend1, label %suspend [i8 0, label %resume1
                                         i8 1, label %cleanup]

if.false:
    %save2 = call token @llvm.coro.save(i8* %hdl)
    call void @async_op2(i8* %hdl)
    %suspend2 = call i1 @llvm.coro.suspend(token %save2, i1 false)
    switch i8 %suspend1, label %suspend [i8 0, label %resume2
                                         i8 1, label %cleanup]
```

Coroutine Promise

A coroutine author or a frontend may designate a distinguished *alloca* that can be used to communicate with the coroutine. This distinguished *alloca* is called **coroutine promise** and is provided as the second parameter to the *coro.id* intrinsic.

The following coroutine designates a 32 bit integer *promise* and uses it to store the current value produced by a coroutine.

```
define i8* @f(i32 %n) {
entry:
    %promise = alloca i32
    %pv = bitcast i32* %promise to i8*
    %id = call token @llvm.coro.id(i32 0, i8* %pv, i8* null, i8* null)
    %need.dyn.alloc = call i1 @llvm.coro.alloc(token %id)
    br i1 %need.dyn.alloc, label %dyn.alloc, label %coro.begin
dyn.alloc:
    %size = call i32 @llvm.coro.size.i32()
    %alloc = call i8* @malloc(i32 %size)
    br label %coro.begin
coro.begin:
    %phi = phi i8* [ null, %entry ], [ %alloc, %dyn.alloc ]
    %hdl = call noalias i8* @llvm.coro.begin(token %id, i8* %phi)
    br label %loop
loop:
    %n.val = phi i32 [ %n, %coro.begin ], [ %inc, %loop ]
    %inc = add nsw i32 %n.val, 1
    store i32 %n.val, i32* %promise
    %0 = call i8 @llvm.coro.suspend(token none, i1 false)
    switch i8 %0, label %suspend [i8 0, label %loop
                                i8 1, label %cleanup]
cleanup:
    %mem = call i8* @llvm.coro.free(token %id, i8* %hdl)
    call void @free(i8* %mem)
    br label %suspend
suspend:
    %unused = call i1 @llvm.coro.end(i8* %hdl, i1 false)
    ret i8* %hdl
}
```

A coroutine consumer can rely on the *coro.promise* intrinsic to access the coroutine promise.

```
define i32 @main() {
entry:
    %hdl = call i8* @f(i32 4)
    %promise.addr.raw = call i8* @llvm.coro.promise(i8* %hdl, i32 4, i1 false)
    %promise.addr = bitcast i8* %promise.addr.raw to i32*
    %val0 = load i32, i32* %promise.addr
    call void @print(i32 %val0)
    call void @llvm.coro.resume(i8* %hdl)
    %val1 = load i32, i32* %promise.addr
    call void @print(i32 %val1)
    call void @llvm.coro.resume(i8* %hdl)
    %val2 = load i32, i32* %promise.addr
    call void @print(i32 %val2)
    call void @llvm.coro.destroy(i8* %hdl)
    ret i32 0
}
```

After example in this section is compiled, result of the compilation will be:

```
define i32 @main() {
entry:
  tail call void @print(i32 4)
  tail call void @print(i32 5)
  tail call void @print(i32 6)
  ret i32 0
}
```

Final Suspend

A coroutine author or a frontend may designate a particular suspend to be final, by setting the second argument of the *coro.suspend* intrinsic to *true*. Such a suspend point has two properties:

- it is possible to check whether a suspended coroutine is at the final suspend point via *coro.done* intrinsic;
- a resumption of a coroutine stopped at the final suspend point leads to undefined behavior. The only possible action for a coroutine at a final suspend point is destroying it via *coro.destroy* intrinsic.

From the user perspective, the final suspend point represents an idea of a coroutine reaching the end. From the compiler perspective, it is an optimization opportunity for reducing number of resume points (and therefore switch cases) in the resume function.

The following is an example of a function that keeps resuming the coroutine until the final suspend point is reached after which point the coroutine is destroyed:

```
define i32 @main() {
entry:
  %hdl = call i8* @f(i32 4)
  br label %while
while:
  call void @llvm.coro.resume(i8* %hdl)
  %done = call i1 @llvm.coro.done(i8* %hdl)
  br i1 %done, label %end, label %while
end:
  call void @llvm.coro.destroy(i8* %hdl)
  ret i32 0
}
```

Usually, final suspend point is a frontend injected suspend point that does not correspond to any explicitly authored suspend point of the high level language. For example, for a Python generator that has only one suspend point:

```
def coroutine(n):
    for i in range(n):
        yield i
```

Python frontend would inject two more suspend points, so that the actual code looks like this:

```
void* coroutine(int n) {
    int current_value;
    <designate current_value to be coroutine promise>
    <SUSPEND> // injected suspend point, so that the coroutine starts suspended
    for (int i = 0; i < n; ++i) {
        current_value = i; <SUSPEND>; // corresponds to "yield i"
    }
    <SUSPEND final=true> // injected final suspend point
}
```

and python iterator `__next__` would look like:

```
int __next__(void* hdl) {
    coro.resume(hdl);
    if (coro.done(hdl)) throw StopIteration();
    return *(int*)coro.promise(hdl, 4, false);
}
```

4.37.3 Intrinsics

Coroutine Manipulation Intrinsics

Intrinsics described in this section are used to manipulate an existing coroutine. They can be used in any function which happen to have a pointer to a *coroutine frame* or a pointer to a *coroutine promise*.

'llvm.coro.destroy' Intrinsic

Syntax:

```
declare void @llvm.coro.destroy(i8* <handle>)
```

Overview:

The 'llvm.coro.destroy' intrinsic destroys a suspended coroutine.

Arguments:

The argument is a coroutine handle to a suspended coroutine.

Semantics:

When possible, the *coro.destroy* intrinsic is replaced with a direct call to the coroutine destroy function. Otherwise it is replaced with an indirect call based on the function pointer for the destroy function stored in the coroutine frame. Destroying a coroutine that is not suspended leads to undefined behavior.

'llvm.coro.resume' Intrinsic

```
declare void @llvm.coro.resume(i8* <handle>)
```

Overview:

The `'llvm.coro.resume'` intrinsic resumes a suspended coroutine.

Arguments:

The argument is a handle to a suspended coroutine.

Semantics:

When possible, the *coro.resume* intrinsic is replaced with a direct call to the coroutine resume function. Otherwise it is replaced with an indirect call based on the function pointer for the resume function stored in the coroutine frame. Resuming a coroutine that is not suspended leads to undefined behavior.

'llvm.coro.done' Intrinsic

```
declare i1 @llvm.coro.done(i8* <handle>)
```

Overview:

The `'llvm.coro.done'` intrinsic checks whether a suspended coroutine is at the final suspend point or not.

Arguments:

The argument is a handle to a suspended coroutine.

Semantics:

Using this intrinsic on a coroutine that does not have a *final suspend* point or on a coroutine that is not suspended leads to undefined behavior.

'llvm.coro.promise' Intrinsic

```
declare i8* @llvm.coro.promise(i8* <ptr>, i32 <alignment>, i1 <from>)
```

Overview:

The `'llvm.coro.promise'` intrinsic obtains a pointer to a *coroutine promise* given a coroutine handle and vice versa.

Arguments:

The first argument is a handle to a coroutine if *from* is false. Otherwise, it is a pointer to a coroutine promise.

The second argument is an alignment requirements of the promise. If a frontend designated *%promise = alloca i32* as a promise, the alignment argument to *coro.promise* should be the alignment of *i32* on the target platform. If a frontend designated *%promise = alloca i32, align 16* as a promise, the alignment argument should be 16. This argument only accepts constants.

The third argument is a boolean indicating a direction of the transformation. If *from* is true, the intrinsic returns a coroutine handle given a pointer to a promise. If *from* is false, the intrinsics return a pointer to a promise from a coroutine handle. This argument only accepts constants.

Semantics:

Using this intrinsic on a coroutine that does not have a coroutine promise leads to undefined behavior. It is possible to read and modify coroutine promise of the coroutine which is currently executing. The coroutine author and a coroutine user are responsible to makes sure there is no data races.

Example:

```
define i8* @f(i32 %n) {
entry:
    %promise = alloca i32
    %pv = bitcast i32* %promise to i8*
    ; the second argument to coro.id points to the coroutine promise.
    %id = call token @llvm.coro.id(i32 0, i8* %pv, i8* null, i8* null)
    ...
    %hdl = call noalias i8* @llvm.coro.begin(token %id, i8* %alloc)
    ...
    store i32 42, i32* %promise ; store something into the promise
    ...
    ret i8* %hdl
}

define i32 @main() {
entry:
    %hdl = call i8* @f(i32 4) ; starts the coroutine and returns its handle
    %promise.addr.raw = call i8* @llvm.coro.promise(i8* %hdl, i32 4, i1 false)
    %promise.addr = bitcast i8* %promise.addr.raw to i32*
    %val = load i32, i32* %promise.addr ; load a value from the promise
    call void @print(i32 %val)
    call void @llvm.coro.destroy(i8* %hdl)
    ret i32 0
}
```

Coroutine Structure Intrinsics

Intrinsics described in this section are used within a coroutine to describe the coroutine structure. They should not be used outside of a coroutine.

'llvm.coro.size' Intrinsic

```
declare i32 @llvm.coro.size.i32()
declare i64 @llvm.coro.size.i64()
```

Overview:

The 'llvm.coro.size' intrinsic returns the number of bytes required to store a *coroutine frame*.

Arguments:

None

Semantics:

The *coro.size* intrinsic is lowered to a constant representing the size of the coroutine frame.

'llvm.coro.begin' Intrinsic

```
declare i8* @llvm.coro.begin(token <id>, i8* <mem>)
```

Overview:

The 'llvm.coro.begin' intrinsic returns an address of the coroutine frame.

Arguments:

The first argument is a token returned by a call to 'llvm.coro.id' identifying the coroutine.

The second argument is a pointer to a block of memory where coroutine frame will be stored if it is allocated dynamically.

Semantics:

Depending on the alignment requirements of the objects in the coroutine frame and/or on the codegen compactness reasons the pointer returned from *coro.begin* may be at offset to the *%mem* argument. (This could be beneficial if instructions that express relative access to data can be more compactly encoded with small positive and negative offsets).

A frontend should emit exactly one *coro.begin* intrinsic per coroutine.

'llvm.coro.free' Intrinsic

```
declare i8* @llvm.coro.free(token %id, i8* <frame>)
```

Overview:

The 'llvm.coro.free' intrinsic returns a pointer to a block of memory where coroutine frame is stored or *null* if this instance of a coroutine did not use dynamically allocated memory for its coroutine frame.

Arguments:

The first argument is a token returned by a call to 'llvm.coro.id' identifying the coroutine.

The second argument is a pointer to the coroutine frame. This should be the same pointer that was returned by prior *coro.begin* call.

Example (custom deallocation function):

```
cleanup:
    %mem = call i8* @llvm.coro.free(token %id, i8* %frame)
    %mem_not_null = icmp ne i8* %mem, null
    br i1 %mem_not_null, label %if.then, label %if.end
if.then:
    call void @CustomFree(i8* %mem)
    br label %if.end
if.end:
    ret void
```

Example (standard deallocation functions):

```
cleanup:
    %mem = call i8* @llvm.coro.free(token %id, i8* %frame)
    call void @free(i8* %mem)
    ret void
```

'llvm.coro.alloc' Intrinsic

```
declare i1 @llvm.coro.alloc(token <id>)
```

Overview:

The 'llvm.coro.alloc' intrinsic returns *true* if dynamic allocation is required to obtain a memory for the coroutine frame and *false* otherwise.

Arguments:

The first argument is a token returned by a call to 'llvm.coro.id' identifying the coroutine.

Semantics:

A frontend should emit at most one *coro.alloc* intrinsic per coroutine. The intrinsic is used to suppress dynamic allocation of the coroutine frame when possible.

Example:

```
entry:
    %id = call token @llvm.coro.id(i32 0, i8* null, i8* null, i8* null)
    %dyn.alloc.required = call i1 @llvm.coro.alloc(token %id)
    br i1 %dyn.alloc.required, label %coro.alloc, label %coro.begin

coro.alloc:
    %frame.size = call i32 @llvm.coro.size()
    %alloc = call i8* @MyAlloc(i32 %frame.size)
    br label %coro.begin

coro.begin:
    %phi = phi i8* [ null, %entry ], [ %alloc, %coro.alloc ]
    %frame = call i8* @llvm.coro.begin(token %id, i8* %phi)
```

'llvm.coro.noop' Intrinsic

```
declare i8* @llvm.coro.noop()
```

Overview:

The `'llvm.coro.noop'` intrinsic returns an address of the coroutine frame of a coroutine that does nothing when resumed or destroyed.

Arguments:

None

Semantics:

This intrinsic is lowered to refer to a private constant coroutine frame. The resume and destroy handlers for this frame are empty functions that do nothing. Note that in different translation units `llvm.coro.noop` may return different pointers.

'llvm.coro.frame' Intrinsic

```
declare i8* @llvm.coro.frame()
```

Overview:

The `'llvm.coro.frame'` intrinsic returns an address of the coroutine frame of the enclosing coroutine.

Arguments:

None

Semantics:

This intrinsic is lowered to refer to the *coro.begin* instruction. This is a frontend convenience intrinsic that makes it easier to refer to the coroutine frame.

'llvm.coro.id' Intrinsic

```
declare token @llvm.coro.id(i32 <align>, i8* <promise>, i8* <coroaddr>,  
                           i8* <fnaddrs>)
```

Overview:

The `'llvm.coro.id'` intrinsic returns a token identifying a coroutine.

Arguments:

The first argument provides information on the alignment of the memory returned by the allocation function and given to *coro.begin* by the first argument. If this argument is 0, the memory is assumed to be aligned to $2 * \text{sizeof}(i8^*)$. This argument only accepts constants.

The second argument, if not *null*, designates a particular *alloca* instruction to be a *coroutine promise*.

The third argument is *null* coming out of the frontend. The CoroEarly pass sets this argument to point to the function this *coro.id* belongs to.

The fourth argument is *null* before coroutine is split, and later is replaced to point to a private global constant array containing function pointers to outlined resume and destroy parts of the coroutine.

Semantics:

The purpose of this intrinsic is to tie together *coro.id*, *coro.alloc* and *coro.begin* belonging to the same coroutine to prevent optimization passes from duplicating any of these instructions unless entire body of the coroutine is duplicated.

A frontend should emit exactly one *coro.id* intrinsic per coroutine.

'llvm.coro.end' Intrinsic

```
declare i1 @llvm.coro.end(i8* <handle>, i1 <unwind>)
```

Overview:

The `'llvm.coro.end'` marks the point where execution of the resume part of the coroutine should end and control should return to the caller.

Arguments:

The first argument should refer to the coroutine handle of the enclosing coroutine. A frontend is allowed to supply null as the first parameter, in this case *coro-early* pass will replace the null with an appropriate coroutine handle value.

The second argument should be *true* if this *coro.end* is in the block that is part of the unwind sequence leaving the coroutine body due to an exception and *false* otherwise.

Semantics:

The purpose of this intrinsic is to allow frontends to mark the cleanup and other code that is only relevant during the initial invocation of the coroutine and should not be present in resume and destroy parts.

This intrinsic is lowered when a coroutine is split into the start, resume and destroy parts. In the start part, it is a no-op, in resume and destroy parts, it is replaced with *ret void* instruction and the rest of the block containing *coro.end* instruction is discarded. In landing pads it is replaced with an appropriate instruction to unwind to caller. The handling of *coro.end* differs depending on whether the target is using landingpad or WinEH exception model.

For landingpad based exception model, it is expected that frontend uses the *coro.end* intrinsic as follows:

```
ehcleanup:
    %InResumePart = call i1 @llvm.coro.end(i8* null, i1 true)
    br i1 %InResumePart, label %eh.resume, label %cleanup.cont

cleanup.cont:
    ; rest of the cleanup

eh.resume:
    %exn = load i8*, i8** %exn.slot, align 8
    %sel = load i32, i32* %ehselector.slot, align 4
    %lpad.val = insertvalue { i8*, i32 } undef, i8* %exn, 0
    %lpad.val29 = insertvalue { i8*, i32 } %lpad.val, i32 %sel, 1
    resume { i8*, i32 } %lpad.val29
```

The *CoroSplit* pass replaces *coro.end* with `True` in the resume functions, thus leading to immediate unwind to the caller, whereas in start function it is replaced with `False`, thus allowing to proceed to the rest of the cleanup code that is only needed during initial invocation of the coroutine.

For Windows Exception handling model, a frontend should attach a funclet bundle referring to an enclosing cleanuppad as follows:

```
ehcleanup:
    %tok = cleanuppad within none []
    %unused = call i1 @llvm.coro.end(i8* null, i1 true) [ "funclet" (token %tok) ]
    cleanupret from %tok unwind label %RestOfTheCleanup
```

The *CoroSplit* pass, if the funclet bundle is present, will insert `cleanupret from %tok unwind to caller` before the *coro.end* intrinsic and will remove the rest of the block.

The following table summarizes the handling of *coro.end* intrinsic.

		In Start Function	In Resume/Destroy Functions
unwind=true		nothing	ret void
	WinEH	nothing	cleanupret unwind to caller
	Landingpad	nothing	nothing

'llvm.coro.suspend' Intrinsic

```
declare i8 @llvm.coro.suspend(token <save>, i1 <final>)
```

Overview:

The 'llvm.coro.suspend' marks the point where execution of the coroutine need to get suspended and control returned back to the caller. Conditional branches consuming the result of this intrinsic lead to basic blocks where coroutine should proceed when suspended (-1), resumed (0) or destroyed (1).

Arguments:

The first argument refers to a token of *coro.save* intrinsic that marks the point when coroutine state is prepared for suspension. If *none* token is passed, the intrinsic behaves as if there were a *coro.save* immediately preceding the *coro.suspend* intrinsic.

The second argument indicates whether this suspension point is *final*. The second argument only accepts constants. If more than one suspend point is designated as final, the resume and destroy branches should lead to the same basic blocks.

Example (normal suspend point):

```
%0 = call i8 @llvm.coro.suspend(token none, i1 false)
switch i8 %0, label %suspend [i8 0, label %resume
                             i8 1, label %cleanup]
```

Example (final suspend point):

```
while.end:
    %s.final = call i8 @llvm.coro.suspend(token none, i1 true)
    switch i8 %s.final, label %suspend [i8 0, label %trap
                                       i8 1, label %cleanup]
trap:
    call void @llvm.trap()
    unreachable
```

Semantics:

If a coroutine that was suspended at the suspend point marked by this intrinsic is resumed via *coro.resume* the control will transfer to the basic block of the 0-case. If it is resumed via *coro.destroy*, it will proceed to the basic block indicated by the 1-case. To suspend, coroutine proceed to the default label.

If suspend intrinsic is marked as final, it can consider the *true* branch unreachable and can perform optimizations that can take advantage of that fact.

'llvm.coro.save' Intrinsic

```
declare token @llvm.coro.save(i8* <handle>)
```

Overview:

The 'llvm.coro.save' marks the point where a coroutine need to update its state to prepare for resumption to be considered suspended (and thus eligible for resumption).

Arguments:

The first argument points to a coroutine handle of the enclosing coroutine.

Semantics:

Whatever coroutine state changes are required to enable resumption of the coroutine from the corresponding suspend point should be done at the point of *coro.save* intrinsic.

Example:

Separate save and suspend points are necessary when a coroutine is used to represent an asynchronous control flow driven by callbacks representing completions of asynchronous operations.

In such a case, a coroutine should be ready for resumption prior to a call to *async_op* function that may trigger resumption of a coroutine from the same or a different thread possibly prior to *async_op* call returning control back to the coroutine:

```
%save1 = call token @llvm.coro.save(i8* %hdl)
call void @async_op1(i8* %hdl)
%suspend1 = call i1 @llvm.coro.suspend(token %save1, i1 false)
switch i8 %suspend1, label %suspend [i8 0, label %resume1
                                     i8 1, label %cleanup]
```

'llvm.coro.param' Intrinsic

```
declare i1 @llvm.coro.param(i8* <original>, i8* <copy>)
```

Overview:

The 'llvm.coro.param' is used by a frontend to mark up the code used to construct and destruct copies of the parameters. If the optimizer discovers that a particular parameter copy is not used after any suspends, it can remove the construction and destruction of the copy by replacing corresponding *coro.param* with *i1 false* and replacing any use of the *copy* with the *original*.

Arguments:

The first argument points to an *alloca* storing the value of a parameter to a coroutine.

The second argument points to an *alloca* storing the value of the copy of that parameter.

Semantics:

The optimizer is free to always replace this intrinsic with *il true*.

The optimizer is also allowed to replace it with *il false* provided that the parameter copy is only used prior to control flow reaching any of the suspend points. The code that would be DCE'd if the *coro.param* is replaced with *il false* is not considered to be a use of the parameter copy.

The frontend can emit this intrinsic if its language rules allow for this optimization.

Example:

Consider the following example. A coroutine takes two parameters *a* and *b* that has a destructor and a move constructor.

```

struct A { ~A(); A(A&&); bool foo(); void bar(); };

task<int> f(A a, A b) {
    if (a.foo())
        return 42;

    a.bar();
    co_await read_async(); // introduces suspend point
    b.bar();
}

```

Note that, uses of *b* is used after a suspend point and thus must be copied into a coroutine frame, whereas *a* does not have to, since it never used after suspend.

A frontend can create parameter copies for *a* and *b* as follows:

```

task<int> f(A a', A b') {
    a = alloca A;
    b = alloca A;
    // move parameters to its copies
    if (coro.param(a', a)) A::A(a, A&& a');
    if (coro.param(b', b)) A::A(b, A&& b');
    ...
    // destroy parameters copies
    if (coro.param(a', a)) A::~~A(a);
    if (coro.param(b', b)) A::~~A(b);
}

```

The optimizer can replace `coro.param(a',a)` with *il false* and replace all uses of *a* with *a'*, since it is not used after suspend.

The optimizer must replace `coro.param(b', b)` with *il true*, since *b* is used after suspend and therefore, it has to reside in the coroutine frame.

4.37.4 Coroutine Transformation Passes

CoroEarly

The pass CoroEarly lowers coroutine intrinsics that hide the details of the structure of the coroutine frame, but, otherwise not needed to be preserved to help later coroutine passes. This pass lowers *coro.frame*, *coro.done*, and *coro.promise* intrinsics.

CoroSplit

The pass CoroSplit buides coroutine frame and outlines resume and destroy parts into separate functions.

CoroElide

The pass CoroElide examines if the inlined coroutine is eligible for heap allocation elision optimization. If so, it replaces *coro.begin* intrinsic with an address of a coroutine frame placed on its caller and replaces *coro.alloc* and *coro.free* intrinsics with *false* and *null* respectively to remove the deallocation code. This pass also replaces *coro.resume* and *coro.destroy* intrinsics with direct calls to resume and destroy functions for a particular coroutine where possible.

CoroCleanup

This pass runs late to lower all coroutine related intrinsics not replaced by earlier passes.

4.37.5 Areas Requiring Attention

1. A coroutine frame is bigger than it could be. Adding stack packing and stack coloring like optimization on the coroutine frame will result in tighter coroutine frames.
2. Take advantage of the lifetime intrinsics for the data that goes into the coroutine frame. Leave lifetime intrinsics as is for the data that stays in allocas.
3. The CoroElide optimization pass relies on coroutine ramp function to be inlined. It would be beneficial to split the ramp function further to increase the chance that it will get inlined into its caller.
4. Design a convention that would make it possible to apply coroutine heap elision optimization across ABI boundaries.
5. Cannot handle coroutines with *inalloca* parameters (used in x86 on Windows).
6. Alignment is ignored by *coro.begin* and *coro.free* intrinsics.
7. Make required changes to make sure that coroutine optimizations work with LTO.
8. More tests, more tests, more tests

4.38 Global Instruction Selection

- *Introduction*
- *Generic Machine IR*
- *Core Pipeline*
- *Maintainability*
- *Progress and Future Work*
- *Porting GlobalISel to A New Target*
- *Resources*

Warning: This document is a work in progress. It reflects the current state of the implementation, as well as open design and implementation issues.

4.38.1 Introduction

GlobalISel is a framework that provides a set of reusable passes and utilities for instruction selection --- translation from LLVM IR to target-specific Machine IR (MIR).

GlobalISel is intended to be a replacement for SelectionDAG and FastISel, to solve three major problems:

- **Performance** --- SelectionDAG introduces a dedicated intermediate representation, which has a compile-time cost.

GlobalISel directly operates on the post-isel representation used by the rest of the code generator, MIR. It does require extensions to that representation to support arbitrary incoming IR: *Generic Machine IR*.

- **Granularity** --- SelectionDAG and FastISel operate on individual basic blocks, losing some global optimization opportunities.

GlobalISel operates on the whole function.

- **Modularity** --- SelectionDAG and FastISel are radically different and share very little code.

GlobalISel is built in a way that enables code reuse. For instance, both the optimized and fast selectors share the *Core Pipeline*, and targets can configure that pipeline to better suit their needs.

4.38.2 Generic Machine IR

Machine IR operates on physical registers, register classes, and (mostly) target-specific instructions.

To bridge the gap with LLVM IR, GlobalISel introduces "generic" extensions to Machine IR:

- *Generic Instructions*
- *Generic Virtual Registers*
- *Register Bank*
- *Low Level Type*

NOTE: The generic MIR (GMIR) representation still contains references to IR constructs (such as `GlobalValue`). Removing those should let us write more accurate tests, or delete IR after building the initial MIR. However, it is not part of the GlobalISel effort.

Generic Instructions

The main addition is support for pre-isel generic machine instructions (e.g., `G_ADD`). Like other target-independent instructions (e.g., `COPY` or `PHI`), these are available on all targets.

TODO: While we're progressively adding instructions, one kind in particular exposes interesting problems: compares and how to represent condition codes. Some targets (x86, ARM) have generic comparisons setting multiple flags, which are then used by predicated variants. Others (IR) specify the predicate in the comparison and users just get a single bit. SelectionDAG uses `SETCC/CONDBR` vs `BR_CC` (and similar for `select`) to represent this.

The `MachineIRBuilder` class wraps the `MachineInstrBuilder` and provides a convenient way to create these generic instructions.

Generic Virtual Registers

Generic instructions operate on a new kind of register: "generic" virtual registers. As opposed to non-generic vregs, they are not assigned a `Register Class`. Instead, generic vregs have a *Low Level Type*, and can be assigned a *Register Bank*.

`MachineRegisterInfo` tracks the same information that it does for non-generic vregs (e.g., use-def chains). Additionally, it also tracks the *Low Level Type* of the register, and, instead of the `TargetRegisterClass`, its *Register Bank*, if any.

For simplicity, most generic instructions only accept generic vregs:

- instead of immediates, they use a gvreg defined by an instruction materializing the immediate value (see *Constant Lowering*).
- instead of physical register, they use a gvreg defined by a `COPY`.

NOTE: We started with an alternative representation, where `MRI` tracks a size for each gvreg, and instructions have lists of types. That had two flaws: the type and size are redundant, and there was no generic way of getting a given operand's type (as there was no 1:1 mapping between instruction types and operands). We considered putting the type in some variant of `MCInstrDesc` instead: See [PR26576](#): [GlobalISel] Generic MachineInstrs need a type but this increases the memory footprint of the related objects

Register Bank

A `Register Bank` is a set of register classes defined by the target. A bank has a size, which is the maximum store size of all covered classes.

In general, cross-class copies inside a bank are expected to be cheaper than copies across banks. They are also coalesceable by the register coalescer, whereas cross-bank copies are not.

Also, equivalent operations can be performed on different banks using different instructions.

For example, X86 can be seen as having 3 main banks: general-purpose, x87, and vector (which could be further split into a bank per domain for single vs double precision instructions).

Register banks are described by a target-provided API, *RegisterBankInfo*.

Low Level Type

Additionally, every generic virtual register has a type, represented by an instance of the `LLT` class.

Like `EVT/MVT/Type`, it has no distinction between unsigned and signed integer types. Furthermore, it also has no distinction between integer and floating-point types: it mainly conveys absolutely necessary information, such as size and number of vector lanes:

- `sN` for scalars
- `pN` for pointers
- `<N x sM>` for vectors
- `unsized` for labels, etc..

`LLT` is intended to replace the usage of `EVT` in `SelectionDAG`.

Here are some `LLT` examples and their `EVT` and `Type` equivalents:

LLT	EVT	IR Type
<code>s1</code>	<code>i1</code>	<code>i1</code>
<code>s8</code>	<code>i8</code>	<code>i8</code>
<code>s32</code>	<code>i32</code>	<code>i32</code>
<code>s32</code>	<code>f32</code>	<code>float</code>
<code>s17</code>	<code>i17</code>	<code>i17</code>
<code>s16</code>	<code>N/A</code>	<code>{i8, i8}</code>
<code>s32</code>	<code>N/A</code>	<code>[4 x i8]</code>
<code>p0</code>	<code>iPTR</code>	<code>i8*, i32*, %opaque*</code>
<code>p2</code>	<code>iPTR</code>	<code>i8 addrspace(2) *</code>
<code><4 x s32></code>	<code>v4f32</code>	<code><4 x float></code>
<code>s64</code>	<code>v1f64</code>	<code><1 x double></code>
<code><3 x s32></code>	<code>v3i32</code>	<code><3 x i32></code>
<code>unsized</code>	<code>Other</code>	<code>label</code>

Rationale: instructions already encode a specific interpretation of types (e.g., `add` vs. `fadd`, or `sdiv` vs. `udiv`). Also encoding that information in the type system requires introducing bitcast with no real advantage for the selector.

Pointer types are distinguished by address space. This matches IR, as opposed to `SelectionDAG` where address space is an attribute on operations. This representation better supports pointers having different sizes depending on their addressspace.

NOTE: Currently, `LLT` requires at least 2 elements in vectors, but some targets have the concept of a '1-element vector'. Representing them as their underlying scalar type is a nice simplification.

TODO: Currently, non-generic virtual registers, defined by non-pre-isel-generic instructions, cannot have a type, and thus cannot be used by a pre-isel generic instruction. Instead, they are given a type using a `COPY`. We could relax that and allow types on all vregs: this would reduce the number of MI required when emitting target-specific MIR early in the pipeline. This should purely be a compile-time optimization.

4.38.3 Core Pipeline

There are four required passes, regardless of the optimization mode:

- *IRTranslator*
 - *API: CallLowering*
 - *Aggregates*
 - *Constant Lowering*
- *Legalizer*
 - *API: LegalizerInfo*
 - * *Rule Processing and Declaring Rules*
 - * *Rule Actions*
 - * *Rule Predicates*
 - * *Composite Rules*
 - * *Other Information*
- *RegBankSelect*
 - *API: RegisterBankInfo*
 - *RegBankSelect Modes*
- *InstructionSelect*
 - *API: InstructionSelector*
 - *SelectionDAG Rule Imports*
 - *PatLeaf Predicates*
 - *Custom SDNodes*
 - *ComplexPatterns*

Additional passes can then be inserted at higher optimization levels or for specific targets. For example, to match the current SelectionDAG set of transformations: MachineCSE and a better MachineCombiner between every pass.

NOTE: In theory, not all passes are always necessary. As an additional compile-time optimization, we could skip some of the passes by setting the relevant MachineFunction properties. For instance, if the IRTranslator did not encounter any illegal instruction, it would set the `legalized` property to avoid running the *Legalizer*. Similarly, we considered specializing the IRTranslator per-target to directly emit target-specific MI. However, we instead decided to keep the core pipeline simple, and focus on minimizing the overhead of the passes in the no-op cases.

IRTranslator

This pass translates the input LLVM IR `Function` to a GMIR `MachineFunction`.

TODO: This currently doesn't support the more complex instructions, in particular those involving control flow (switch, invoke, ...). For switch in particular, we can initially use the `LowerSwitch` pass.

API: CallLowering

The `IRTranslator` (using the `CallLowering` target-provided utility) also implements the ABI's calling convention by lowering calls, returns, and arguments to the appropriate physical register usage and instruction sequences.

Aggregates

Aggregates are lowered to a single scalar vreg. This differs from `SelectionDAG`'s multiple vregs via `GetValueVTs`.

TODO: As some of the bits are undef (padding), we should consider augmenting the representation with additional metadata (in effect, caching `computeKnownBits` information on vregs). See [PR26161: \[GlobalISel\] Value to vreg during IR to MachineInstr translation for aggregate type](#)

Constant Lowering

The `IRTranslator` lowers `Constant` operands into uses of gvregs defined by `G_CONSTANT` or `G_FCONSTANT` instructions. Currently, these instructions are always emitted in the entry basic block. In a `MachineFunction`, each `Constant` is materialized by a single gvreg.

This is beneficial as it allows us to fold constants into immediate operands during *InstructionSelect*, while still avoiding redundant materializations for expensive non-foldable constants. However, this can lead to unnecessary spills and reloads in an -O0 pipeline, as these vregs can have long live ranges.

TODO: We're investigating better placement of these instructions, in fast and optimized modes.

Legalizer

This pass transforms the generic machine instructions such that they are legal.

A legal instruction is defined as:

- **selectable** --- the target will later be able to select it to a target-specific (non-generic) instruction.
- operating on **vregs that can be loaded and stored** -- if necessary, the target can select a `G_LOAD/G_STORE` of each gvreg operand.

As opposed to `SelectionDAG`, there are no legalization phases. In particular, 'type' and 'operation' legalization are not separate.

Legalization is iterative, and all state is contained in GMIR. To maintain the validity of the intermediate code, instructions are introduced:

- `G_MERGE_VALUES` --- concatenate multiple registers of the same size into a single wider register.
- `G_UNMERGE_VALUES` --- extract multiple registers of the same size from a single wider register.
- `G_EXTRACT` --- extract a simple register (as contiguous sequences of bits) from a single wider register.

As they are expected to be temporary byproducts of the legalization process, they are combined at the end of the *Legalizer* pass. If any remain, they are expected to always be selectable, using loads and stores if necessary.

The legality of an instruction may only depend on the instruction itself and must not depend on any context in which the instruction is used. However, after deciding that an instruction is not legal, using the context of the instruction to decide how to legalize the instruction is permitted. As an example, if we have a `G_FOO` instruction of the form:

```
%1:_(s32) = G_CONSTANT i32 1
%2:_(s32) = G_FOO %0:_(s32), %1:_(s32)
```

it's impossible to say that `G_FOO` is legal iff `%1` is a `G_CONSTANT` with value 1. However, the following:

```
%2:_(s32) = G_FOO %0:_(s32), i32 1
```

can say that it's legal iff operand 2 is an immediate with value 1 because that information is entirely contained within the single instruction.

API: LegalizerInfo

The recommended¹ API looks like this:

```
getActionDefinitionsBuilder({G_ADD, G_SUB, G_MUL, G_AND, G_OR, G_XOR, G_SHL})
    .legalFor({s32, s64, v2s32, v4s32, v2s64})
    .clampScalar(0, s32, s64)
    .widenScalarToNextPow2(0)
    .clampNumElements(0, v2s32, v4s32)
    .clampNumElements(0, v2s64, v2s64)
    .moreElementsToNextPow2(0);
```

and describes a set of rules by which we can either declare an instruction legal or decide which action to take to make it more legal.

At the core of this ruleset is the `LegalityQuery` which describes the instruction. We use a description rather than the instruction to both allow other passes to determine legality without having to create an instruction and also to limit the information available to the predicates to that which is safe to rely on. Currently, the information available to the predicates that determine legality contains:

- The opcode for the instruction
- The type of each type index (see `type0`, `type1`, etc.)
- The size in bytes and atomic ordering for each `MachineMemOperand`

Rule Processing and Declaring Rules

The `getActionDefinitionsBuilder` function generates a ruleset for the given opcode(s) that rules can be added to. If multiple opcodes are given, they are all permanently bound to the same ruleset. The rules in a ruleset are executed from top to bottom and will start again from the top if an instruction is legalized as a result of the rules. If the ruleset is exhausted without satisfying any rule, then it is considered unsupported.

When it doesn't declare the instruction legal, each pass over the rules may request that one type changes to another type. Sometimes this can cause multiple types to change but we avoid this as much as possible as making multiple changes can make it difficult to avoid infinite loops where, for example, narrowing one type causes another to be too small and widening that type causes the first one to be too big.

¹ An API is broadly similar to `SelectionDAG/TargetLowering` is available but is not recommended as a more powerful API is available.

In general, it's advisable to declare instructions legal as close to the top of the rule as possible and to place any expensive rules as low as possible. This helps with performance as testing for legality happens more often than legalization and legalization can require multiple passes over the rules.

As a concrete example, consider the rule:

```
getActionDefinitionsBuilder({G_ADD, G_SUB, G_MUL, G_AND, G_OR, G_XOR, G_SHL})
    .legalFor({s32, s64, v2s32, v4s32, v2s64})
    .clampScalar(0, s32, s64)
    .widenScalarToNextPow2(0);
```

and the instruction:

```
%2:_(s7) = G_ADD %0:_(s7), %1:_(s7)
```

this doesn't meet the predicate for the *.legalFor()* as *s7* is not one of the listed types so it falls through to the *.clampScalar()*. It does meet the predicate for this rule as the type is smaller than the *s32* and this rule instructs the legalizer to change type 0 to *s32*. It then restarts from the top. This time it does satisfy *.legalFor()* and the resulting output is:

```
%3:_(s32) = G_ANYEXT %0:_(s7)
%4:_(s32) = G_ANYEXT %1:_(s7)
%5:_(s32) = G_ADD %3:_(s32), %4:_(s32)
%2:_(s7) = G_TRUNC %5:_(s32)
```

where the *G_ADD* is legal and the other instructions are scheduled for processing by the legalizer.

Rule Actions

There are various rule factories that append rules to a ruleset but they have a few actions in common:

- *legalIf()*, *legalFor()*, etc. declare an instruction to be legal if the predicate is satisfied.
- *narrowScalarIf()*, *narrowScalarFor()*, etc. declare an instruction to be illegal if the predicate is satisfied and indicates that narrowing the scalars in one of the types to a specific type would make it more legal. This action supports both scalars and vectors.
- *widenScalarIf()*, *widenScalarFor()*, etc. declare an instruction to be illegal if the predicate is satisfied and indicates that widening the scalars in one of the types to a specific type would make it more legal. This action supports both scalars and vectors.
- *fewerElementsIf()*, *fewerElementsFor()*, etc. declare an instruction to be illegal if the predicate is satisfied and indicates reducing the number of vector elements in one of the types to a specific type would make it more legal. This action supports vectors.
- *moreElementsIf()*, *moreElementsFor()*, etc. declare an instruction to be illegal if the predicate is satisfied and indicates increasing the number of vector elements in one of the types to a specific type would make it more legal. This action supports vectors.
- *lowerIf()*, *lowerFor()*, etc. declare an instruction to be illegal if the predicate is satisfied and indicates that replacing it with equivalent instruction(s) would make it more legal. Support for this action differs for each opcode.
- *libcallIf()*, *libcallFor()*, etc. declare an instruction to be illegal if the predicate is satisfied and indicates that replacing it with a libcall would make it more legal. Support for this action differs for each opcode.
- *customIf()*, *customFor()*, etc. declare an instruction to be illegal if the predicate is satisfied and indicates that the backend developer will supply a means of making it more legal.

- `unsupportedIf()`, `unsupportedFor()`, etc. declare an instruction to be illegal if the predicate is satisfied and indicates that there is no way to make it legal and the compiler should fail.
- `fallback()` falls back on an older API and should only be used while porting existing code from that API.

Rule Predicates

The rule factories also have predicates in common:

- `legal()`, `lower()`, etc. are always satisfied.
- `legalIf()`, `narrowScalarIf()`, etc. are satisfied if the user-supplied `LegalityPredicate` function returns true. This predicate has access to the information in the `LegalityQuery` to make its decision. User-supplied predicates can also be combined using `all(P0, P1, ...)`.
- `legalFor()`, `narrowScalarFor()`, etc. are satisfied if the type matches one in a given set of types. For example `.legalFor({s16, s32})` declares the instruction legal if type 0 is either s16 or s32. Additional versions for two and three type indices are generally available. For these, all the type indices considered together must match all the types in one of the tuples. So `.legalFor({{s16, s32}, {s32, s64}})` will only accept `{s16, s32}`, or `{s32, s64}` but will not accept `{s16, s64}`.
- `legalForTypesWithMemSize()`, `narrowScalarForTypesWithMemSize()`, etc. are similar to `legalFor()`, `narrowScalarFor()`, etc. but additionally require a `MachineMemOperand` to have a given size in each tuple.
- `legalForCartesianProduct()`, `narrowScalarForCartesianProduct()`, etc. are satisfied if each type index matches one element in each of the independent sets. So `.legalForCartesianProduct({s16, s32}, {s32, s64})` will accept `{s16, s32}`, `{s16, s64}`, `{s32, s32}`, and `{s32, s64}`.

Composite Rules

There are some composite rules for common situations built out of the above facilities:

- `widenScalarToNextPow2()` is like `widenScalarIf()` but is satisfied iff the type size in bits is not a power of 2 and selects a target type that is the next largest power of 2.
- `minScalar()` is like `widenScalarIf()` but is satisfied iff the type size in bits is smaller than the given minimum and selects the minimum as the target type. Similarly, there is also a `maxScalar()` for the maximum and a `clampScalar()` to do both at once.
- `minScalarSameAs()` is like `minScalar()` but the minimum is taken from another type index.
- `moreElementsToNextMultiple()` is like `moreElementsToNextPow2()` but is based on multiples of X rather than powers of 2.

Other Information

TODO: An alternative worth investigating is to generalize the API to represent actions using `std::function` that implements the action, instead of explicit enum tokens (`Legal`, `WidenScalar`, ...).

TODO: Moreover, we could use TableGen to initially infer legality of operation from existing patterns (as any pattern we can select is by definition legal). Expanding that to describe legalization actions is a much larger but potentially useful project.

RegBankSelect

This pass constrains the *Generic Virtual Registers* operands of generic instructions to some *Register Bank*.

It iteratively maps instructions to a set of per-operand bank assignment. The possible mappings are determined by the target-provided *RegisterBankInfo*. The mapping is then applied, possibly introducing `COPY` instructions if necessary.

It traverses the `MachineFunction` top down so that all operands are already mapped when analyzing an instruction.

This pass could also remap target-specific instructions when beneficial. In the future, this could replace the `ExeDeps-Fix` pass, as we can directly select the best variant for an instruction that's available on multiple banks.

API: RegisterBankInfo

The `RegisterBankInfo` class describes multiple aspects of register banks.

- **Banks:** `addRegBankCoverage` --- which register bank covers each register class.
- **Cross-Bank Copies:** `copyCost` --- the cost of a `COPY` from one bank to another.
- **Default Mapping:** `getInstrMapping` --- the default bank assignments for a given instruction.
- **Alternative Mapping:** `getInstrAlternativeMapping` --- the other possible bank assignments for a given instruction.

TODO: All this information should eventually be static and generated by TableGen, mostly using existing information augmented by bank descriptions.

TODO: `getInstrMapping` is currently separate from `getInstrAlternativeMapping` because the latter is more expensive: as we move to static mapping info, both methods should be free, and we should merge them.

RegBankSelect Modes

`RegBankSelect` currently has two modes:

- **Fast** --- For each instruction, pick a target-provided "default" bank assignment. This is the default at `-O0`.
- **Greedy** --- For each instruction, pick the cheapest of several target-provided bank assignment alternatives.

We intend to eventually introduce an additional optimizing mode:

- **Global** --- Across multiple instructions, pick the cheapest combination of bank assignments.

NOTE: On AArch64, we are considering using the Greedy mode even at `-O0` (or perhaps at backend `-O1`): because *Low Level Type* doesn't distinguish floating point from integer scalars, the default assignment for loads and stores is the integer bank, introducing cross-bank copies on most floating point operations.

InstructionSelect

This pass transforms generic machine instructions into equivalent target-specific instructions. It traverses the `MachineFunction` bottom-up, selecting uses before definitions, enabling trivial dead code elimination.

API: InstructionSelector

The target implements the `InstructionSelector` class, containing the target-specific selection logic proper.

The instance is provided by the subtarget, so that it can specialize the selector by subtarget feature (with, e.g., a vector selector overriding parts of a general-purpose common selector). We might also want to parameterize it by `MachineFunction`, to enable selector variants based on function attributes like `optsize`.

The simple API consists of:

```
virtual bool select (MachineInstr &MI)
```

This target-provided method is responsible for mutating (or replacing) a possibly-generic MI into a fully target-specific equivalent. It is also responsible for doing the necessary constraining of `gvs` into the appropriate register classes as well as passing through `COPY` instructions to the register allocator.

The `InstructionSelector` can fold other instructions into the selected MI, by walking the use-def chain of the `vreg` operands. As `GlobalISel` is Global, this folding can occur across basic blocks.

SelectionDAG Rule Imports

TableGen will import `SelectionDAG` rules and provide the following function to execute them:

```
bool selectImpl (MachineInstr &MI)
```

The `--stats` option can be used to determine what proportion of rules were successfully imported. The easiest way to use this is to copy the `-gen-globalisel tablegen` command from `ninja -v` and modify it.

Similarly, the `--warn-on-skipped-patterns` option can be used to obtain the reasons that rules weren't imported. This can be used to focus on the most important rejection reasons.

PatLeaf Predicates

PatLeafs cannot be imported because their C++ is implemented in terms of `SDNode` objects. PatLeafs that handle immediate predicates should be replaced by `ImmLeaf`, `IntImmLeaf`, or `FPImmLeaf` as appropriate.

There's no standard answer for other PatLeafs. Some standard predicates have been baked into TableGen but this should not generally be done.

Custom SDNodes

Custom `SDNodes` should be mapped to Target Pseudos using `GINodeEquiv`. This will cause the instruction selector to import them but you will also need to ensure the target pseudo is introduced to the MIR before the instruction selector. Any preceding pass is suitable but the legalizer will be a particularly common choice.

ComplexPatterns

ComplexPatterns cannot be imported because their C++ is implemented in terms of `SDNode` objects. GlobalISel versions should be defined with `GIComplexOperandMatcher` and mapped to `ComplexPattern` with `GIComplexPatternEquiv`.

The following predicates are useful for porting `ComplexPattern`:

- `isBaseWithConstantOffset()` - Check for base+offset structures
- `isOperandImmEqual()` - Check for a particular constant
- `isObviouslySafeToFold()` - Check for reasons an instruction can't be sunk and folded into another.

There are some important points for the C++ implementation:

- Don't modify MIR in the predicate
- Renderer lambdas should capture by value to avoid use-after-free. They will be used after the predicate returns.
- Only create instructions in a renderer lambda. GlobalISel won't clean up things you create but don't use.

4.38.4 Maintainability

Iterative Transformations

Passes are split into small, iterative transformations, with all state represented in the MIR.

This differs from SelectionDAG (in particular, the legalizer) using various in-memory side-tables.

MIR Serialization

Generic Machine IR is serializable (see *Machine IR (MIR) Format Reference Manual*). Combined with *Iterative Transformations*, this enables much finer-grained testing, rather than requiring large and fragile IR-to-assembly tests.

The current "stage" in the *Core Pipeline* is represented by a set of `MachineFunctionProperties`:

- `legalized`
- `regBankSelected`
- `selected`

MachineVerifier

The pass approach lets us use the `MachineVerifier` to enforce invariants. For instance, a `regBankSelected` function may not have gvregs without a bank.

TODO: The `MachineVerifier` being monolithic, some of the checks we want to do can't be integrated to it: GlobalISel is a separate library, so we can't directly reference it from CodeGen. For instance, legality checks are currently done in `RegBankSelect/InstructionSelect` proper. We could `#ifdef` out the checks, or we could add some sort of verifier API.

4.38.5 Progress and Future Work

The initial goal is to replace FastISel on AArch64. The next step will be to replace SelectionDAG as the optimized ISel.

NOTE: While we iterate on GlobalISel, we strive to avoid affecting the performance of SelectionDAG, FastISel, or the other MIR passes. For instance, the types of *Generic Virtual Registers* are stored in a separate table in `MachineRegisterInfo`, that is destroyed after *InstructionSelect*.

FastISel Replacement

For the initial FastISel replacement, we intend to fallback to SelectionDAG on selection failures.

Currently, compile-time of the fast pipeline is within 1.5x of FastISel. We're optimistic we can get to within 1.1/1.2x, but beating FastISel will be challenging given the multi-pass approach. Still, supporting all IR (via a complete legalizer) and avoiding the fallback to SelectionDAG in the worst case should enable better amortized performance than SelectionDAG+FastISel.

NOTE: We considered never having a fallback to SelectionDAG, instead deciding early whether a given function is supported by GlobalISel or not. The decision would be based on *Legalizer* queries. We abandoned that for two reasons: a) on IR inputs, we'd need to basically simulate the *IRTranslator*; b) to be robust against unforeseen failures and to enable iterative improvements.

Support For Other Targets

In parallel, we're investigating adding support for other - ideally quite different - targets. For instance, there is some initial AMDGPU support.

4.38.6 Porting GlobalISel to A New Target

There are four major classes to implement by the target:

- *CallLowering* --- lower calls, returns, and arguments according to the ABI.
- *RegisterBankInfo* --- describe *Register Bank* coverage, cross-bank copy cost, and the mapping of operands onto banks for each instruction.
- *LegalizerInfo* --- describe what is legal, and how to legalize what isn't.
- *InstructionSelector* --- select generic MIR to target-specific MIR.

Additionally:

- *TargetPassConfig* --- create the passes constituting the pipeline, including additional passes not included in the *Core Pipeline*.

- *Future Work*
 - *Trace Analysis Tools*
 - *More Platforms*

4.39.1 Introduction

XRay is a function call tracing system which combines compiler-inserted instrumentation points and a runtime library that can dynamically enable and disable the instrumentation.

More high level information about XRay can be found in the [XRay whitepaper](#).

This document describes how to use XRay as implemented in LLVM.

4.39.2 XRay in LLVM

XRay consists of three main parts:

- Compiler-inserted instrumentation points.
- A runtime library for enabling/disabling tracing at runtime.
- A suite of tools for analysing the traces.

NOTE: As of July 25, 2018, XRay is only available for the following architectures running Linux: x86_64, arm7 (no thumb), aarch64, powerpc64le, mips, mipsel, mips64, mips64el, NetBSD: x86_64, FreeBSD: x86_64 and OpenBSD: x86_64.

The compiler-inserted instrumentation points come in the form of nop-sleds in the final generated binary, and an ELF section named `xray_instr_map` which contains entries pointing to these instrumentation points. The runtime library relies on being able to access the entries of the `xray_instr_map`, and overwrite the instrumentation points at runtime.

4.39.3 Using XRay

You can use XRay in a couple of ways:

- Instrumenting your C/C++/Objective-C/Objective-C++ application.
- Generating LLVM IR with the correct function attributes.

The rest of this section covers these main ways and later on how to customise what XRay does in an XRay-instrumented binary.

Instrumenting your C/C++/Objective-C Application

The easiest way of getting XRay instrumentation for your application is by enabling the `-fxray-instrument` flag in your clang invocation.

For example:

```
clang -fxray-instrument ...
```

By default, functions that have at least 200 instructions will get XRay instrumentation points. You can tweak that number through the `-fxray-instruction-threshold=` flag:

```
clang -fxray-instrument -fxray-instruction-threshold=1 ...
```

You can also specifically instrument functions in your binary to either always or never be instrumented using source-level attributes. You can do it using the GCC-style attributes or C++11-style attributes.

```
[[clang::xray_always_instrument]] void always_instrumented();  
[[clang::xray_never_instrument]] void never_instrumented();  
void alt_always_instrumented() __attribute__((xray_always_instrument));  
void alt_never_instrumented() __attribute__((xray_never_instrument));
```

When linking a binary, you can either manually link in the *XRay Runtime Library* or use `clang` to link it in automatically with the `-fxray-instrument` flag. Alternatively, you can statically link-in the XRay runtime library

from compiler-rt -- those archive files will take the name of *libclang_rt.xray-{arch}* where *{arch}* is the mnemonic supported by clang (x86_64, arm7, etc.).

LLVM Function Attribute

If you're using LLVM IR directly, you can add the `function-instrument` string attribute to your functions, to get the similar effect that the C/C++/Objective-C source-level attributes would get:

```
define i32 @always_instrument() uwtable "function-instrument"="xray-always" {
    ; ...
}

define i32 @never_instrument() uwtable "function-instrument"="xray-never" {
    ; ...
}
```

You can also set the `xray-instruction-threshold` attribute and provide a numeric string value for how many instructions should be in the function before it gets instrumented.

```
define i32 @maybe_instrument() uwtable "xray-instruction-threshold"="2" {
    ; ...
}
```

Special Case File

Attributes can be imbued through the use of special case files instead of adding them to the original source files. You can use this to mark certain functions and classes to be never, always, or instrumented with first-argument logging from a file. The file's format is described below:

```
# Comments are supported
[always]
fun:always_instrument
fun:log_arg1=arg1 # Log the first argument for the function

[never]
fun:never_instrument
```

These files can be provided through the `-fxray-attr-list=` flag to clang. You may have multiple files loaded through multiple instances of the flag.

XRay Runtime Library

The XRay Runtime Library is part of the compiler-rt project, which implements the runtime components that perform the patching and unpatching of inserted instrumentation points. When you use `clang` to link your binaries and the `-fxray-instrument` flag, it will automatically link in the XRay runtime.

The default implementation of the XRay runtime will enable XRay instrumentation before `main` starts, which works for applications that have a short lifetime. This implementation also records all function entry and exit events which may result in a lot of records in the resulting trace.

Also by default the filename of the XRay trace is `xray-log.XXXXXXX` where the `XXXXXX` part is randomly generated.

These options can be controlled through the `XRAY_OPTIONS` environment variable, where we list down the options and their defaults below.

Option	Type	Default	Description
patch_premain	bool	false	Whether to patch instrumentation points before main.
xray_mode	const char*	" "	Default mode to install and initialize before main.
xray_logfile_base	const char*	xray-log.	Filename base for the XRay logfile.
verbosity	int	0	Runtime verbosity level.

If you choose to not use the default logging implementation that comes with the XRay runtime and/or control when/how the XRay instrumentation runs, you may use the XRay APIs directly for doing so. To do this, you'll need to include the `xray_log_interface.h` from the compiler-rt `xray` directory. The important API functions we list below:

- `__xray_log_register_mode(...)`: Register a logging implementation against a string Mode identifier. The implementation is an instance of `XRayLogImpl` defined in `xray/xray_log_interface.h`.
- `__xray_log_select_mode(...)`: Select the mode to install, associated with a string Mode identifier. Only implementations registered with `__xray_log_register_mode(...)` can be chosen with this function.
- `__xray_log_init_mode(...)`: This function allows for initializing and re-initializing an installed logging implementation. See `xray/xray_log_interface.h` for details, part of the XRay compiler-rt installation.

Once a logging implementation has been initialized, it can be "stopped" by finalizing the implementation through the `__xray_log_finalize()` function. The finalization routine is the opposite of the initialization. When finalized, an implementation's data can be cleared out through the `__xray_log_flushLog()` function. For implementations that support in-memory processing, these should register an iterator function to provide access to the data via the `__xray_log_set_buffer_iterator(...)` which allows code calling the `__xray_log_process_buffers(...)` function to deal with the data in memory.

All of this is better explained in the `xray/xray_log_interface.h` header.

Basic Mode

XRay supports a basic logging mode which will trace the application's execution, and periodically append to a single log. This mode can be installed/enabled by setting `xray_mode=xray-basic` in the `XRAY_OPTIONS` environment variable. Combined with `patch_premain=true` this can allow for tracing applications from start to end.

Like all the other modes installed through `__xray_log_select_mode(...)`, the implementation can be configured through the `__xray_log_init_mode(...)` function, providing the mode string and the flag options. Basic-mode specific defaults can be provided in the `XRAY_BASIC_OPTIONS` environment variable.

Flight Data Recorder Mode

XRay supports a logging mode which allows the application to only capture a fixed amount of memory's worth of events. Flight Data Recorder (FDR) mode works very much like a plane's "black box" which keeps recording data to memory in a fixed-size circular queue of buffers, and have the data available programmatically until the buffers are finalized and flushed. To use FDR mode on your application, you may set the `xray_mode` variable to `xray-fdr` in the `XRAY_OPTIONS` environment variable. Additional options to the FDR mode implementation can be provided in the `XRAY_FDR_OPTIONS` environment variable. Programmatic configuration can be done by calling `__xray_log_init_mode("xray-fdr", <configuration string>)` once it has been selected/installed.

When the buffers are flushed to disk, the result is a binary trace format described by [XRay FDR format](#)

When FDR mode is on, it will keep writing and recycling memory buffers until the logging implementation is finalized -- at which point it can be flushed and re-initialised later. To do this programmatically, we follow the workflow provided below:

```
// Patch the sleds, if we haven't yet.
auto patch_status = __xray_patch();

// Maybe handle the patch_status errors.

// When we want to flush the log, we need to finalize it first, to give
// threads a chance to return buffers to the queue.
auto finalize_status = __xray_log_finalize();
if (finalize_status != XRAY_LOG_FINALIZED) {
    // maybe retry, or bail out.
}

// At this point, we are sure that the log is finalized, so we may try
// flushing the log.
auto flush_status = __xray_log_flushLog();
if (flush_status != XRAY_LOG_FLUSHED) {
    // maybe retry, or bail out.
}
```

The default settings for the FDR mode implementation will create logs named similarly to the basic log implementation, but will have a different log format. All the trace analysis tools (and the trace reading library) will support all versions of the FDR mode format as we add more functionality and record types in the future.

NOTE: We do not promise perpetual support for when we update the log versions we support going forward. Deprecation of the formats will be announced and discussed on the developers mailing list.

Trace Analysis Tools

We currently have the beginnings of a trace analysis tool in LLVM, which can be found in the `tools/llvm-xray` directory. The `llvm-xray` tool currently supports the following subcommands:

- `extract`: Extract the instrumentation map from a binary, and return it as YAML.
- `account`: Performs basic function call accounting statistics with various options for sorting, and output formats (supports CSV, YAML, and console-friendly TEXT).
- `convert`: Converts an XRay log file from one format to another. We can convert from binary XRay traces (both basic and FDR mode) to YAML, [flame-graph](#) friendly text formats, as well as *Chrome Trace Viewer* (*catapult*) <<https://github.com/catapult-project/catapult>> formats.
- `graph`: Generates a DOT graph of the function call relationships between functions found in an XRay trace.
- `stack`: Reconstructs function call stacks from a timeline of function calls in an XRay trace.

These subcommands use various library components found as part of the XRay libraries, distributed with the LLVM distribution. These are:

- `llvm/XRay/Trace.h`: A trace reading library for conveniently loading an XRay trace of supported forms, into a convenient in-memory representation. All the analysis tools that deal with traces use this implementation.
- `llvm/XRay/Graph.h`: A semi-generic graph type used by the `graph` subcommand to conveniently represent a function call graph with statistics associated with edges and vertices.
- `llvm/XRay/InstrumentationMap.h`: A convenient tool for analyzing the instrumentation map in XRay-instrumented object files and binaries. The `extract` and `stack` subcommands uses this particular library.

4.39.4 Future Work

There are a number of ongoing efforts for expanding the toolset building around the XRay instrumentation system.

Trace Analysis Tools

- Work is in progress to integrate with or develop tools to visualize findings from an XRay trace. Particularly, the `stack` tool is being expanded to output formats that allow graphing and exploring the duration of time in each call stack.
- With a large instrumented binary, the size of generated XRay traces can quickly become unwieldy. We are working on integrating pruning techniques and heuristics for the analysis tools to sift through the traces and surface only relevant information.

More Platforms

We're looking forward to contributions to port XRay to more architectures and operating systems.

4.40 Debugging with XRay

This document shows an example of how you would go about analyzing applications built with XRay instrumentation. Here we will attempt to debug `llc` compiling some sample LLVM IR generated by Clang.

- *Building with XRay*
- *Getting Traces*
- *The `llvm-xray` Tool*
- *Controlling Fidelity*
 - *Instruction Threshold*
 - *Instrumentation Attributes*
- *The XRay stack tool*
- *Flame Graph Generation*
- *Chrome Trace Viewer Visualization*
- *Further Exploration*
- *Next Steps*

4.40.1 Building with XRay

To debug an application with XRay instrumentation, we need to build it with a Clang that supports the `-fxray-instrument` option. See [XRay](#) for more technical details of how XRay works for background information.

In our example, we need to add `-fxray-instrument` to the list of flags passed to Clang when building a binary. Note that we need to link with Clang as well to get the XRay runtime linked in appropriately. For building `llc` with XRay, we do something similar below for our LLVM build:

```
$ mkdir -p llvm-build && cd llvm-build
# Assume that the LLVM sources are at ../llvm
$ cmake -GNinja ../llvm -DCMAKE_BUILD_TYPE=Release \
    -DCMAKE_C_FLAGS_RELEASE="-fxray-instrument" -DCMAKE_CXX_FLAGS="-fxray-instrument"
↪ \
# Once this finishes, we should build llc
$ ninja llc
```

To verify that we have an XRay instrumented binary, we can use `objdump` to look for the `xray_instr_map` section.

```
$ objdump -h -j xray_instr_map ./bin/llc
./bin/llc:      file format elf64-x86-64

Sections:
Idx Name          Size      VMA           LMA             File off  Algn
 14 xray_instr_map 00002fc0  00000000041516c6  00000000041516c6  03d516c6  2**0
                CONTENTS, ALLOC, LOAD, READONLY, DATA
```

4.40.2 Getting Traces

By default, XRay does not write out the trace files or patch the application before main starts. If we run `llc` it should work like a normally built binary. If we want to get a full trace of the application's operations (of the functions we do end up instrumenting with XRay) then we need to enable XRay at application start. To do this, XRay checks the `XRAY_OPTIONS` environment variable.

```
# The following doesn't create an XRay trace by default.
$ ./bin/llc input.ll

# We need to set the XRAY_OPTIONS to enable some features.
$ XRAY_OPTIONS="patch_premain=true xray_mode=xray-basic verbosity=1" ./bin/llc input.
↪ ll
==69819==XRay: Log file in 'xray-log.llc.m35qPB'
```

At this point we now have an XRay trace we can start analysing.

4.40.3 The `llvm-xray` Tool

Having a trace then allows us to do basic accounting of the functions that were instrumented, and how much time we're spending in parts of the code. To make sense of this data, we use the `llvm-xray` tool which has a few subcommands to help us understand our trace.

One of the things we can do is to get an accounting of the functions that have been instrumented. We can see an example accounting with `llvm-xray account`:

```
$ llvm-xray account xray-log.llc.m35qPB -top=10 -sort=sum -sortorder=dsc -instr_map ./
↳ bin/llc
Functions with latencies: 29
   funcid      count [      min,          med,          90p,          99p,          max]
↳ sum function
   187          360 [ 0.000000, 0.000001, 0.000014, 0.000032, 0.000075] 0.

↳ 000310 Verifier.cpp:1967:0: (anonymous
↳ namespace)::Verifier::visitFunction(llvm::Function const&)
   123            1 [ 0.000302, 0.000302, 0.000302, 0.000302, 0.000302] 0.
↳ 000302 LLVMContextImpl.cpp:54:0: llvm::LLVMContextImpl::~~LLVMContextImpl()
   139           46 [ 0.000000, 0.000002, 0.000006, 0.000008, 0.000019] 0.
↳ 000138 TargetLowering.cpp:506:0:
↳ llvm::TargetLowering::SimplifyDemandedBits(llvm::SDValue, llvm::APInt const&,
↳ llvm::APInt&, llvm::APInt&, llvm::TargetLowering::TargetLoweringOpt&, unsigned int,
↳ bool) const
```

This shows us that for our input file, `llc` spent the most cumulative time in the lexer (a total of 1 millisecond). If we wanted for example to work with this data in a spreadsheet, we can output the results as CSV using the `-format=csv` option to the command for further analysis.

If we want to get a textual representation of the raw trace we can use the `llvm-xray convert` tool to get YAML output. The first few lines of that output for an example trace would look like the following:

```
$ llvm-xray convert -f yaml -symbolize -instr_map=./bin/llc xray-log.llc.m35qPB
---
header:
```

(continues on next page)

(continued from previous page)

```

4.40.4 Controlling Fidelity

So far in our examples, we haven't been getting full coverage of the functions we have in the binary. To get that, we need to modify the compiler flags so that we can instrument more (if not all) the functions we have in the binary. We have two options for doing that, and we explore both of these below.

Instruction Threshold

The first "blunt" way of doing this is by setting the minimum threshold for function bodies to 1. We can do that with the `-fxray-instruction-threshold=N` flag when building our binary. We rebuild `llc` with this option and observe the results:

```

$ rm CMakeCache.txt
$ cmake -GNinja ../llvm -DCMAKE_BUILD_TYPE=Release \
  -DCMAKE_C_FLAGS_RELEASE="-fxray-instrument -fxray-instruction-threshold=1" \
  -DCMAKE_CXX_FLAGS="-fxray-instrument -fxray-instruction-threshold=1"
$ ninja llc
$ XRAY_OPTIONS="patch_premain=true" ./bin/llc input.ll

```

(continues on next page)

(continued from previous page)

```

```

Instrumentation Attributes

The other way is to use configuration files for selecting which functions should always be instrumented by the compiler. This gives us a way of ensuring that certain functions are either always or never instrumented by not having to add the attribute to the source.

To use this feature, you can define one file for the functions to always instrument, and another for functions to never instrument. The format of these files are exactly the same as the SanitizerLists files that control similar things for the sanitizer implementations. For example:

```

# xray-attr-list.txt
# always instrument functions that match the following filters:
[always]
fun:main

# never instrument functions that match the following filters:
[never]
fun:__cxx_*

```

Given the file above we can re-build by providing it to the `-fxray-attr-list=` flag to clang. You can have multiple files, each defining different sets of attribute sets, to be combined into a single list by clang.

4.40.5 The XRay stack tool

Given a trace, and optionally an instrumentation map, the `llvm-xray stack` command can be used to analyze a call stack graph constructed from the function call timeline.

The way to use the command is to output the top stacks by call count and time spent.

```
$ llvm-xray stack xray-log.llc.5rqxkU -instr_map ./bin/llc

Unique Stacks: 3069
Top 10 Stacks by leaf sum:

Sum: 9633790
lvl  function                                     count
↪      sum
#0   main                                         1
↪   58421550
#1   compileModule(char**, llvm::LLVMContext&)    1
↪   51440360
#2   llvm::legacy::PassManagerImpl::run(llvm::Module&) 1
↪   40535375
#3   llvm::FPPassManager::runOnModule(llvm::Module&) 2
↪   39337525
#4   llvm::FPPassManager::runOnFunction(llvm::Function&) 6
↪   39331465
#5   llvm::PMDDataManager::verifyPreservedAnalysis(llvm::Pass*) 399
↪   16628590
#6   llvm::PMToplevelManager::findAnalysisPass(void const*) 4584
↪   15155600
#7   llvm::PMDDataManager::findAnalysisPass(void const*, bool) 32088
↪   9633790
..etc..
```

In the default mode, identical stacks on different threads are independently aggregated. In a multithreaded program, you may end up having identical call stacks fill your list of top calls.

To address this, you may specify the `-aggregate-threads` or `-per-thread-stacks` flags. `-per-thread-stacks` treats the thread id as an implicit root in each call stack tree, while `-aggregate-threads` combines identical stacks from all threads.

4.40.6 Flame Graph Generation

The `llvm-xray stack` tool may also be used to generate flamegraphs for visualizing your instrumented invocations. The tool does not generate the graphs themselves, but instead generates a format that can be used with Brendan Gregg's FlameGraph tool, currently available on [github](#).

To generate output for a flamegraph, a few more options are necessary.

- `-all-stacks` - Emits all of the stacks.
- `-stack-format` - Choose the flamegraph output format 'flame'.
- `-aggregation-type` - Choose the metric to graph.

You may pipe the command output directly to the flamegraph tool to obtain an svg file.

```
$llvm-xray stack xray-log.llc.5rqxkU -instr_map ./bin/llc -stack-format=flame -  
↪aggregation-type=time -all-stacks | \  
/path/to/FlameGraph/flamegraph.pl > flamegraph.svg
```

If you open the svg in a browser, mouse events allow exploring the call stacks.

4.40.7 Chrome Trace Viewer Visualization

We can also generate a trace which can be loaded by the Chrome Trace Viewer from the same generated trace:

```
$ llvm-xray convert -symbolize -instr_map=./bin/llc \  
-output-format=trace_event xray-log.llc.5rqxkU \  
| gzip > llc-trace.txt.gz
```

From a Chrome browser, navigating to `chrome:///tracing` allows us to load the `sample-trace.txt.gz` file to visualize the execution trace.

4.40.8 Further Exploration

The `llvm-xray` tool has a few other subcommands that are in various stages of being developed. One interesting subcommand that can highlight a few interesting things is the `graph` subcommand. Given for example the following toy program that we build with XRay instrumentation, we can see how the generated graph may be a helpful indicator of where time is being spent for the application.

```
// sample.cc  
#include <iostream>  
#include <thread>  
  
[[clang::xray_always_instrument]] void f() {  
    std::cerr << '.';  
}  
  
[[clang::xray_always_instrument]] void g() {  
    for (int i = 0; i < 1 << 10; ++i) {  
        std::cerr << '-';  
    }  
}  
  
int main(int argc, char* argv[]) {  
    std::thread t1([] {  
        for (int i = 0; i < 1 << 10; ++i)  
            f();  
    });  
    std::thread t2([] {  
        g();  
    });  
    t1.join();  
    t2.join();  
    std::cerr << '\n';  
}
```

We then build the above with XRay instrumentation:

```
$ clang++ -o sample -O3 sample.cc -std=c++11 -fxray-instrument -fxray-instruction-  
↪threshold=1  
$ XRAY_OPTIONS="patch_premain=true xray_mode=xray-basic" ./sample
```

We can then explore the graph rendering of the trace generated by this sample application. We assume you have the graphviz tools available in your system, including both `unflatten` and `dot`. If you prefer rendering or exploring the graph using another tool, then that should be feasible as well. `llvm-xray graph` will create DOT format graphs which should be usable in most graph rendering applications. One example invocation of the `llvm-xray graph` command should yield some interesting insights to the workings of C++ applications:

```
$ llvm-xray graph xray-log.sample.* -m sample -color-edges=sum -edge-label=sum \  
| unflatten -f -l10 | dot -Tsvg -o sample.svg
```

4.40.9 Next Steps

If you have some interesting analyses you'd like to implement as part of the `llvm-xray` tool, please feel free to propose them on the `llvm-dev@` mailing list. The following are some ideas to inspire you in getting involved and potentially making things better.

- Implement a query/filtering library that allows for finding patterns in the XRay traces.
- Collecting function call stacks and how often they're encountered in the XRay trace.

4.41 XRay Flight Data Recorder Trace Format

Version 1 as of 2017-07-20

- *Introduction*
- *General*
- *Header Section*
- *Data Section*
 - *Function Records*
 - *Metadata Records*
 - *NewBuffer Records*
 - *WallClockTime Records*
 - *NewCpuId Records*
 - *TSCWrap Records*
 - *CallArgument Records*
 - *CustomEventMarker Records*
 - *EndOfBuffer Records*
- *Format Grammar and Invariants*
 - *Function Record Order*

4.41.1 Introduction

When gathering XRay traces in Flight Data Recorder mode, each thread of an application will claim buffers to fill with trace data, which at some point is finalized and flushed.

A goal of the profiler is to minimize overhead, the flushed data directly corresponds to the buffer.

This document describes the format of a trace file.

4.41.2 General

Each trace file corresponds to a sequence of events in a particular thread.

The file has a header followed by a sequence of discriminated record types.

The endianness of byte fields matches the endianness of the platform which produced the trace file.

4.41.3 Header Section

A trace file begins with a 32 byte header.

Field	Size (bytes)	Description
version	2	Anticipates versioned readers. This document describes the format when version == 1
type	2	An enumeration encoding the type of trace. Flight Data Recorder mode traces have type == 1
bitfield	4	Holds parameters that are not aligned to bytes. Further described below.
cycle_frequency	8	The frequency in hertz of the CPU oscillator used to measure duration of events in ticks.
buffer_size	8	The size in bytes of the data portion of the trace following the header.
reserved	8	Reserved for future use.

The bitfield parameter of the file header is composed of the following fields.

Field	Size (bits)	Description
constant_tsc	1	Whether the platform's timestamp counter used to record ticks between events ticks at a constant frequency despite CPU frequency changes. 0 == non-constant. 1 == constant.
non-stop_tsc	1	Whether the tsc continues to count despite whether the CPU is in a low power state. 0 == stop. 1 == non-stop.
reserved	30	Not meaningful.

4.41.4 Data Section

Following the header in a trace is a data section with size matching the `buffer_size` field in the header.

The data section is a stream of elements of different types.

There are a few categories of data in the sequence.

- **Function Records:** Function Records contain the timing of entry into and exit from function execution. Function Records have 8 bytes each.
- **Metadata Records:** Metadata records serve many purposes. Mostly, they capture information that may be too costly to record for each function, but that is required to contextualize the fine-grained timings. They also are used as markers for user-defined Event Data payloads. Metadata records have 16 bytes each.
- **Event Data:** Free form data may be associated with events that are traced by the binary and encode data defined by a handler function. Event data is always preceded with a marker record which indicates how large it is.
- **Function Arguments:** The arguments to some functions are included in the trace. These are either pointer addresses or primitives that are read and logged independently of their types in a high level language. To the tracer, they are all numbers. Function Records that have attached arguments will indicate their presence on the function entry record. We only support logging contiguous function argument sequences starting with argument zero, which will be the "this" pointer for member function invocations. For example, we don't support logging the first and third argument.

A reader of the memory format must maintain a state machine. The format makes no attempt to pad for alignment, and it is not seekable.

Function Records

Function Records have an 8 byte layout. This layout encodes information to reconstruct a call stack of instrumented function and their durations.

Field	Size (bits)	Description
discriminant	1	Indicates whether a reader should read a Function or Metadata record. Set to 0 for Function records.
action	3	Specifies whether the function is being entered, exited, or is a non-standard entry or exit produced by optimizations.
function_id	28	A numeric ID for the function. Resolved to a name via the xray instrumentation map. The instrumentation map is built by xray at compile time into an object file and pairs the function ids to addresses. It is used for patching and as a lookup into the binary's symbols to obtain names.
tsc_delta	2	The number of ticks of the timestamp counter since a previous record recorded a delta or other TSC resetting event.

On little-endian machines, the bitfields are ordered from least significant bit to most significant bit. A reader can read an 8 bit value and apply the mask `0x01` for the discriminant. Similarly, they can read 32 bits and unsigned shift right by `0x04` to obtain the `function_id` field.

On big-endian machine, the bitfields are written in order from most significant bit to least significant bit. A reader would read an 8 bit value and unsigned shift right by 7 bits for the discriminant. The `function_id` field could be obtained by reading a 32 bit value and applying the mask `0x0FFFFFFF`.

Function action types are as follows.

Type	Number	Description
Entry	0	Typical function entry.
Exit	1	Typical function exit.
Tail_Exit	2	An exit from a function due to tail call optimization.
Entry_Args	3	A function entry that records arguments.

Entry_Args records do not contain the arguments themselves. Instead, metadata records for each of the logged args follow the function record in the stream.

Metadata Records

Interspersed throughout the buffer are 16 byte Metadata records. For typically instrumented binaries, they will be sparser than Function records, and they provide a fuller picture of the binary execution state.

Metadata record layout is partially record dependent, but they share a common structure.

The same bit field rules described for function records apply to the first byte of MetadataRecords. Within this byte, little endian machines use lsb to msb ordering and big endian machines use msb to lsb ordering.

Field	Size	Description
discriminant	1 bit	Indicates whether a reader should read a Function or Metadata record. Set to 1 for Metadata records.
record_kind	7 bits	The type of Metadata record.
data	15 bytes	A data field used differently for each record type.

Here is a table of the enumerated record kinds.

Number	Type
0	NewBuffer
1	EndOfBuffer
2	NewCPUId
3	TSCWrap
4	WallTimeMarker
5	CustomEventMarker
6	CallArgument

NewBuffer Records

Each buffer begins with a NewBuffer record immediately after the header. It records the thread ID of the thread that the trace belongs to.

Its data segment is as follows.

Field	Size (bytes)	Description
thread_Id	2	Thread ID for buffer.
reserved	13	Unused.

WallClockTime Records

Following the NewBuffer record, each buffer records an absolute time as a frame of reference for the durations recorded by timestamp counter deltas.

Its data segment is as follows.

Field	Size (bytes)	Description
seconds	8	Seconds on absolute timescale. The starting point is unspecified and depends on the implementation and platform configured by the tracer.
microseconds	4	The microsecond component of the time.
reserved	3	Unused.

NewCpuId Records

Each function entry invokes a routine to determine what CPU is executing. Typically, this is done with readtscp, which reads the timestamp counter at the same time.

If the tracing detects that the execution has switched CPUs or if this is the first instrumented entry point, the tracer will output a NewCpuId record.

Its data segment is as follows.

Field	Size (bytes)	Description
cpu_id	2	CPU Id.
absolute_tsc	8	The absolute value of the timestamp counter.
reserved	5	Unused.

TSCWrap Records

Since each function record uses a 32 bit value to represent the number of ticks of the timestamp counter since the last reference, it is possible for this value to overflow, particularly for sparsely instrumented binaries.

When this delta would not fit into a 32 bit representation, a reference absolute timestamp counter record is written in the form of a TSCWrap record.

Its data segment is as follows.

Field	Size (bytes)	Description
absolute_tsc	8	Timestamp counter value.
reserved	7	Unused.

CallArgument Records

Immediately following an Entry_Args type function record, there may be one or more CallArgument records that contain the traced function's parameter values.

The order of the CallArgument Record sequency corresponds one to one with the order of the function parameters.

CallArgument data segment:

Field	Size (bytes)	Description
argument	8	Numeric argument (may be pointer address).
reserved	7	Unused.

CustomEventMarker Records

XRay provides the feature of logging custom events. This may be leveraged to record tracing info for RPCs or similarly trace data that is application specific.

Custom Events themselves are an unstructured (application defined) segment of memory with arbitrary size within the buffer. They are preceded by CustomEventMarkers to indicate their presence and size.

CustomEventMarker data segment:

Field	Size (bytes)	Description
event_size	4	Size of preceeded event.
absolute_tsc	8	A timestamp counter of the event.
reserved	3	Unused.

EndOfBuffer Records

An EndOfBuffer record type indicates that there is no more trace data in this buffer. The reader is expected to seek past the remaining buffer_size expressed before the start of buffer and look for either another header or EOF.

4.41.5 Format Grammar and Invariants

Not all sequences of Metadata records and Function records are valid data. A sequence should be parsed as a state machine. The expectations for a valid format can be expressed as a context free grammar.

This is an attempt to explain the format with statements in EBNF format.

- Format := Header ThreadBuffer* EOF
- ThreadBuffer := NewBuffer WallClockTime NewCPUId BodySequence* End
- BodySequence := NewCPUId | TSCWrap | Function | CustomEvent
- Function := (Function_Entry_Args CallArgument*) | Function_Other_Type
- CustomEvent := CustomEventMarker CustomEventUnstructuredMemory
- End := EndOfBuffer RemainingBufferSizeToSkip

Function Record Order

There are a few clarifications that may help understand what is expected of Function records.

- Functions with an Exit are expected to have a corresponding Entry or Entry_Args function record precede them in the trace.
- Tail_Exit Function records record the Function ID of the function whose return address the program counter will take. In other words, the final function that would be popped off of the call stack if tail call optimization was not used.
- Not all functions marked for instrumentation are necessarily in the trace. The tracer uses heuristics to preserve the trace for non-trivial functions.
- Not every entry must have a traced Exit or Tail Exit. The buffer may run out of space or the program may request for the tracer to finalize to return the buffer before an instrumented function exits.

4.42 The PDB File Format

- *Introduction*
- *File Layout*
 - *The MSF Container*
 - *Streams*
- *CodeView*

4.42.1 Introduction

PDB (Program Database) is a file format invented by Microsoft and which contains debug information that can be consumed by debuggers and other tools. Since officially supported APIs exist on Windows for querying debug information from PDBs even without the user understanding the internals of the file format, a large ecosystem of tools has been built for Windows to consume this format. In order for Clang to be able to generate programs that can interoperate with these tools, it is necessary for us to generate PDB files ourselves.

At the same time, LLVM has a long history of being able to cross-compile from any platform to any platform, and we wish for the same to be true here. So it is necessary for us to understand the PDB file format at the byte-level so that we can generate PDB files entirely on our own.

This manual describes what we know about the PDB file format today. The layout of the file, the various streams contained within, the format of individual records within, and more.

We would like to extend our heartfelt gratitude to Microsoft, without whom we would not be where we are today. Much of the knowledge contained within this manual was learned through reading code published by Microsoft on their [GitHub repo](#).

4.42.2 File Layout

Important: Unless otherwise specified, all numeric values are encoded in little endian. If you see a type such as `uint16_t` or `uint64_t` going forward, always assume it is little endian!

The MSF File Format

- *File Layout*
- *The Superblock*
- *The Free Block Map*
- *The Stream Directory*
- *Alignment and Block Boundaries*

File Layout

The MSF file format consists of the following components:

1. *The Superblock*
2. *The Free Block Map* (also known as Free Page Map, or FPM)
3. Data

Each component is stored as an indexed block, the length of which is specified in `SuperBlock::BlockSize`. The file consists of 1 or more iterations of the following pattern (sometimes referred to as an "interval"):

1. 1 block of data
2. Free Block Map 1 (corresponds to `SuperBlock::FreeBlockMapBlock 1`)
3. Free Block Map 2 (corresponds to `SuperBlock::FreeBlockMapBlock 2`)
4. `SuperBlock::BlockSize - 3` blocks of data

In the first interval, the first data block is used to store *The Superblock*.

The following diagram demonstrates the general layout of the file (I denotes the end of an interval, and is for visualization purposes only):

Block Index	0	1	2	3 - 4095		4096	4097	4098	4099 - 8191	-		...
Meaning	<i>The Superblock</i>	Free Block Map 1	Free Block Map 2	Data		Data	FPM1	FPM2	Data			...

The file may end after any block, including immediately after a FPM1.

Note: LLVM only supports 4096 byte blocks (sometimes referred to as the "BigMsf" variant), so the rest of this document will assume a block size of 4096.

The Superblock

At file offset 0 in an MSF file is the MSF *SuperBlock*, which is laid out as follows:

```
struct SuperBlock {
    char FileMagic[sizeof(Magic)];
    ulittle32_t BlockSize;
    ulittle32_t FreeBlockMapBlock;
    ulittle32_t NumBlocks;
    ulittle32_t NumDirectoryBytes;
    ulittle32_t Unknown;
    ulittle32_t BlockMapAddr;
};
```

- **FileMagic** - Must be equal to "Microsoft C / C++ MSF 7.00\\r\\n" followed by the bytes 1A 44 53 00 00 00.
- **BlockSize** - The block size of the internal file system. Valid values are 512, 1024, 2048, and 4096 bytes. Certain aspects of the MSF file layout vary depending on the block sizes. For the purposes of LLVM, we handle only block sizes of 4KiB, and all further discussion assumes a block size of 4KiB.
- **FreeBlockMapBlock** - The index of a block within the file, at which begins a bitfield representing the set of all blocks within the file which are "free" (i.e. the data within that block is not used). See [The Free Block Map](#) for more information. **Important:** FreeBlockMapBlock can only be 1 or 2!
- **NumBlocks** - The total number of blocks in the file. NumBlocks * BlockSize should equal the size of the file on disk.
- **NumDirectoryBytes** - The size of the stream directory, in bytes. The stream directory contains information about each stream's size and the set of blocks that it occupies. It will be described in more detail later.
- **BlockMapAddr** - The index of a block within the MSF file. At this block is an array of ulittle32_t's listing the blocks that the stream directory resides on. For large MSF files, the stream directory (which describes the block layout of each stream) may not fit entirely on a single block. As a result, this extra layer of indirection is introduced, whereby this block contains the list of blocks that the stream directory occupies, and the stream directory itself can be stitched together accordingly. The number of ulittle32_t's in this array is given by `ceil(NumDirectoryBytes / BlockSize)`.

The Free Block Map

The Free Block Map (sometimes referred to as the Free Page Map, or FPM) is a series of blocks which contains a bit flag for every block in the file. The flag will be set to 0 if the block is in use, and 1 if the block is unused.

Each file contains two FPMs, one of which is active at any given time. This feature is designed to support incremental and atomic updates of the underlying MSF file. While writing to an MSF file, if the active FPM is FPM1, you can write your new modified bitfield to FPM2, and vice versa. Only when you commit the file to disk do you need to swap the value in the SuperBlock to point to the new FreeBlockMapBlock.

The Free Block Maps are stored as a series of single blocks throughout the file at intervals of BlockSize. Because each FPM block is of size BlockSize bytes, it contains 8 times as many bits as an interval has blocks. This means that the first block of each FPM refers to the first 8 intervals of the file (the first 32768 blocks), the second block of each FPM refers to the next 8 blocks, and so on. This results in far more FPM blocks being present than are required, but in order to maintain backwards compatibility the format must stay this way.

The Stream Directory

The Stream Directory is the root of all access to the other streams in an MSF file. Beginning at byte 0 of the stream directory is the following structure:

```
struct StreamDirectory {
    ulittle32_t NumStreams;
    ulittle32_t StreamSizes[NumStreams];
    ulittle32_t StreamBlocks[NumStreams][];
};
```

And this structure occupies exactly `SuperBlock->NumDirectoryBytes` bytes. Note that each of the last two arrays is of variable length, and in particular that the second array is jagged.

Example: Suppose a hypothetical PDB file with a 4KiB block size, and 4 streams of lengths {1000 bytes, 8000 bytes, 16000 bytes, 9000 bytes}.

Stream 0: $\text{ceil}(1000 / 4096) = 1$ block

Stream 1: $\text{ceil}(8000 / 4096) = 2$ blocks

Stream 2: $\text{ceil}(16000 / 4096) = 4$ blocks

Stream 3: $\text{ceil}(9000 / 4096) = 3$ blocks

In total, 10 blocks are used. Let's see what the stream directory might look like:

```
struct StreamDirectory {
    ulittle32_t NumStreams = 4;
    ulittle32_t StreamSizes[] = {1000, 8000, 16000, 9000};
    ulittle32_t StreamBlocks[][] = {
        {4},
        {5, 6},
        {11, 9, 7, 8},
        {10, 15, 12}
    };
};
```

In total, this occupies $15 * 4 = 60$ bytes, so `SuperBlock->NumDirectoryBytes` would equal 60, and `SuperBlock->BlockMapAddr` would be an array of one `ulittle32_t`, since $60 \leq \text{SuperBlock->BlockSize}$.

Note also that the streams are discontinuous, and that part of stream 3 is in the middle of part of stream 2. You cannot assume anything about the layout of the blocks!

Alignment and Block Boundaries

As may be clear by now, it is possible for a single field (whether it be a high level record, a long string field, or even a single `uint16`) to begin and end in separate blocks. For example, if the block size is 4096 bytes, and a `uint16` field begins at the last byte of the current block, then it would need to end on the first byte of the next block. Since blocks are not necessarily contiguously laid out in the file, this means that both the consumer and the producer of an MSF file must be prepared to split data apart accordingly. In the aforementioned example, the high byte of the `uint16` would be written to the last byte of block N, and the low byte would be written to the first byte of block N+1, which could be tens of thousands of bytes later (or even earlier!) in the file, depending on what the stream directory says.

The PDB Info Stream (aka the PDB Stream)

- *Stream Header*
- *Named Stream Map*
- *PDB Feature Codes*
- *Matching a PDB to its executable*

Stream Header

At offset 0 of the PDB Stream is a header with the following layout:

```
struct PdbStreamHeader {
    ulittle32_t Version;
    ulittle32_t Signature;
    ulittle32_t Age;
    Guid UniqueId;
};
```

- **Version** - A Value from the following enum:

```
enum class PdbStreamVersion : uint32_t {
    VC2 = 19941610,
    VC4 = 19950623,
    VC41 = 19950814,
    VC50 = 19960307,
    VC98 = 19970604,
    VC70Dep = 19990604,
    VC70 = 20000404,
    VC80 = 20030901,
    VC110 = 20091201,
    VC140 = 20140508,
};
```

While the meaning of this field appears to be obvious, in practice we have never observed a value other than `VC70`, even with modern versions of the toolchain, and it is unclear why the other values exist. It is assumed that certain aspects of the PDB stream's layout, and perhaps even that of the other streams, will change if the value is something other than `VC70`.

- **Signature** - A 32-bit time-stamp generated with a call to `time()` at the time the PDB file is written. Note that due to the inherent uniqueness problems of using a timestamp with 1-second granularity, this field does not really serve its intended purpose, and as such is typically ignored in favor of the `Guid` field, described below.
- **Age** - The number of times the PDB file has been written. This can be used along with `Guid` to match the PDB to its corresponding executable.
- **Guid** - A 128-bit identifier guaranteed to be unique across space and time. In general, this can be thought of as the result of calling the Win32 API `UuidCreate`, although LLVM cannot rely on that, as it must work on non-Windows platforms.

Named Stream Map

Following the header is a serialized hash table whose key type is a string, and whose value type is an integer. The existence of a mapping $X \rightarrow Y$ means that the stream with the name X has stream index Y in the underlying MSF file. Note that not all streams are named (for example, the *TPI Stream* has a fixed index and as such there is no need to look up its index by name). In practice, there are usually only a small number of named streams and these are enumerated in the table of streams in *The PDB File Format*. A corollary of this is if a stream does have a name (and as such is in the named stream map) then consulting the Named Stream Map is likely to be the only way to discover the stream's MSF stream index. Several important streams (such as the global string table, which is called `/names`) can only be located this way, and so it is important to both produce and consume this correctly as tools will not function correctly without it.

Important: Some streams are located by fixed indices (e.g. TPI Stream has index 2), but other streams are located by fixed names (e.g. the string table is called `/names`) and can only be located by consulting the Named Stream Map.

The on-disk layout of the Named Stream Map consists of 2 components. The first is a buffer of string data prefixed by a 32-bit length. The second is a serialized hash table whose key and value types are both `uint32_t`. The key is the offset of a null-terminated string in the string data buffer specifying the name of the stream, and the value is the MSF stream index of the stream with said name. Note that although the key is an integer, the hash function used to find the right bucket hashes the string at the corresponding offset in the string data buffer.

The on-disk layout of the serialized hash table is described at *The PDB Serialized Hash Table Format*.

Note that the entire Named Stream Map is not length-prefixed, so the only way to get to the data following it is to de-serialize it in its entirety.

PDB Feature Codes

Following the Named Stream Map, and consuming all remaining bytes of the PDB Stream is a list of values from the following enumeration:

```
enum class PdbRaw_FeatureSig : uint32_t {
    VC110 = 20091201,
    VC140 = 20140508,
    NoTypeMerge = 0x4D544F4E,
    MinimalDebugInfo = 0x494E494D,
};
```

The meaning of these values is summarized by the following table:

Flag	Meaning
VC110	<ul style="list-style-type: none"> • No other features flags are present • PDB contains an <i>IPI Stream</i>
VC140	<ul style="list-style-type: none"> • Other feature flags may be present • PDB contains an <i>IPI Stream</i>
NoTypeMerge	<ul style="list-style-type: none"> • Presumably duplicate types can appear in the TPI Stream, although it's unclear why this might happen.
MinimalDebugInfo	<ul style="list-style-type: none"> • Program was linked with /DEBUG:FASTLINK • There is no TPI / IPI stream, all type info is contained in the original object files.

Matching a PDB to its executable

The linker is responsible for writing both the PDB and the final executable, and as a result is the only entity capable of writing the information necessary to match the PDB to the executable.

In order to accomplish this, the linker generates a guid for the PDB (or re-uses the existing guid if it is linking incrementally) and increments the Age field.

The executable is a PE/COFF file, and part of a PE/COFF file is the presence of number of "directories". For our purposes here, we are interested in the "debug directory". The exact format of a debug directory is described by the `IMAGE_DEBUG_DIRECTORY` structure. For this particular case, the linker emits a debug directory of type `IMAGE_DEBUG_TYPE_CODEVIEW`. The format of this record is defined in `llvm/DebugInfo/CodeView/CVDebugRecord.h`, but it suffices to say here only that it includes the same Guid and Age fields. At runtime, a debugger or tool can scan the COFF executable image for the presence of a debug directory of the correct type and verify that the Guid and Age match.

The PDB TPI and IPI Streams

- *Introduction*
- *TPI vs IPI Stream*
- *Type Indices*
- *Stream Header*
- *CodeView Type Record List*

Introduction

The PDB TPI Stream (Index 2) and IPI Stream (Index 4) contain information about all types used in the program. It is organized as a *header* followed by a list of *CodeView Type Records*. Types are referenced from various streams and records throughout the PDB by their *type index*. In general, the sequence of type records following the *header* forms a topologically sorted DAG (directed acyclic graph), which means that a type record B can only refer to the type A if $A.TypeIndex < B.TypeIndex$. While there are rare cases where this property will not hold (particularly when dealing with object files compiled with MASM), an implementation should try very hard to make this property hold, as it means the entire type graph can be constructed in a single pass.

Important: Type records form a topologically sorted DAG (directed acyclic graph).

TPI vs IPI Stream

Recent versions of the PDB format (aka all versions covered by this document) have 2 streams with identical layout, henceforth referred to as the TPI stream and IPI stream. Subsequent contents of this document describing the on-disk format apply equally whether it is for the TPI Stream or the IPI Stream. The only difference between the two is in *which* CodeView records are allowed to appear in each one, summarized by the following table:

TPI Stream	IPI Stream
LF_POINTER	LF_FUNC_ID
LF_MODIFIER	LF_MFUNC_ID
LF_PROCEDURE	LF_BUILDINFO
LF_MFUNCTION	LF_SUBSTR_LIST
LF_LABEL	LF_STRING_ID
LF_ARGLIST	LF_UDT_SRC_LINE
LF_FIELDLIST	LF_UDT_MOD_SRC_LINE
LF_ARRAY	
LF_CLASS	
LF_STRUCTURE	
LF_INTERFACE	
LF_UNION	
LF_ENUM	
LF_TYPESERVER2	
LF_VFTABLE	
LF_VTSHAPE	
LF_BITFIELD	
LF_METHODLIST	
LF_PRECOMP	
LF_ENDPRECOMP	

The usage of these records is described in more detail in *CodeView Type Records*.

Type Indices

A type index is a 32-bit integer that uniquely identifies a type inside of an object file's `.debug$T` section or a PDB file's TPI or IPI stream. The value of the type index for the first type record from the TPI stream is given by the `TypeIndexBegin` member of the *TPI Stream Header* although in practice this value is always equal to 0x1000 (4096).

Any type index with a high bit set is considered to come from the IPI stream, although this appears to be more of a hack, and LLVM does not generate type indices of this nature. They can, however, be observed in Microsoft PDBs occasionally, so one should be prepared to handle them. Note that having the high bit set is not a necessary condition to determine whether a type index comes from the IPI stream, it is only sufficient.

Once the high bit is cleared, any type index \geq `TypeIndexBegin` is presumed to come from the appropriate stream, and any type index less than this is a bitmask which can be decomposed as follows:

- **Kind** - A value from the following enum:

```
enum class SimpleTypeKind : uint32_t {
    None = 0x0000,           // uncharacterized type (no type)
    Void = 0x0003,           // void
    NotTranslated = 0x0007,  // type not translated by cvpack
    HRESULT = 0x0008,        // OLE/COM HRESULT

    SignedCharacter = 0x0010, // 8 bit signed
    UnsignedCharacter = 0x0020, // 8 bit unsigned
    NarrowCharacter = 0x0070,  // really a char
    WideCharacter = 0x0071,   // wide char
    Character16 = 0x007a,     // char16_t
    Character32 = 0x007b,     // char32_t

    SByte = 0x0068,          // 8 bit signed int
    Byte = 0x0069,           // 8 bit unsigned int
    Int16Short = 0x0011,     // 16 bit signed
    UInt16Short = 0x0021,    // 16 bit unsigned
    Int16 = 0x0072,          // 16 bit signed int
    UInt16 = 0x0073,         // 16 bit unsigned int
    Int32Long = 0x0012,      // 32 bit signed
    UInt32Long = 0x0022,     // 32 bit unsigned
    Int32 = 0x0074,          // 32 bit signed int
    UInt32 = 0x0075,         // 32 bit unsigned int
    Int64Quad = 0x0013,      // 64 bit signed
    UInt64Quad = 0x0023,     // 64 bit unsigned
    Int64 = 0x0076,          // 64 bit signed int
    UInt64 = 0x0077,         // 64 bit unsigned int
    Int128Oct = 0x0014,      // 128 bit signed int
    UInt128Oct = 0x0024,     // 128 bit unsigned int
    Int128 = 0x0078,         // 128 bit signed int
    UInt128 = 0x0079,        // 128 bit unsigned int

    Float16 = 0x0046,         // 16 bit real
    Float32 = 0x0040,         // 32 bit real
    Float32PartialPrecision = 0x0045, // 32 bit PP real
    Float48 = 0x0044,         // 48 bit real
}
```

(continues on next page)

(continued from previous page)

```

Float64 = 0x0041,           // 64 bit real
Float80 = 0x0042,           // 80 bit real
Float128 = 0x0043,          // 128 bit real

Complex16 = 0x0056,         // 16 bit complex
Complex32 = 0x0050,         // 32 bit complex
Complex32PartialPrecision = 0x0055, // 32 bit PP complex
Complex48 = 0x0054,         // 48 bit complex
Complex64 = 0x0051,         // 64 bit complex
Complex80 = 0x0052,         // 80 bit complex
Complex128 = 0x0053,        // 128 bit complex

Boolean8 = 0x0030, // 8 bit boolean
Boolean16 = 0x0031, // 16 bit boolean
Boolean32 = 0x0032, // 32 bit boolean
Boolean64 = 0x0033, // 64 bit boolean
Boolean128 = 0x0034, // 128 bit boolean
};

```

- **Mode** - A value from the following enum:

```

enum class SimpleTypeMode : uint32_t {
    Direct = 0,           // Not a pointer
    NearPointer = 1,      // Near pointer
    FarPointer = 2,       // Far pointer
    HugePointer = 3,      // Huge pointer
    NearPointer32 = 4,     // 32 bit near pointer
    FarPointer32 = 5,      // 32 bit far pointer
    NearPointer64 = 6,     // 64 bit near pointer
    NearPointer128 = 7    // 128 bit near pointer
};

```

Note that for pointers, the bitness is represented in the mode. So a `void*` would have a type index with `Mode=NearPointer32`, `Kind=Void` if built for 32-bits but a type index with `Mode=NearPointer64`, `Kind=Void` if built for 64-bits.

By convention, the type index for `std::nullptr_t` is constructed the same way as the type index for `void*`, but using the bitless enumeration value `NearPointer`.

Stream Header

At offset 0 of the TPI Stream is a header with the following layout:

```

struct TpiStreamHeader {
    uint32_t Version;
    uint32_t HeaderSize;
    uint32_t TypeIndexBegin;
    uint32_t TypeIndexEnd;
    uint32_t TypeRecordBytes;

    uint16_t HashStreamIndex;
    uint16_t HashAuxStreamIndex;
    uint32_t HashKeySize;
    uint32_t NumHashBuckets;
};

```

(continues on next page)

(continued from previous page)

```

int32_t HashValueBufferOffset;
uint32_t HashValueBufferLength;

int32_t IndexOffsetBufferOffset;
uint32_t IndexOffsetBufferLength;

int32_t HashAdjBufferOffset;
uint32_t HashAdjBufferLength;
};

```

- **Version** - A value from the following enum.

```

enum class TpiStreamVersion : uint32_t {
    V40 = 19950410,
    V41 = 19951122,
    V50 = 19961031,
    V70 = 19990903,
    V80 = 20040203,
};

```

Similar to the *PDB Stream*, this value always appears to be V80, and no other values have been observed. It is assumed that should another value be observed, the layout described by this document may not be accurate.

- **HeaderSize** - `sizeof(TpiStreamHeader)`
- **TypeIndexBegin** - The numeric value of the type index representing the first type record in the TPI stream. This is usually the value 0x1000 as type indices lower than this are reserved (see *Type Indices* for a discussion of reserved type indices).
- **TypeIndexEnd** - One greater than the numeric value of the type index representing the last type record in the TPI stream. The total number of type records in the TPI stream can be computed as `TypeIndexEnd - TypeIndexBegin`.
- **TypeRecordBytes** - The number of bytes of type record data following the header.
- **HashStreamIndex** - The index of a stream which contains a list of hashes for every type record. This value may be -1, indicating that hash information is not present. In practice a valid stream index is always observed, so any producer implementation should be prepared to emit this stream to ensure compatibility with tools which may expect it to be present.
- **HashAuxStreamIndex** - Presumably the index of a stream which contains a separate hash table, although this has not been observed in practice and it's unclear what it might be used for.
- **HashKeySize** - The size of a hash value (usually 4 bytes).
- **NumHashBuckets** - The number of buckets used to generate the hash values in the aforementioned hash streams.
- **HashValueBufferOffset / HashValueBufferLength** - The offset and size within the TPI Hash Stream of the list of hash values. It should be assumed that there are either 0 hash values, or a number equal to the number of type records in the TPI stream (`TypeIndexEnd - TypeIndexBegin`). Thus, if `HashBufferLength` is not equal to $(\text{TypeIndexEnd} - \text{TypeIndexBegin}) * \text{HashKeySize}$ we can consider the PDB malformed.
- **IndexOffsetBufferOffset / IndexOffsetBufferLength** - The offset and size within the TPI Hash Stream of the Type Index Offsets Buffer. This is a list of pairs of `uint32_t`'s where the first value is a *Type Index* and the second value is the offset in the type record data of the type with this index. This can be used to do a binary search followed by a linear search to get $O(\log n)$ lookup by type index.
- **HashAdjBufferOffset / HashAdjBufferLength** - The offset and size within the TPI hash stream of a serialized hash table whose keys are the hash values in the hash value buffer and whose values are type indices. This

appears to be useful in incremental linking scenarios, so that if a type is modified an entry can be created mapping the old hash value to the new type index so that a PDB file consumer can always have the most up to date version of the type without forcing the incremental linker to garbage collect and update references that point to the old version to now point to the new version. The layout of this hash table is described in *The PDB Serialized Hash Table Format*.

CodeView Type Record List

Following the header, there are `TypeRecordBytes` bytes of data that represent a variable length array of *CodeView type records*. The number of such records (e.g. the length of the array) can be determined by computing the value `Header.TypeIndexEnd - Header.TypeIndexBegin`.

$O(\log(n))$ access is provided by way of the Type Index Offsets array (if present) described previously.

The PDB DBI (Debug Info) Stream

- *Introduction*
- *Stream Header*
- *Substreams*
 - *Module Info Substream*
 - *Section Contribution Substream*
 - *Section Map Substream*
 - *File Info Substream*
 - *Type Server Map Substream*
 - *EC Substream*
 - *Optional Debug Header Stream*

Introduction

The PDB DBI Stream (Index 3) is one of the largest and most important streams in a PDB file. It contains information about how the program was compiled, (e.g. compilation flags, etc), the compilands (e.g. object files) that were used to link together the program, the source files which were used to build the program, as well as references to other streams that contain more detailed information about each compiland, such as the CodeView symbol records contained within each compiland and the source and line information for functions and other symbols within each compiland.

Stream Header

At offset 0 of the DBI Stream is a header with the following layout:

```
struct DbStreamHeader {
    int32_t VersionSignature;
    uint32_t VersionHeader;
    uint32_t Age;
    uint16_t GlobalStreamIndex;
    uint16_t BuildNumber;
    uint16_t PublicStreamIndex;
    uint16_t PdbDllVersion;
    uint16_t SymRecordStream;
    uint16_t PdbDllRbld;
    int32_t ModInfoSize;
    int32_t SectionContributionSize;
    int32_t SectionMapSize;
    int32_t SourceInfoSize;
    int32_t TypeServerMapSize;
    uint32_t MFCTypeServerIndex;
    int32_t OptionalDbgHeaderSize;
    int32_t ECSubstreamSize;
    uint16_t Flags;
    uint16_t Machine;
    uint32_t Padding;
};
```

- **VersionSignature** - Unknown meaning. Appears to always be -1.
- **VersionHeader** - A value from the following enum.

```
enum class DbStreamVersion : uint32_t {
    VC41 = 930803,
    V50 = 19960307,
    V60 = 19970606,
    V70 = 19990903,
    V110 = 20091201
};
```

Similar to the *PDB Stream*, this value always appears to be V70, and it is not clear what the other values are for.

- **Age** - The number of times the PDB has been written. Equal to the same field from the *PDB Stream header*.
- **GlobalStreamIndex** - The index of the *Global Symbol Stream*, which contains CodeView symbol records for all global symbols. Actual records are stored in the symbol record stream, and are referenced from this stream.
- **BuildNumber** - A bitfield containing values representing the major and minor version number of the toolchain (e.g. 12.0 for MSVC 2013) used to build the program, with the following layout:

```
uint16_t MinorVersion : 8;  
uint16_t MajorVersion : 7;  
uint16_t NewVersionFormat : 1;
```

For the purposes of LLVM, we assume `NewVersionFormat` to be always true. If it is false, the layout above does not apply and the reader should consult the [Microsoft Source Code](#) for further guidance.

- **PublicStreamIndex** - The index of the *Public Symbol Stream*, which contains CodeView symbol records for all public symbols. Actual records are stored in the symbol record stream, and are referenced from this stream.
- **PdbDllVersion** - The version number of `mspdbXXXX.dll` used to produce this PDB. Note this obviously does not apply for LLVM as LLVM does not use `mspdb.dll`.
- **SymRecordStream** - The stream containing all CodeView symbol records used by the program. This is used for deduplication, so that many different compilands can refer to the same symbols without having to include the full record content inside of each module stream.
- **PdbDllRbld** - Unknown
- **MFCTypeServerIndex** - The index of the MFC type server in the *Type Server Map Substream*.
- **Flags** - A bitfield with the following layout, containing various information about how the program was built:

```
uint16_t WasIncrementallyLinked : 1;  
uint16_t ArePrivateSymbolsStripped : 1;  
uint16_t HasConflictingTypes : 1;  
uint16_t Reserved : 13;
```

The only one of these that is not self-explanatory is `HasConflictingTypes`. Although undocumented, `link.exe` contains a hidden flag `/DEBUG:CTYPES`. If it is passed to `link.exe`, this field will be set. Otherwise it will not be set. It is unclear what this flag does, although it seems to have subtle implications on the algorithm used to look up type records.

- **Machine** - A value from the `CV_CPU_TYPE_e` enumeration. Common values are `0x8664` (x86-64) and `0x14C` (x86).

Immediately after the fixed-size DBI Stream header are 7 variable-length *substreams*. The following 7 fields of the DBI Stream header specify the number of bytes of the corresponding substream. Each substream's contents will be described in detail *below*. The length of the entire DBI Stream should equal 64 (the length of the header above) plus the value of each of the following 7 fields.

- **ModInfoSize** - The length of the *Module Info Substream*.
- **SectionContributionSize** - The length of the *Section Contribution Substream*.
- **SectionMapSize** - The length of the *Section Map Substream*.
- **SourceInfoSize** - The length of the *File Info Substream*.
- **TypeServerMapSize** - The length of the *Type Server Map Substream*.
- **OptionalDbgHeaderSize** - The length of the *Optional Debug Header Stream*.
- **ECSubstreamSize** - The length of the *EC Substream*.

Substreams

Module Info Substream

Begins at offset 0 immediately after the *header*. The module info substream is an array of variable-length records, each one describing a single module (e.g. object file) linked into the program. Each record in the array has the format:

```
struct ModInfo {
    uint32_t Unused1;
    struct SectionContribEntry {
        uint16_t Section;
        char Padding1[2];
        int32_t Offset;
        int32_t Size;
        uint32_t Characteristics;
        uint16_t ModuleIndex;
        char Padding2[2];
        uint32_t DataCrc;
        uint32_t RelocCrc;
    } SectionContr;
    uint16_t Flags;
    uint16_t ModuleSymStream;
    uint32_t SymByteSize;
    uint32_t C11ByteSize;
    uint32_t C13ByteSize;
    uint16_t SourceFileCount;
    char Padding[2];
    uint32_t Unused2;
    uint32_t SourceFileNameIndex;
    uint32_t PdbFilePathNameIndex;
    char ModuleName[];
    char ObjFileName[];
};
```

- **SectionContr** - Describes the properties of the section in the final binary which contain the code and data from this module.

SectionContr.Characteristics corresponds to the Characteristics field of the `IMAGE_SECTION_HEADER` structure.

- **Flags** - A bitfield with the following format:

```
// ``true`` if this ModInfo has been written since reading the PDB. This is
// likely used to support incremental linking, so that the linker can decide
// if it needs to commit changes to disk.
uint16_t Dirty : 1;
// ``true`` if EC information is present for this module. EC is presumed to
// stand for "Edit & Continue", which LLVM does not support. So this flag
// will always be false.
uint16_t EC : 1;
uint16_t Unused : 6;
// Type Server Index for this module. This is assumed to be related to /Zi,
// but as LLVM treats /Zi as /Z7, this field will always be invalid for LLVM
// generated PDBs.
uint16_t TSM : 8;
```

- **ModuleSymStream** - The index of the stream that contains symbol information for this module. This includes CodeView symbol information as well as source and line information. If this field is -1, then no additional debug

info will be present for this module (for example, this is what happens when you strip private symbols from a PDB).

- **SymByteSize** - The number of bytes of data from the stream identified by `ModuleSymStream` that represent CodeView symbol records.
- **C11ByteSize** - The number of bytes of data from the stream identified by `ModuleSymStream` that represent C11-style CodeView line information.
- **C13ByteSize** - The number of bytes of data from the stream identified by `ModuleSymStream` that represent C13-style CodeView line information. At most one of `C11ByteSize` and `C13ByteSize` will be non-zero. Modern PDBs always use C13 instead of C11.
- **SourceFileCount** - The number of source files that contributed to this module during compilation.
- **SourceFileNameIndex** - The offset in the names buffer of the primary translation unit used to build this module. All PDB files observed to date always have this value equal to 0.
- **PdbFilePathNameIndex** - The offset in the names buffer of the PDB file containing this module's symbol information. This has only been observed to be non-zero for the special * `Linker` * module.
- **ModuleName** - The module name. This is usually either a full path to an object file (either directly passed to `link.exe` or from an archive) or a string of the form `Import:<dll name>`.
- **ObjFileName** - The object file name. In the case of an module that is linked directly passed to `link.exe`, this is the same as **ModuleName**. In the case of a module that comes from an archive, this is usually the full path to the archive.

Section Contribution Substream

Begins at offset 0 immediately after the *Module Info Substream* ends, and consumes `Header->SectionContributionSize` bytes. This substream begins with a single `uint32_t` which will be one of the following values:

```
enum class SectionContrSubstreamVersion : uint32_t {  
    Ver60 = 0xeffe0000 + 19970605,  
    V2 = 0xeffe0000 + 20140516  
};
```

`Ver60` is the only value which has been observed in a PDB so far. Following this is an array of fixed-length structures. If the version is `Ver60`, it is an array of `SectionContribEntry` structures (this is the nested structure from the `ModInfo` type. If the version is `V2`, it is an array of `SectionContribEntry2` structures, defined as follows:

```
struct SectionContribEntry2 {  
    SectionContribEntry SC;  
    uint32_t ISectCoff;  
};
```

The purpose of the second field is not well understood. The name implies that is the index of the COFF section, but this also describes the existing field `SectionContribEntry::Section`.

Section Map Substream

Begins at offset 0 immediately after the *Section Contribution Substream* ends, and consumes `Header->SectionMapSize` bytes. This substream begins with an 4 byte header followed by an array of fixed-length records. The header and records have the following layout:

```
struct SectionMapHeader {
    uint16_t Count;      // Number of segment descriptors
    uint16_t LogCount;   // Number of logical segment descriptors
};

struct SectionMapEntry {
    uint16_t Flags;      // See the SectionMapEntryFlags enum below.
    uint16_t Ovl;        // Logical overlay number
    uint16_t Group;      // Group index into descriptor array.
    uint16_t Frame;      //
    uint16_t SectionName; // Byte index of segment / group name in string table, or
    ↪ 0xFFFF.
    uint16_t ClassName;  // Byte index of class in string table, or 0xFFFF.
    uint32_t Offset;      // Byte offset of the logical segment within physical
    ↪ segment. If group is set in flags, this is the offset of the group.
    uint32_t SectionLength; // Byte count of the segment or group.
};

enum class SectionMapEntryFlags : uint16_t {
    Read = 1 << 0,      // Segment is readable.
    Write = 1 << 1,     // Segment is writable.
    Execute = 1 << 2,   // Segment is executable.
    AddressIs32Bit = 1 << 3, // Descriptor describes a 32-bit linear address.
    IsSelector = 1 << 8,  // Frame represents a selector.
    IsAbsoluteAddress = 1 << 9, // Frame represents an absolute address.
    IsGroup = 1 << 10    // If set, descriptor represents a group.
};
```

Many of these fields are not well understood, so will not be discussed further.

File Info Substream

Begins at offset 0 immediately after the *Section Map Substream* ends, and consumes `Header->SourceInfoSize` bytes. This substream defines the mapping from module to the source files that contribute to that module. Since multiple modules can use the same source file (for example, a header file), this substream uses a string table to store each unique file name only once, and then have each module use offsets into the string table rather than embedding the string's value directly. The format of this substream is as follows:

```
struct FileInfoSubstream {
    uint16_t NumModules;
    uint16_t NumSourceFiles;

    uint16_t ModIndices[NumModules];
    uint16_t ModFileCounts[NumModules];
    uint32_t FileNameOffsets[NumSourceFiles];
    char NamesBuffer[][NumSourceFiles];
};
```

NumModules - The number of modules for which source file information is contained within this substream. Should match the corresponding value from the `ref:dbi_header`.

NumSourceFiles: In theory this is supposed to contain the number of source files for which this substream contains information. But that would present a problem in that the width of this field being 16-bits would prevent one from having more than 64K source files in a program. In early versions of the file format, this seems to have been the case. In order to support more than this, this field of the is simply ignored, and computed dynamically by summing up the values of the `ModFileCounts` array (discussed below). In short, this value should be ignored.

ModIndices - This array is present, but does not appear to be useful.

ModFileCountArray - An array of `NumModules` integers, each one containing the number of source files which contribute to the module at the specified index. While each individual module is limited to 64K contributing source files, the union of all modules' source files may be greater than 64K. The real number of source files is thus computed by summing this array. Note that summing this array does not give the number of *unique* source files, only the total number of source file contributions to modules.

FileNameOffsets - An array of `NumSourceFiles` integers (where `NumSourceFiles` here refers to the 32-bit value obtained from summing `ModFileCountArray`), where each integer is an offset into `NamesBuffer` pointing to a null terminated string.

NamesBuffer - An array of null terminated strings containing the actual source file names.

Type Server Map Substream

Begins at offset 0 immediately after the *File Info Substream* ends, and consumes `Header->TypeServerMapSize` bytes. Neither the purpose nor the layout of this substream is understood, although it is assumed to related somehow to the usage of `/Zi` and `mspdbsrv.exe`. This substream will not be discussed further.

EC Substream

Begins at offset 0 immediately after the *Type Server Map Substream* ends, and consumes `Header->ECSubstreamSize` bytes. This is presumed to be related to Edit & Continue support in MSVC. LLVM does not support Edit & Continue, so this stream will not be discussed further.

Optional Debug Header Stream

Begins at offset 0 immediately after the *EC Substream* ends, and consumes `Header->OptionalDbgHeaderSize` bytes. This field is an array of stream indices (e.g. `uint16_t`'s), each of which identifies a stream index in the larger MSF file which contains some additional debug information. Each position of this array has a special meaning, allowing one to determine what kind of debug information is at the referenced stream. 11 indices are currently understood, although it's possible there may be more. The layout of each stream generally corresponds exactly to a particular type of debug data directory from the PE/COFF file. The format of these fields can be found in the [Microsoft PE/COFF Specification](#). If any of these fields is -1, it means the corresponding type of debug info is not present in the PDB.

FPO Data - `DbgStreamArray[0]`. The data in the referenced stream is an array of `FPO_DATA` structures. This contains the relocated contents of any `.debug$F` section from any of the linker inputs.

Exception Data - `DbgStreamArray[1]`. The data in the referenced stream is a debug data directory of type `IMAGE_DEBUG_TYPE_EXCEPTION`.

Fixup Data - `DbgStreamArray[2]`. The data in the referenced stream is a debug data directory of type `IMAGE_DEBUG_TYPE_FIXUP`.

Omap To Src Data - `DbgStreamArray[3]`. The data in the referenced stream is a debug data directory of type `IMAGE_DEBUG_TYPE_OMAP_TO_SRC`. This is used for mapping addresses between instrumented and uninstrumented code.

Omap From Src Data - `DbgStreamArray[4]`. The data in the referenced stream is a debug data directory of type `IMAGE_DEBUG_TYPE_OMAP_FROM_SRC`. This is used for mapping addresses between instrumented and uninstrumented code.

Section Header Data - `DbgStreamArray[5]`. A dump of all section headers from the original executable.

Token / RID Map - `DbgStreamArray[6]`. The layout of this stream is not understood, but it is assumed to be a mapping from CLR Token to CLR Record ID. Refer to [ECMA 335](#) for more information.

Xdata - `DbgStreamArray[7]`. A copy of the `.xdata` section from the executable.

Pdata - `DbgStreamArray[8]`. This is assumed to be a copy of the `.pdata` section from the executable, but that would make it identical to `DbgStreamArray[1]`. The difference between these two indices is not well understood.

New FPO Data - `DbgStreamArray[9]`. The data in the referenced stream is a debug data directory of type `IMAGE_DEBUG_TYPE_FPO`. Note that this is different from `DbgStreamArray[0]` in that `.debug$F` sections are only emitted by MASM. Thus, it is possible for both to appear in the same PDB if both MASM object files and cl object files are linked into the same program.

Original Section Header Data - `DbgStreamArray[10]`. Similar to `DbgStreamArray[5]`, but contains the section headers before any binary translation has been performed. This can be used in conjunction with `DbgStreamArray[3]` and `DbgStreamArray[4]` to map instrumented and uninstrumented addresses.

The Module Information Stream

- *Introduction*
- *Stream Layout*
- *The CodeView Symbol Substream*

Introduction

The Module Info Stream (henceforth referred to as the Modi stream) contains information about a single module (object file, import library, etc that contributes to the binary this PDB contains debug information about. There is one modi stream for each module, and the mapping between modi stream index and module is contained in the *DBI Stream*. The modi stream for a single module contains line information for the compiland, as well as all CodeView information for the symbols defined in the compiland. Finally, there is a "global refs" substream which is not well understood.

Stream Layout

A modi stream is laid out as follows:

```
struct ModiStream {
    uint32_t Signature;
    uint8_t Symbols[SymbolSize-4];
    uint8_t C11LineInfo[C11Size];
    uint8_t C13LineInfo[C13Size];

    uint32_t GlobalRefsSize;
    uint8_t GlobalRefs[GlobalRefsSize];
};
```

- **Signature** - Unknown. In practice only the value of 4 has been observed. It is hypothesized that this value corresponds to the set of `CV_SIGNATURE_xx` defines in `cvinfo.h`, with the value of 4 meaning that this module has C13 line information (as opposed to C11 line information). A corollary of this is that we expect to only ever see C13 line info, and that we do not understand the format of C11 line info.
- **Symbols** - The *CodeView Symbol Substream*. `SymbolSize` is equal to the value of `SymByteSize` for the corresponding module's entry in the *Module Info Substream* of the *DBI Stream*.
- **C11LineInfo** - A block containing CodeView line information in C11 format. `C11Size` is equal to the value of `C11ByteSize` from the *Module Info Substream* of the *DBI Stream*. If this value is 0, then C11 line information is not present. As mentioned previously, the format of C11 line info is not understood and we assume all line in modern PDBs to be in C13 format.
- **C13LineInfo** - A block containing CodeView line information in C13 format. `C13Size` is equal to the value of `C13ByteSize` from the *Module Info Substream* of the *DBI Stream*. If this value is 0, then C13 line information is not present.
- **GlobalRefs** - The meaning of this substream is not understood.

The CodeView Symbol Substream

The CodeView Symbol Substream. This is an array of variable length records describing the functions, variables, inlining information, and other symbols defined in the compilant. The entire array consumes `SymbolSize-4` bytes. The format of a CodeView Symbol Record (and thusly, an array of CodeView Symbol Records) is described in *CodeView Symbol Records*.

The PDB Public Symbol Stream

The PDB Global Symbol Stream

The PDB Serialized Hash Table Format

Introduction

One of the design goals of the PDB format is to provide accelerated access to debug information, and for this reason there are several occasions where hash tables are serialized and embedded directly to the file, rather than requiring a consumer to read a list of values and reconstruct the hash table on the fly.

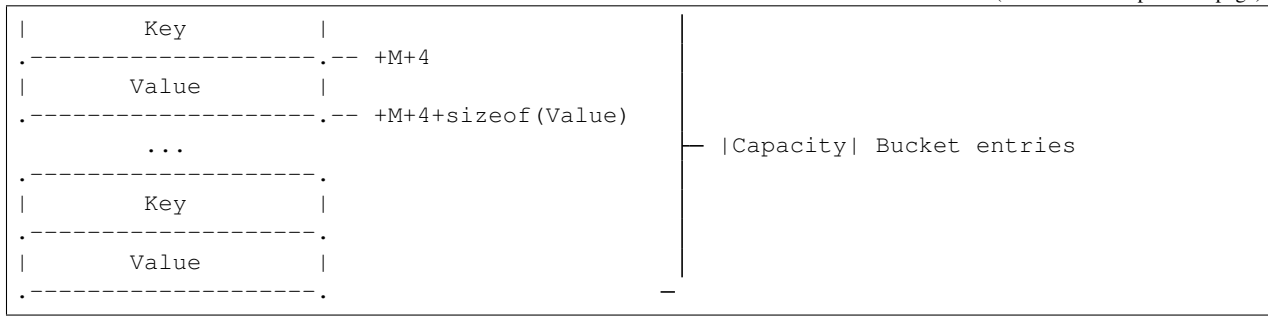

The serialization format supports hash tables of arbitrarily large size and capacity, as well as value types and hash functions. The only supported key value type is a `uint32`. The only requirement is that the producer and consumer agree on the hash function. As such, the hash function can is not discussed further in this document, it is assumed that for a particular instance of a PDB file hash table, the appropriate hash function is being used.

On-Disk Format

Size	+0
Capacity	+4
Present Bit Vector	+8
Deleted Bit Vector	+N
	+M

(continues on next page)

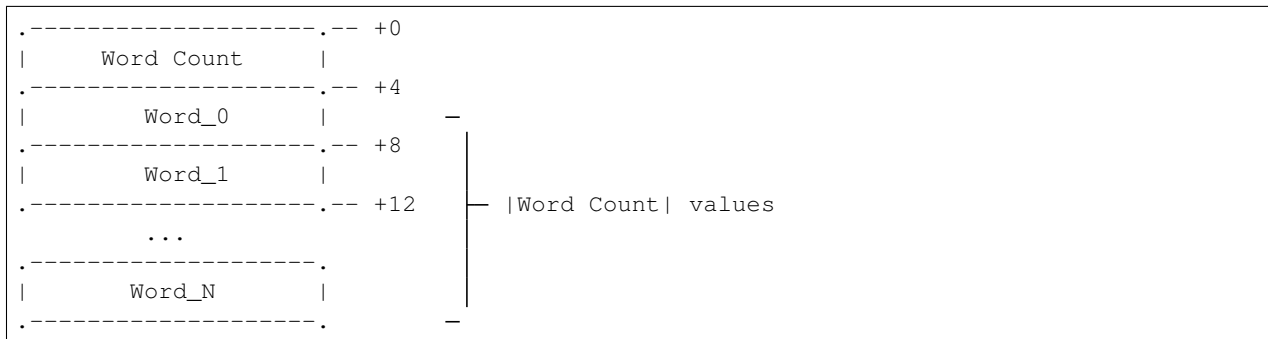

(continued from previous page)

- **Size** - The number of values contained in the hash table.
- **Capacity** - The number of buckets in the hash table. Producers should maintain a load factor of no greater than $2/3 * \text{Capacity} + 1$.
- **Present Bit Vector** - A serialized bit vector which contains information about which buckets have valid values. If the bucket has a value, the corresponding bit will be set, and if the bucket doesn't have a value (either because the bucket is empty or because the value is a tombstone value) the bit will be unset.
- **Deleted Bit Vector** - A serialized bit vector which contains information about which buckets have tombstone values. If the entry in this bucket is deleted, the bit will be set, otherwise it will be unset.
- **Keys and Values** - A list of `Capacity` hash buckets, where the first entry is the key (always a `uint32`), and the second entry is the value. The state of each bucket (valid, empty, deleted) can be determined by examining the present and deleted bit vectors.

Present and Deleted Bit Vectors

The bit vectors indicating the status of each bucket are serialized as follows:

The words, when viewed as a contiguous block of bytes, represent a bit vector with the following layout:

where the k 'th bit of this bit vector represents the status of the k 'th bucket in the hash table.

Introduction

This document describes the usage and serialization format of the various CodeView symbol records that LLVM understands. Like *CodeView Type Records*, we describe only the important types which are generated by modern C++ toolchains.

Record Categories

Symbol records share one major similarity with *type records*: They start with the same *record prefix*, which we will not describe again (refer to the previous link for a description). As a result of this, a sequence of symbol records can be processed with largely the same code as that which processes type records. There are several important differences between symbol and type records:

- Symbol records only appear in the *The PDB Public Symbol Stream*, *The PDB Global Symbol Stream*, and *Module Info Streams*.
- Type records only appear in the *TPI & IPI streams*.
- While types are referenced from other CodeView records via *type indices*, symbol records are referenced by the byte offset of the record in the stream that it appears in.
- Types can reference types (via type indices), and symbols can reference both types (via type indices) and symbols (via offsets), but types can never reference symbols.
- There is no notion of *Leaf Records* and *Member Records* as there are with types. Every symbol record describes its own length.
- Certain special symbol records begin a "scope". For these records, all following records up until the next S_END record are "children" of this symbol record. For example, given a symbol record which describes a certain function, all local variables of this function would appear following the function up until the corresponding S_END record.

Finally, there are three general categories of symbol record, grouped by where they are legal to appear in a PDB file. Public Symbols (which appear only in the *publics stream*), Global Symbols (which appear only in the *globals stream*) and module symbols (which appear in the *module info stream*).

Public Symbols

Public symbols are the CodeView equivalent of DWARF `.debug_pubnames`. There is one public symbol record for every function or variable in the program that has a mangled name. The *Publics Stream*, which contains these records, additionally contains a hash table that allows one to quickly locate a record by mangled name.

S_PUB32 (0x110e)

There is only type of public symbol, an S_PUB32 which describes a mangled name, a flag indicating what kind of symbol it is (e.g. function, variable), and the symbol's address. The *Section Map Substream* of the *DBI Stream* can be consulted to determine what module this address corresponds to, and from there that module's *module debug stream* can be consulted to locate full information for the symbol with the given address.

Global Symbols

While there is one *public symbol* for every symbol in the program with *external* linkage, there is one global symbol for every symbol in the program with linkage (including internal linkage). As a result, global symbols do not describe a mangled name *or* an address, since symbols with internal linkage need not have any mangling at all, and also may not have an address. Thus, all global symbols simply refer directly to the full symbol record via a module/offset combination.

Similarly to *public symbols*, all global symbols are contained in a single *Globals Stream*, which contains a hash table mapping fully qualified name to the corresponding record in the globals stream (which as mentioned, then contains information allowing one to locate the full record in the corresponding module symbol stream).

Note that a consequence and limitation of this design is that program-wide lookup by anything other than an exact textually matching fully-qualified name of whatever the compiler decided to emit is impractical. This differs from DWARF, where even though we don't necessarily have O(1) lookup by basename within a given scope (including O(1) scope, we at least have O(n) access within a given scope).

Important: Program-wide lookup of names by anything other than an exact textually matching fully qualified name is not possible.

Introduction

This document describes the usage and serialization format of the various CodeView type records that LLVM understands. This document does not describe every single CodeView type record that is defined. In some cases, this is because the records are clearly deprecated and can only appear in very old software (e.g. the 16-bit types). On other cases, it is because the records have never been observed in practice. This could be because they are only generated for non-C++ code (e.g. Visual Basic, C#), or because they have been made obsolete by newer records, or any number of other reasons. However, the records we describe here should cover 99% of type records that one can expect to encounter when dealing with modern C++ toolchains.

Record Categories

We can think of a sequence of CodeView type records as an array of variable length *leaf records*. Each such record describes its own length as part of a fixed-size header, as well as the kind of record it is. Leaf records are either padded to 4 bytes (if this type stream appears in a TPI/IPI stream of a PDB) or not padded at all (if this type stream appears in the `.debug$T` section of an object file). Padding is implemented by inserting a decreasing sequence of `<_padding_records>` that terminates with `LF_PAD0`.

The final category of record is a `member record`. One particular leaf type -- `LF_FIELDLIST` -- contains a series of embedded records. While the outer `LF_FIELDLIST` describes its length (like any other leaf record), the embedded records -- called `member records` do not.

Leaf Records

All leaf records begin with the following 4 byte prefix:

```
struct RecordHeader {
    uint16_t RecordLen; // Record length, not including this 2 byte field.
    uint16_t RecordKind; // Record kind enum.
};
```

LF_POINTER (0x1002)

Usage: Describes a pointer to another type.

Layout:

```

.-----+0
| Referent Type |
.-----+4
| Attributes |
.-----+8
| Member Ptr Info | Only present if |Attributes| indicates this is a member
↳pointer.
.-----+E

```

Attributes is a bitfield with the following layout:

```

.-----+
↳| Unused | Flags | Size | Modifiers | Mode |
↳| Kind |
.-----+
| | | | |
↳| | | | |
0x100 | | | | |
↳+0x5 +0x0 +0x16 +0x13 +0xD +0x8

```

where the various fields are defined by the following enums:

```

enum class PointerKind : uint8_t {
    Near16 = 0x00, // 16 bit pointer
    Far16 = 0x01, // 16:16 far pointer
    Huge16 = 0x02, // 16:16 huge pointer
    BasedOnSegment = 0x03, // based on segment
    BasedOnValue = 0x04, // based on value of base
    BasedOnSegmentValue = 0x05, // based on segment value of base
    BasedOnAddress = 0x06, // based on address of base
    BasedOnSegmentAddress = 0x07, // based on segment address of base
    BasedOnType = 0x08, // based on type
    BasedOnSelf = 0x09, // based on self
    Near32 = 0x0a, // 32 bit pointer
    Far32 = 0x0b, // 16:32 pointer
    Near64 = 0x0c, // 64 bit pointer
};
enum class PointerMode : uint8_t {
    Pointer = 0x00, // "normal" pointer
    LValueReference = 0x01, // "old" reference
    PointerToDataMember = 0x02, // pointer to data member
    PointerToMemberFunction = 0x03, // pointer to member function
    RValueReference = 0x04, // r-value reference
};
enum class PointerModifiers : uint8_t {
    None = 0x00, // "normal" pointer
    Flat32 = 0x01, // "flat" pointer
    Volatile = 0x02, // pointer is marked volatile
    Const = 0x04, // pointer is marked const
    Unaligned = 0x08, // pointer is marked unaligned
};

```

(continues on next page)

(continued from previous page)

```

    Restrict = 0x10,                // pointer is marked restrict
};
enum class PointerFlags : uint8_t {
    WinRTSmartPointer = 0x01,       // pointer is a WinRT smart pointer
    LValueRefThisPointer = 0x02,    // pointer is a 'this' pointer of a member function,
    ↪with ref qualifier (e.g. void X::foo() &)
    RValueRefThisPointer = 0x04     // pointer is a 'this' pointer of a member function,
    ↪with ref qualifier (e.g. void X::foo() &&)
};

```

The `Size` field of the `Attributes` bitmask is a 1-byte value indicating the pointer size. For example, a `void*` would have a size of either 4 or 8 depending on the target architecture. On the other hand, if `Mode` indicates that this is a pointer to member function or pointer to data member, then the size can be any implementation defined number.

The `Member Ptr Info` field of the `LF_POINTER` record is only present if the attributes indicate that this is a pointer to member.

Note that "plain" pointers to primitive types are not represented by `LF_POINTER` records, they are indicated by special reserved *TypeIndex values*.

The MSF Container

A PDB file is an MSF (Multi-Stream Format) file. An MSF file is a "file system within a file". It contains multiple streams (aka files) which can represent arbitrary data, and these streams are divided into blocks which may not necessarily be contiguously laid out within the MSF container file. Additionally, the MSF contains a stream directory (aka MFT) which describes how the streams (files) are laid out within the MSF.

For more information about the MSF container format, stream directory, and block layout, see [The MSF File Format](#).

Streams

The PDB format contains a number of streams which describe various information such as the types, symbols, source files, and compilands (e.g. object files) of a program, as well as some additional streams containing hash tables that are used by debuggers and other tools to provide fast lookup of records and types by name, and various other information about how the program was compiled such as the specific toolchain used, and more. A summary of streams contained in a PDB file is as follows:

Name	Stream Index	Contents
Old Directory	<ul style="list-style-type: none"> Fixed Stream Index 0 	<ul style="list-style-type: none"> Previous MSF Stream Directory
PDB Stream	<ul style="list-style-type: none"> Fixed Stream Index 1 	<ul style="list-style-type: none"> Basic File Information Fields to match EXE to this PDB Map of named streams to stream indices
TPI Stream	<ul style="list-style-type: none"> Fixed Stream Index 2 	<ul style="list-style-type: none"> CodeView Type Records Index of TPI Hash Stream
DBI Stream	<ul style="list-style-type: none"> Fixed Stream Index 3 	<ul style="list-style-type: none"> Module/Compiland Information Indices of individual module streams Indices of public / global streams Section Contribution Information Source File Information References to streams containing FPO / PGO Data
IPI Stream	<ul style="list-style-type: none"> Fixed Stream Index 4 	<ul style="list-style-type: none"> CodeView Type Records Index of IPI Hash Stream
/LinkInfo	<ul style="list-style-type: none"> Contained in PDB Stream Named Stream map 	<ul style="list-style-type: none"> Unknown
/src/headerblock	<ul style="list-style-type: none"> Contained in PDB Stream Named Stream map 	<ul style="list-style-type: none"> Summary of embedded source file content (e.g. natvis files)
/names	<ul style="list-style-type: none"> Contained in PDB Stream Named Stream map 	<ul style="list-style-type: none"> PDB-wide global string table used for string de-duplication
Module Info Stream	<ul style="list-style-type: none"> Contained in DBI Stream One for each compiland 	<ul style="list-style-type: none"> CodeView Symbol Records for this module Line Number Information
Public Stream	<ul style="list-style-type: none"> Contained in DBI Stream 	<ul style="list-style-type: none"> Public (Exported) Symbol Records Index of Public Hash Stream
Global Stream	<ul style="list-style-type: none"> Contained in DBI Stream 	<ul style="list-style-type: none"> Single combined master symbol-table Index of Global Hash Stream
2042	Chapter 4. Subsystem Documentation	
TPI Hash Stream	<ul style="list-style-type: none"> Contained in TPI Stream 	<ul style="list-style-type: none"> Hash table for looking up TPI records by name

More information about the structure of each of these can be found on the following pages:

The PDB Info Stream (aka the PDB Stream) Information about the PDB Info Stream and how it is used to match PDBs to EXEs.

The PDB TPI and IPI Streams Information about the TPI stream and the CodeView records contained within.

The PDB DBI (Debug Info) Stream Information about the DBI stream and relevant substreams including the Module Substreams, source file information, and CodeView symbol records contained within.

The Module Information Stream Information about the Module Information Stream, of which there is one for each compilation unit and the format of symbols contained within.

The PDB Public Symbol Stream Information about the Public Symbol Stream.

The PDB Global Symbol Stream Information about the Global Symbol Stream.

The PDB Serialized Hash Table Format Information about the serialized hash table format used internally to represent things such as the Named Stream Map and the Hash Adjusters in the *TPI/IPI Stream*.

4.42.3 CodeView

CodeView is another format which comes into the picture. While MSF defines the structure of the overall file, and PDB defines the set of streams that appear within the MSF file and the format of those streams, CodeView defines the format of **symbol and type records** that appear within specific streams. Refer to the pages on *CodeView Symbol Records* and *CodeView Type Records* for more information about the CodeView format.

4.43 Control Flow Verification Tool Design Document

- *Objective*
- *Location*
- *Background*
- *Design Ideas*
 - *Other Design Notes*

4.43.1 Objective

This document provides an overview of an external tool to verify the protection mechanisms implemented by Clang's *Control Flow Integrity* (CFI) schemes (`-fsanitize=cfi`). This tool, provided a binary or DSO, should infer whether indirect control flow operations are protected by CFI, and should output these results in a human-readable form.

This tool should also be added as part of Clang's continuous integration testing framework, where modifications to the compiler ensure that CFI protection schemes are still present in the final binary.

4.43.2 Location

This tool will be present as a part of the LLVM toolchain, and will reside in the `"/llvm/tools/llvm-cfi-verify"` directory, relative to the LLVM trunk. It will be tested in two methods:

- Unit tests to validate code sections, present in `"/llvm/unittests/tools/llvm-cfi-verify"`.
- Integration tests, present in `"/llvm/tools/clang/test/LLVMCFIVerify"`. These integration tests are part of clang as part of a continuous integration framework, ensuring updates to the compiler that reduce CFI coverage on indirect control flow instructions are identified.

4.43.3 Background

This tool will continuously validate that CFI directives are properly implemented around all indirect control flows by analysing the output machine code. The analysis of machine code is important as it ensures that any bugs present in linker or compiler do not subvert CFI protections in the final shipped binary.

Unprotected indirect control flow instructions will be flagged for manual review. These unexpected control flows may simply have not been accounted for in the compiler implementation of CFI (e.g. indirect jumps to facilitate switch statements may not be fully protected).

It may be possible in the future to extend this tool to flag unnecessary CFI directives (e.g. CFI directives around a static call to a non-polymorphic base type). This type of directive has no security implications, but may present performance impacts.

4.43.4 Design Ideas

This tool will disassemble binaries and DSO's from their machine code format and analyse the disassembled machine code. The tool will inspect virtual calls and indirect function calls. This tool will also inspect indirect jumps, as inlined functions and jump tables should also be subject to CFI protections. Non-virtual calls (`-fsanitize=cfi-nvcall`) and cast checks (`-fsanitize=cfi-*cast*`) are not implemented due to a lack of information provided by the bytecode.

The tool would operate by searching for indirect control flow instructions in the disassembly. A control flow graph would be generated from a small buffer of the instructions surrounding the 'target' control flow instruction. If the target instruction is branched-to, the fallthrough of the branch should be the CFI trap (on x86, this is a `ud2` instruction). If the target instruction is the fallthrough (i.e. immediately succeeds) of a conditional jump, the conditional jump target should be the CFI trap. If an indirect control flow instruction does not conform to one of these formats, the target will be noted as being CFI-unprotected.

Note that in the second case outlined above (where the target instruction is the fallthrough of a conditional jump), if the target represents a `vcall` that takes arguments, these arguments may be pushed to the stack after the branch but before the target instruction. In these cases, a secondary 'spill graph' is constructed, to ensure the register argument used by the indirect jump/call is not spilled from the stack at any point in the interim period. If there are no spills that affect the target register, the target is marked as CFI-protected.

Other Design Notes

Only machine code sections that are marked as executable will be subject to this analysis. Non-executable sections do not require analysis as any execution present in these sections has already violated the control flow integrity.

Suitable extensions may be made at a later date to include analysis for indirect control flow operations across DSO boundaries. Currently, these CFI features are only experimental with an unstable ABI, making them unsuitable for analysis.

The tool currently only supports the x86, x86_64, and AArch64 architectures.

4.44 Speculative Load Hardening

4.44.1 A Spectre Variant #1 Mitigation Technique

Author: Chandler Carruth - chandlerc@google.com

4.44.2 Problem Statement

Recently, Google Project Zero and other researchers have found information leak vulnerabilities by exploiting speculative execution in modern CPUs. These exploits are currently broken down into three variants:

- GPZ Variant #1 (a.k.a. Spectre Variant #1): Bounds check (or predicate) bypass
- GPZ Variant #2 (a.k.a. Spectre Variant #2): Branch target injection
- GPZ Variant #3 (a.k.a. Meltdown): Rogue data cache load

For more details, see the Google Project Zero blog post and the Spectre research paper:

- <https://googleprojectzero.blogspot.com/2018/01/reading-privileged-memory-with-side.html>
- <https://spectreattack.com/spectre.pdf>

The core problem of GPZ Variant #1 is that speculative execution uses branch prediction to select the path of instructions speculatively executed. This path is speculatively executed with the available data, and may load from memory and leak the loaded values through various side channels that survive even when the speculative execution is unwound due to being incorrect. Mispredicted paths can cause code to be executed with data inputs that never occur in correct executions, making checks against malicious inputs ineffective and allowing attackers to use malicious data inputs to leak secret data. Here is an example, extracted and simplified from the Project Zero paper:

```
struct array {
    unsigned long length;
    unsigned char data[];
};
struct array *arr1 = ...; // small array
struct array *arr2 = ...; // array of size 0x400
unsigned long untrusted_offset_from_caller = ...;
if (untrusted_offset_from_caller < arr1->length) {
    unsigned char value = arr1->data[untrusted_offset_from_caller];
    unsigned long index2 = ((value&1)*0x100)+0x200;
    unsigned char value2 = arr2->data[index2];
}
```

The key of the attack is to call this with `untrusted_offset_from_caller` that is far outside of the bounds when the branch predictor will predict that it will be in-bounds. In that case, the body of the `if` will be executed

speculatively, and may read secret data into `value` and leak it via a cache-timing side channel when a dependent access is made to populate `value2`.

4.44.3 High Level Mitigation Approach

While several approaches are being actively pursued to mitigate specific branches and/or loads inside especially risky software (most notably various OS kernels), these approaches require manual and/or static analysis aided auditing of code and explicit source changes to apply the mitigation. They are unlikely to scale well to large applications. We are proposing a comprehensive mitigation approach that would apply automatically across an entire program rather than through manual changes to the code. While this is likely to have a high performance cost, some applications may be in a good position to take this performance / security tradeoff.

The specific technique we propose is to cause loads to be checked using branchless code to ensure that they are executing along a valid control flow path. Consider the following C-pseudo-code representing the core idea of a predicate guarding potentially invalid loads:

```
void leak(int data);
void example(int* pointer1, int* pointer2) {
    if (condition) {
        // ... lots of code ...
        leak(*pointer1);
    } else {
        // ... more code ...
        leak(*pointer2);
    }
}
```

This would get transformed into something resembling the following:

```
uintptr_t all_ones_mask = std::numerical_limits<uintptr_t>::max();
uintptr_t all_zeros_mask = 0;
void leak(int data);
void example(int* pointer1, int* pointer2) {
    uintptr_t predicate_state = all_ones_mask;
    if (condition) {
        // Assuming ?: is implemented using branchless logic...
        predicate_state = !condition ? all_zeros_mask : predicate_state;
        // ... lots of code ...
        //
        // Harden the pointer so it can't be loaded
        pointer1 &= predicate_state;
        leak(*pointer1);
    } else {
        predicate_state = condition ? all_zeros_mask : predicate_state;
        // ... more code ...
        //
        // Alternative: Harden the loaded value
        int value2 = *pointer2 & predicate_state;
        leak(value2);
    }
}
```

The result should be that if the `if (condition) {` branch is mis-predicted, there is a *data* dependency on the condition used to zero out any pointers prior to loading through them or to zero out all of the loaded bits. Even though this code pattern may still execute speculatively, *invalid* speculative executions are prevented from leaking secret data from memory (but note that this data might still be loaded in safe ways, and some regions of memory are required to not hold secrets, see below for detailed limitations). This approach only requires the underlying hardware have a

way to implement a branchless and unpredicted conditional update of a register's value. All modern architectures have support for this, and in fact such support is necessary to correctly implement constant time cryptographic primitives.

Crucial properties of this approach:

- It is not preventing any particular side-channel from working. This is important as there are an unknown number of potential side channels and we expect to continue discovering more. Instead, it prevents the observation of secret data in the first place.
- It accumulates the predicate state, protecting even in the face of nested *correctly* predicted control flows.
- It passes this predicate state across function boundaries to provide *interprocedural protection*.
- When hardening the address of a load, it uses a *destructive* or *non-reversible* modification of the address to prevent an attacker from reversing the check using attacker-controlled inputs.
- It does not completely block speculative execution, and merely prevents *mis*-speculated paths from leaking secrets from memory (and stalls speculation until this can be determined).
- It is completely general and makes no fundamental assumptions about the underlying architecture other than the ability to do branchless conditional data updates and a lack of value prediction.
- It does not require programmers to identify all possible secret data using static source code annotations or code vulnerable to a variant #1 style attack.

Limitations of this approach:

- It requires re-compiling source code to insert hardening instruction sequences. Only software compiled in this mode is protected.
- The performance is heavily dependent on a particular architecture's implementation strategy. We outline a potential x86 implementation below and characterize its performance.
- It does not defend against secret data already loaded from memory and residing in registers or leaked through other side-channels in non-speculative execution. Code dealing with this, e.g cryptographic routines, already uses constant-time algorithms and code to prevent side-channels. Such code should also scrub registers of secret data following [these guidelines](#).
- To achieve reasonable performance, many loads may not be checked, such as those with compile-time fixed addresses. This primarily consists of accesses at compile-time constant offsets of global and local variables. Code which needs this protection and intentionally stores secret data must ensure the memory regions used for secret data are necessarily dynamic mappings or heap allocations. This is an area which can be tuned to provide more comprehensive protection at the cost of performance.
- *Hardened loads* may still load data from *valid* addresses if not *attacker-controlled* addresses. To prevent these from reading secret data, the low 2gb of the address space and 2gb above and below any executable pages should be protected.

Credit:

- The core idea of tracing misspeculation through data and marking pointers to block misspeculated loads was developed as part of a HACS 2018 discussion between Chandler Carruth, Paul Kocher, Thomas Pornin, and several other individuals.
- Core idea of masking out loaded bits was part of the original mitigation suggested by Jann Horn when these attacks were reported.

Indirect Branches, Calls, and Returns

It is possible to attack control flow other than conditional branches with variant #1 style mispredictions.

- A prediction towards a hot call target of a virtual method can lead to it being speculatively executed when an expected type is used (often called "type confusion").
- A hot case may be speculatively executed due to prediction instead of the correct case for a switch statement implemented as a jump table.
- A hot common return address may be predicted incorrectly when returning from a function.

These code patterns are also vulnerable to Spectre variant #2, and as such are best mitigated with a [retpoline](#) on x86 platforms. When a mitigation technique like retpoline is used, speculation simply cannot proceed through an indirect control flow edge (or it cannot be mispredicted in the case of a filled RSB) and so it is also protected from variant #1 style attacks. However, some architectures, micro-architectures, or vendors do not employ the retpoline mitigation, and on future x86 hardware (both Intel and AMD) it is expected to become unnecessary due to hardware-based mitigation.

When not using a retpoline, these edges will need independent protection from variant #1 style attacks. The analogous approach to that used for conditional control flow should work:

```
uintptr_t all_ones_mask = std::numerical_limits<uintptr_t>::max();
uintptr_t all_zeros_mask = 0;
void leak(int data);
void example(int* pointer1, int* pointer2) {
    uintptr_t predicate_state = all_ones_mask;
    switch (condition) {
    case 0:
        // Assuming ?: is implemented using branchless logic...
        predicate_state = (condition != 0) ? all_zeros_mask : predicate_state;
        // ... lots of code ...
        //
        // Harden the pointer so it can't be loaded
        pointer1 &= predicate_state;
        leak(*pointer1);
        break;

    case 1:
        predicate_state = (condition != 1) ? all_zeros_mask : predicate_state;
        // ... more code ...
        //
        // Alternative: Harden the loaded value
        int value2 = *pointer2 & predicate_state;
        leak(value2);
        break;

        // ...
    }
}
```

The core idea remains the same: validate the control flow using data-flow and use that validation to check that loads cannot leak information along misspeculated paths. Typically this involves passing the desired target of such control flow across the edge and checking that it is correct afterwards. Note that while it is tempting to think that this mitigates variant #2 attacks, it does not. Those attacks go to arbitrary gadgets that don't include the checks.

Variant #1.1 and #1.2 attacks: "Bounds Check Bypass Store"

Beyond the core variant #1 attack, there are techniques to extend this attack. The primary technique is known as "Bounds Check Bypass Store" and is discussed in this research paper: <https://people.csail.mit.edu/vlk/spectre11.pdf>

We will analyze these two variants independently. First, variant #1.1 works by speculatively storing over the return address after a bounds check bypass. This speculative store then ends up being used by the CPU during speculative execution of the return, potentially directing speculative execution to arbitrary gadgets in the binary. Let's look at an example.

```
unsigned char local_buffer[4];
unsigned char *untrusted_data_from_caller = ...;
unsigned long untrusted_size_from_caller = ...;
if (untrusted_size_from_caller < sizeof(local_buffer)) {
    // Speculative execution enters here with a too-large size.
    memcpy(local_buffer, untrusted_data_from_caller,
           untrusted_size_from_caller);
    // The stack has now been smashed, writing an attacker-controlled
    // address over the return address.
    minor_processing(local_buffer);
    return;
    // Control will speculate to the attacker-written address.
}
```

However, this can be mitigated by hardening the load of the return address just like any other load. This is sometimes complicated because x86 for example *implicitly* loads the return address off the stack. However, the implementation technique below is specifically designed to mitigate this implicit load by using the stack pointer to communicate misspeculation between functions. This additionally causes a misspeculation to have an invalid stack pointer and never be able to read the speculatively stored return address. See the detailed discussion below.

For variant #1.2, the attacker speculatively stores into the vtable or jump table used to implement an indirect call or indirect jump. Because this is speculative, this will often be possible even when these are stored in read-only pages. For example:

```
class FancyObject : public BaseObject {
public:
    void DoSomething() override;
};

void f(unsigned long attacker_offset, unsigned long attacker_data) {
    FancyObject object = getMyObject();
    unsigned long *arr[4] = getFourDataPointers();
    if (attacker_offset < 4) {
        // We have bypassed the bounds check speculatively.
        unsigned long *data = arr[attacker_offset];
        // Now we have computed a pointer inside of `object`, the vptr.
        *data = attacker_data;
        // The vptr points to the virtual table and we speculatively clobber that.
        g(object); // Hand the object to some other routine.
    }
}

// In another file, we call a method on the object.
void g(BaseObject &object) {
    object.DoSomething();
    // This speculatively calls the address stored over the vtable.
}
```

Mitigating this requires hardening loads from these locations, or mitigating the indirect call or indirect jump. Any of these are sufficient to block the call or jump from using a speculatively stored value that has been read back.

For both of these, using retpolines would be equally sufficient. One possible hybrid approach is to use retpolines for indirect call and jump, while relying on SLH to mitigate returns.

Another approach that is sufficient for both of these is to harden all of the speculative stores. However, as most stores aren't interesting and don't inherently leak data, this is expected to be prohibitively expensive given the attack it is defending against.

4.44.4 Implementation Details

There are a number of complex details impacting the implementation of this technique, both on a particular architecture and within a particular compiler. We discuss proposed implementation techniques for the x86 architecture and the LLVM compiler. These are primarily to serve as an example, as other implementation techniques are very possible.

x86 Implementation Details

On the x86 platform we break down the implementation into three core components: accumulating the predicate state through the control flow graph, checking the loads, and checking control transfers between procedures.

Accumulating Predicate State

Consider baseline x86 instructions like the following, which test three conditions and if all pass, loads data from memory and potentially leaks it through some side channel:

```
# %bb.0:                                     # %entry
    pushq    %rax
    testl    %edi, %edi
    jne      .LBB0_4
# %bb.1:                                     # %then1
    testl    %esi, %esi
    jne      .LBB0_4
# %bb.2:                                     # %then2
    testl    %edx, %edx
    je       .LBB0_3
.LBB0_4:                                     # %exit
    popq     %rax
    retq
.LBB0_3:                                     # %danger
    movl     (%rcx), %edi
    callq    leak
    popq     %rax
    retq
```

When we go to speculatively execute the load, we want to know whether any of the dynamically executed predicates have been misspeculated. To track that, along each conditional edge, we need to track the data which would allow that edge to be taken. On x86, this data is stored in the flags register used by the conditional jump instruction. Along both edges after this fork in control flow, the flags register remains alive and contains data that we can use to build up our accumulated predicate state. We accumulate it using the x86 conditional move instruction which also reads the flag registers where the state resides. These conditional move instructions are known to not be predicted on any x86 processors, making them immune to misprediction that could reintroduce the vulnerability. When we insert the conditional moves, the code ends up looking like the following:

```
# %bb.0:                                     # %entry
    pushq    %rax
```

(continues on next page)

(continued from previous page)

```

        xorl    %eax, %eax                # Zero out initial predicate state.
        movq    $-1, %r8                 # Put all-ones mask into a register.
        testl   %edi, %edi
        jne     .LBB0_1
# %bb.2:                                     # %then1
        cmovneq %r8, %rax                 # Conditionally update predicate state.
        testl   %esi, %esi
        jne     .LBB0_1
# %bb.3:                                     # %then2
        cmovneq %r8, %rax                 # Conditionally update predicate state.
        testl   %edx, %edx
        je      .LBB0_4
.LBB0_1:
        cmoveq  %r8, %rax                 # Conditionally update predicate state.
        popq    %rax
        retq
.LBB0_4:                                     # %danger
        cmovneq %r8, %rax                 # Conditionally update predicate state.
        ...

```

Here we create the "empty" or "correct execution" predicate state by zeroing `%rax`, and we create a constant "incorrect execution" predicate value by putting `-1` into `%r8`. Then, along each edge coming out of a conditional branch we do a conditional move that in a correct execution will be a no-op, but if misspeculated, will replace the `%rax` with the value of `%r8`. Misspeculating any one of the three predicates will cause `%rax` to hold the "incorrect execution" value from `%r8` as we preserve incoming values when execution is correct rather than overwriting it.

We now have a value in `%rax` in each basic block that indicates if at some point previously a predicate was mispredicted. And we have arranged for that value to be particularly effective when used below to harden loads.

Indirect Call, Branch, and Return Predicates

There is no analogous flag to use when tracing indirect calls, branches, and returns. The predicate state must be accumulated through some other means. Fundamentally, this is the reverse of the problem posed in CFI: we need to check where we came from rather than where we are going. For function-local jump tables, this is easily arranged by testing the input to the jump table within each destination (not yet implemented, use `retpolines`):

```

        pushq   %rax
        xorl    %eax, %eax                # Zero out initial predicate state.
        movq    $-1, %r8                 # Put all-ones mask into a register.
        jmpq    *.LJTI0_0(,%rdi,8)       # Indirect jump through table.
.LBB0_2:                                     # %sw.bb
        testq   $0, %rdi                 # Validate index used for jump table.
        cmovneq %r8, %rax                 # Conditionally update predicate state.
        ...
        jmp     _Z4leaki                  # TAILCALL
.LBB0_3:                                     # %sw.bb1
        testq   $1, %rdi                 # Validate index used for jump table.
        cmovneq %r8, %rax                 # Conditionally update predicate state.
        ...
        jmp     _Z4leaki                  # TAILCALL
.LBB0_5:                                     # %sw.bb10
        testq   $2, %rdi                 # Validate index used for jump table.
        cmovneq %r8, %rax                 # Conditionally update predicate state.

```

Returns have a simple mitigation technique on x86-64 (or other ABIs which have what is called a "red zone" region beyond the end of the stack). This region is guaranteed to be preserved across interrupts and context switches, making the return address used in returning to the current code remain on the stack and valid to read. We can emit code in the caller to verify that a return edge was not mispredicted:

```

callq    other_function
return_addr:
testq    -8(%rsp), return_addr  # Validate return address.
cmovneq  %r8, %rax              # Update predicate state.

```

For an ABI without a "red zone" (and thus unable to read the return address from the stack), we can compute the expected return address prior to the call into a register preserved across the call and use that similarly to the above.

Indirect calls (and returns in the absence of a red zone ABI) pose the most significant challenge to propagate. The simplest technique would be to define a new ABI such that the intended call target is passed into the called function and checked in the entry. Unfortunately, new ABIs are quite expensive to deploy in C and C++. While the target function could be passed in TLS, we would still require complex logic to handle a mixture of functions compiled with and without this extra logic (essentially, making the ABI backwards compatible). Currently, we suggest using retpolines here and will continue to investigate ways of mitigating this.

Optimizations, Alternatives, and Tradeoffs

Merely accumulating predicate state involves significant cost. There are several key optimizations we employ to minimize this and various alternatives that present different tradeoffs in the generated code.

First, we work to reduce the number of instructions used to track the state:

- Rather than inserting a `cmovCC` instruction along every conditional edge in the original program, we track each set of condition flags we need to capture prior to entering each basic block and reuse a common `cmovCC` sequence for those.
 - We could further reuse suffixes when there are multiple `cmovCC` instructions required to capture the set of flags. Currently this is believed to not be worth the cost as paired flags are relatively rare and suffixes of them are exceedingly rare.
- A common pattern in x86 is to have multiple conditional jump instructions that use the same flags but handle different conditions. Naively, we could consider each fallthrough between them an "edge" but this causes a much more complex control flow graph. Instead, we accumulate the set of conditions necessary for fallthrough and use a sequence of `cmovCC` instructions in a single fallthrough edge to track it.

Second, we trade register pressure for simpler `cmovCC` instructions by allocating a register for the "bad" state. We could read that value from memory as part of the conditional move instruction, however, this creates more micro-ops and requires the load-store unit to be involved. Currently, we place the value into a virtual register and allow the register allocator to decide when the register pressure is sufficient to make it worth spilling to memory and reloading.

Hardening Loads

Once we have the predicate accumulated into a special value for correct vs. misspeculated, we need to apply this to loads in a way that ensures they do not leak secret data. There are two primary techniques for this: we can either harden the loaded value to prevent observation, or we can harden the address itself to prevent the load from occurring. These have significantly different performance tradeoffs.

Hardening loaded values

The most appealing way to harden loads is to mask out all of the bits loaded. The key requirement is that for each bit loaded, along the misspeculated path that bit is always fixed at either 0 or 1 regardless of the value of the bit loaded. The most obvious implementation uses either an `and` instruction with an all-zero mask along misspeculated paths and an all-one mask along correct paths, or an `or` instruction with an all-one mask along misspeculated paths and an all-zero mask along correct paths. Other options become less appealing such as multiplying by zero, or multiple shift instructions. For reasons we elaborate on below, we end up suggesting you use `or` with an all-ones mask, making the x86 instruction sequence look like the following:

```
...
.LBB0_4:                                # %danger
    cmovneq %r8, %rax                    # Conditionally update predicate state.
    movl    (%rsi), %edi                 # Load potentially secret data from %rsi.
    orl     %eax, %edi
```

Other useful patterns may be to fold the load into the `or` instruction itself at the cost of a register-to-register copy.

There are some challenges with deploying this approach:

1. Many loads on x86 are folded into other instructions. Separating them would add very significant and costly register pressure with prohibitive performance cost.
2. Loads may not target a general purpose register requiring extra instructions to map the state value into the correct register class, and potentially more expensive instructions to mask the value in some way.
3. The flags registers on x86 are very likely to be live, and challenging to preserve cheaply.
4. There are many more values loaded than pointers & indices used for loads. As a consequence, hardening the result of a load requires substantially more instructions than hardening the address of the load (see below).

Despite these challenges, hardening the result of the load critically allows the load to proceed and thus has dramatically less impact on the total speculative / out-of-order potential of the execution. There are also several interesting techniques to try and mitigate these challenges and make hardening the results of loads viable in at least some cases. However, we generally expect to fall back when unprofitable from hardening the loaded value to the next approach of hardening the address itself.

Loads folded into data-invariant operations can be hardened after the operation

The first key to making this feasible is to recognize that many operations on x86 are "data-invariant". That is, they have no (known) observable behavior differences due to the particular input data. These instructions are often used when implementing cryptographic primitives dealing with private key data because they are not believed to provide any side-channels. Similarly, we can defer hardening until after them as they will not in-and-of-themselves introduce a speculative execution side-channel. This results in code sequences that look like:

```
...  
.LBB0_4:                                # %danger  
    cmovneq %r8, %rax                  # Conditionally update predicate state.  
    addl    (%rsi), %edi               # Load and accumulate without leaking.  
    orl     %eax, %edi
```

While an addition happens to the loaded (potentially secret) value, that doesn't leak any data and we then immediately harden it.

Hardening of loaded values deferred down the data-invariant expression graph

We can generalize the previous idea and sink the hardening down the expression graph across as many data-invariant operations as desirable. This can use very conservative rules for whether something is data-invariant. The primary goal should be to handle multiple loads with a single hardening instruction:

```
...  
.LBB0_4:                                # %danger  
    cmovneq %r8, %rax                  # Conditionally update predicate state.  
    addl    (%rsi), %edi               # Load and accumulate without leaking.  
    addl    4(%rsi), %edi              # Continue without leaking.  
    addl    8(%rsi), %edi  
    orl     %eax, %edi                 # Mask out bits from all three loads.
```

Preserving the flags while hardening loaded values on Haswell, Zen, and newer processors

Sadly, there are no useful instructions on x86 that apply a mask to all 64 bits without touching the flag registers. However, we can harden loaded values that are narrower than a word (fewer than 32-bits on 32-bit systems and fewer than 64-bits on 64-bit systems) by zero-extending the value to the full word size and then shifting right by at least the number of original bits using the BMI2 `shrxq` instruction:

```
...  
.LBB0_4:                                # %danger  
    cmovneq %r8, %rax                  # Conditionally update predicate state.  
    addl    (%rsi), %edi               # Load and accumulate 32 bits of data.  
    shrxq   %rax, %rdi, %rdi           # Shift out all 32 bits loaded.
```

Because on x86 the zero-extend is free, this can efficiently harden the loaded value.

Hardening the address of the load

When hardening the loaded value is inapplicable, most often because the instruction directly leaks information (like `cmp` or `jmpq`), we switch to hardening the *address* of the load instead of the loaded value. This avoids increasing register pressure by unfolding the load or paying some other high cost.

To understand how this works in practice, we need to examine the exact semantics of the x86 addressing modes which, in its fully general form, looks like `(%base,%index,scale)offset`. Here `%base` and `%index` are 64-bit registers that can potentially be any value, and may be attacker controlled, and `scale` and `offset` are fixed immediate values. `scale` must be 1, 2, 4, or 8, and `offset` can be any 32-bit sign extended value. The exact computation performed to find the address is then: `%base + (scale * %index) + offset` under 64-bit 2's complement modular arithmetic.

One issue with this approach is that, after hardening, the `%base + (scale * %index)` subexpression will compute a value near zero (`-1 + (scale * -1)`) and then a large, positive `offset` will index into memory within the first two gigabytes of address space. While these offsets are not attacker controlled, the attacker could choose to attack a load which happens to have the desired offset and then successfully read memory in that region. This significantly raises the burden on the attacker and limits the scope of attack but does not eliminate it. To fully close the attack we must work with the operating system to preclude mapping memory in the low two gigabytes of address space.

64-bit load checking instructions

We can use the following instruction sequences to check loads. We set up `%r8` in these examples to hold the special value of `-1` which will be moved over `%rax` in misspeculated paths.

Single register addressing mode:

```
...
.LBB0_4:                                # %danger
    cmovneq %r8, %rax                    # Conditionally update predicate state.
    orq     %rax, %rsi                   # Mask the pointer if misspeculating.
    movl    (%rsi), %edi
```

Two register addressing mode:

```
...
.LBB0_4:                                # %danger
    cmovneq %r8, %rax                    # Conditionally update predicate state.
    orq     %rax, %rsi                   # Mask the pointer if misspeculating.
    orq     %rax, %rcx                   # Mask the index if misspeculating.
    movl    (%rsi,%rcx), %edi
```

This will result in a negative address near zero or in `offset` wrapping the address space back to a small positive address. Small, negative addresses will fault in user-mode for most operating systems, but targets which need the high address space to be user accessible may need to adjust the exact sequence used above. Additionally, the low addresses will need to be marked unreadable by the OS to fully harden the load.

RIP-relative addressing is even easier to break

There is a common addressing mode idiom that is substantially harder to check: addressing relative to the instruction pointer. We cannot change the value of the instruction pointer register and so we have the harder problem of forcing `%base + scale * %index + offset` to be an invalid address, by *only* changing `%index`. The only advantage we have is that the attacker also cannot modify `%base`. If we use the fast instruction sequence above, but only apply it to the index, we will always access `%rip + (scale * -1) + offset`. If the attacker can find a load which with this address happens to point to secret data, then they can reach it. However, the loader and base libraries can also simply refuse to map the heap, data segments, or stack within 2gb of any of the text in the program, much like it can reserve the low 2gb of address space.

The flag registers again make everything hard

Unfortunately, the technique of using `orq`-instructions has a serious flaw on x86. The very thing that makes it easy to accumulate state, the flag registers containing predicates, causes serious problems here because they may be alive and used by the loading instruction or subsequent instructions. On x86, the `orq` instruction **sets** the flags and will override anything already there. This makes inserting them into the instruction stream very hazardous. Unfortunately, unlike when hardening the loaded value, we have no fallback here and so we must have a fully general approach available.

The first thing we must do when generating these sequences is try to analyze the surrounding code to prove that the flags are not in fact alive or being used. Typically, it has been set by some other instruction which just happens to set the flags register (much like ours!) with no actual dependency. In those cases, it is safe to directly insert these instructions. Alternatively we may be able to move them earlier to avoid clobbering the used value.

However, this may ultimately be impossible. In that case, we need to preserve the flags around these instructions:

```
...
.LBB0_4:                                # %danger
    cmovneq %r8, %rax                    # Conditionally update predicate state.
    pushfq
    orq     %rax, %rcx                    # Mask the pointer if misspeculating.
    orq     %rax, %rdx                    # Mask the index if misspeculating.
    popfq
    movl    (%rcx,%rdx), %edi
```

Using the `pushf` and `popf` instructions saves the flags register around our inserted code, but comes at a high cost. First, we must store the flags to the stack and reload them. Second, this causes the stack pointer to be adjusted dynamically, requiring a frame pointer be used for referring to temporaries spilled to the stack, etc.

On newer x86 processors we can use the `lahf` and `sahf` instructions to save all of the flags besides the overflow flag in a register rather than on the stack. We can then use `seto` and `add` to save and restore the overflow flag in a register. Combined, this will save and restore flags in the same manner as above but using two registers rather than the stack. That is still very expensive if slightly less expensive than `pushf` and `popf` in most cases.

A flag-less alternative on Haswell, Zen and newer processors

Starting with the BMI2 x86 instruction set extensions available on Haswell and Zen processors, there is an instruction for shifting that does not set any flags: `shrx`. We can use this and the `leaq` instruction to implement analogous code sequences to the above ones. However, these are still very marginally slower, as there are fewer ports able to dispatch shift instructions in most modern x86 processors than there are for `or` instructions.

Fast, single register addressing mode:

```
...
.LBB0_4:                                # %danger
    cmovneq %r8, %rax                    # Conditionally update predicate state.
    shrxq   %rax, %rsi, %rsi              # Shift away bits if misspeculating.
    movl    (%rsi), %edi
```

This will collapse the register to zero or one, and everything but the offset in the addressing mode to be less than or equal to 9. This means the full address can only be guaranteed to be less than $(1 \ll 31) + 9$. The OS may wish to protect an extra page of the low address space to account for this

Optimizations

A very large portion of the cost for this approach comes from checking loads in this way, so it is important to work to optimize this. However, beyond making the instruction sequences to *apply* the checks efficient (for example by avoiding `pushfq` and `popfq` sequences), the only significant optimization is to check fewer loads without introducing a vulnerability. We apply several techniques to accomplish that.

Don't check loads from compile-time constant stack offsets

We implement this optimization on x86 by skipping the checking of loads which use a fixed frame pointer offset.

The result of this optimization is that patterns like reloading a spilled register or accessing a global field don't get checked. This is a very significant performance win.

Don't check dependent loads

A core part of why this mitigation strategy works is that it establishes a data-flow check on the loaded address. However, this means that if the address itself was already loaded using a checked load, there is no need to check a dependent load provided it is within the same basic block as the checked load, and therefore has no additional predicates guarding it. Consider code like the following:

```
...
.LBB0_4:                                # %danger
    movq    (%rcx), %rdi
    movl    (%rdi), %edx
```

This will get transformed into:

```
...
.LBB0_4:                                # %danger
    cmovneq %r8, %rax                    # Conditionally update predicate state.
    orq     %rax, %rcx                   # Mask the pointer if misspeculating.
    movq    (%rcx), %rdi                 # Hardened load.
    movl    (%rdi), %edx                 # Unhardened load due to dependent addr.
```

This doesn't check the load through `%rdi` as that pointer is dependent on a checked load already.

Protect large, load-heavy blocks with a single lfence

It may be worth using a single `lfence` instruction at the start of a block which begins with a (very) large number of loads that require independent protection *and* which require hardening the address of the load. However, this is unlikely to be profitable in practice. The latency hit of the hardening would need to exceed that of an `lfence` when *correctly* speculatively executed. But in that case, the `lfence` cost is a complete loss of speculative execution (at a minimum). So far, the evidence we have of the performance cost of using `lfence` indicates few if any hot code patterns where this trade off would make sense.

Tempting optimizations that break the security model

Several optimizations were considered which didn't pan out due to failure to uphold the security model. One in particular is worth discussing as many others will reduce to it.

We wondered whether only the *first* load in a basic block could be checked. If the check works as intended, it forms an invalid pointer that doesn't even virtual-address translate in the hardware. It should fault very early on in its processing. Maybe that would stop things in time for the misspeculated path to fail to leak any secrets. This doesn't end up working because the processor is fundamentally out-of-order, even in its speculative domain. As a consequence, the attacker could cause the initial address computation itself to stall and allow an arbitrary number of unrelated loads (including attacked loads of secret data) to pass through.

Interprocedural Checking

Modern x86 processors may speculate into called functions and out of functions to their return address. As a consequence, we need a way to check loads that occur after a misspeculated predicate but where the load and the misspeculated predicate are in different functions. In essence, we need some interprocedural generalization of the predicate state tracking. A primary challenge to passing the predicate state between functions is that we would like to not require a change to the ABI or calling convention in order to make this mitigation more deployable, and further would like code mitigated in this way to be easily mixed with code not mitigated in this way and without completely losing the value of the mitigation.

Embed the predicate state into the high bit(s) of the stack pointer

We can use the same technique that allows hardening pointers to pass the predicate state into and out of functions. The stack pointer is trivially passed between functions and we can test for it having the high bits set to detect when it has been marked due to misspeculation. The callsite instruction sequence looks like (assuming a misspeculated state value of `-1`):

```
...
.LBB0_4:                                # %danger
    cmovneq %r8, %rax                    # Conditionally update predicate state.
    shlq    $47, %rax
    orq     %rax, %rsp
    callq   other_function
    movq    %rsp, %rax
    sarq    63, %rax                     # Sign extend the high bit to all bits.
```

This first puts the predicate state into the high bits of `%rsp` before calling the function and then reads it back out of high bits of `%rsp` afterward. When correctly executing (speculatively or not), these are all no-ops. When misspeculating, the stack pointer will end up negative. We arrange for it to remain a canonical address, but otherwise leave the low bits alone to allow stack adjustments to proceed normally without disrupting this. Within the called function, we can extract this predicate state and then reset it on return:

```
other_function:
    # prolog
    callq   other_function
    movq    %rsp, %rax
    sarq    63, %rax                     # Sign extend the high bit to all bits.
    # ...

.LBB0_N:
```

(continues on next page)

(continued from previous page)

```

cmovneq %r8, %rax           # Conditionally update predicate state.
shlq    $47, %rax
orq     %rax, %rsp
retq

```

This approach is effective when all code is mitigated in this fashion, and can even survive very limited reaches into unmitigated code (the state will round-trip in and back out of an unmitigated function, it just won't be updated). But it does have some limitations. There is a cost to merging the state into `%rsp` and it doesn't insulate mitigated code from misspeculation in an unmitigated caller.

There is also an advantage to using this form of interprocedural mitigation: by forming these invalid stack pointer addresses we can prevent speculative returns from successfully reading speculatively written values to the actual stack. This works first by forming a data-dependency between computing the address of the return address on the stack and our predicate state. And even when satisfied, if a misprediction causes the state to be poisoned the resulting stack pointer will be invalid.

Rewrite API of internal functions to directly propagate predicate state

(Not yet implemented.)

We have the option with internal functions to directly adjust their API to accept the predicate as an argument and return it. This is likely to be marginally cheaper than embedding into `%rsp` for entering functions.

Use `lfence` to guard function transitions

An `lfence` instruction can be used to prevent subsequent loads from speculatively executing until all prior mispredicted predicates have resolved. We can use this broader barrier to speculative loads executing between functions. We emit it in the entry block to handle calls, and prior to each return. This approach also has the advantage of providing the strongest degree of mitigation when mixed with unmitigated code by halting all misspeculation entering a function which is mitigated, regardless of what occurred in the caller. However, such a mixture is inherently more risky. Whether this kind of mixture is a sufficient mitigation requires careful analysis.

Unfortunately, experimental results indicate that the performance overhead of this approach is very high for certain patterns of code. A classic example is any form of recursive evaluation engine. The hot, rapid call and return sequences exhibit dramatic performance loss when mitigated with `lfence`. This component alone can regress performance by 2x or more, making it an unpleasant tradeoff even when only used in a mixture of code.

Use an internal TLS location to pass predicate state

We can define a special thread-local value to hold the predicate state between functions. This avoids direct ABI implications by using a side channel between callers and callees to communicate the predicate state. It also allows implicit zero-initialization of the state, which allows non-checked code to be the first code executed.

However, this requires a load from TLS in the entry block, a store to TLS before every call and every ret, and a load from TLS after every call. As a consequence it is expected to be substantially more expensive even than using `%rsp` and potentially `lfence` within the function entry block.

Define a new ABI and/or calling convention

We could define a new ABI and/or calling convention to explicitly pass the predicate state in and out of functions. This may be interesting if none of the alternatives have adequate performance, but it makes deployment and adoption dramatically more complex, and potentially infeasible.

4.44.5 High-Level Alternative Mitigation Strategies

There are completely different alternative approaches to mitigating variant 1 attacks. [Most discussion](#) so far focuses on mitigating specific known attackable components in the Linux kernel (or other kernels) by manually rewriting the code to contain an instruction sequence that is not vulnerable. For x86 systems this is done by either injecting an `lfence` instruction along the code path which would leak data if executed speculatively or by rewriting memory accesses to have branch-less masking to a known safe region. On Intel systems, `lfence` will prevent the speculative load of secret data. On AMD systems `lfence` is currently a no-op, but can be made dispatch-serializing by setting an MSR, and thus preclude misspeculation of the code path ([mitigation G-2 + V1-1](#)).

However, this relies on finding and enumerating all possible points in code which could be attacked to leak information. While in some cases static analysis is effective at doing this at scale, in many cases it still relies on human judgement to evaluate whether code might be vulnerable. Especially for software systems which receive less detailed scrutiny but remain sensitive to these attacks, this seems like an impractical security model. We need an automatic and systematic mitigation strategy.

Automatic `lfence` on Conditional Edges

A natural way to scale up the existing hand-coded mitigations is simply to inject an `lfence` instruction into both the target and fallthrough destinations of every conditional branch. This ensures that no predicate or bounds check can be bypassed speculatively. However, the performance overhead of this approach is, simply put, catastrophic. Yet it remains the only truly "secure by default" approach known prior to this effort and serves as the baseline for performance.

One attempt to address the performance overhead of this and make it more realistic to deploy is [MSVC's /Qspectre switch](#). Their technique is to use static analysis within the compiler to only insert `lfence` instructions into conditional edges at risk of attack. However, [initial analysis](#) has shown that this approach is incomplete and only catches a small and limited subset of attackable patterns which happen to resemble very closely the initial proofs of concept. As such, while its performance is acceptable, it does not appear to be an adequate systematic mitigation.

4.44.6 Performance Overhead

The performance overhead of this style of comprehensive mitigation is very high. However, it compares very favorably with previously recommended approaches such as the `lfence` instruction. Just as users can restrict the scope of `lfence` to control its performance impact, this mitigation technique could be restricted in scope as well.

However, it is important to understand what it would cost to get a fully mitigated baseline. Here we assume targeting a Haswell (or newer) processor and using all of the tricks to improve performance (so leaves the low 2gb unprotected and +/- 2gb surrounding any PC in the program). We ran both Google's microbenchmark suite and a large highly-tuned server built using ThinLTO and PGO. All were built with `-march=haswell` to give access to BMI2 instructions, and benchmarks were run on large Haswell servers. We collected data both with an `lfence`-based mitigation and load hardening as presented here. The summary is that mitigating with load hardening is 1.77x faster than mitigating with `lfence`, and the overhead of load hardening compared to a normal program is likely between a 10% overhead and a 50% overhead with most large applications seeing a 30% overhead or less.

Benchmark	`lfence`	Load Hardening	Mitigated Speedup		-----:	-----:	-----:
-----:		Google microbenchmark suite	-74.8%	-36.4%	**2.5x**		Large server QPS (using ThinLTO & PGO)
-62%	-29%	**1.8x**					

Below is a visualization of the microbenchmark suite results which helps show the distribution of results that is somewhat lost in the summary. The y-axis is a log-scale speedup ratio of load hardening relative to `lfence` (up -> faster -> better). Each box-and-whiskers represents one microbenchmark which may have many different metrics measured. The red line marks the median, the box marks the first and third quartiles, and the whiskers mark the min and max.

We don't yet have benchmark data on SPEC or the LLVM test suite, but we can work on getting that. Still, the above should give a pretty clear characterization of the performance, and specific benchmarks are unlikely to reveal especially interesting properties.

Future Work: Fine Grained Control and API-Integration

The performance overhead of this technique is likely to be very significant and something users wish to control or reduce. There are interesting options here that impact the implementation strategy used.

One particularly appealing option is to allow both opt-in and opt-out of this mitigation at reasonably fine granularity such as on a per-function basis, including intelligent handling of inlining decisions -- protected code can be prevented from inlining into unprotected code, and unprotected code will become protected when inlined into protected code. For systems where only a limited set of code is reachable by externally controlled inputs, it may be possible to limit the scope of mitigation through such mechanisms without compromising the application's overall security. The performance impact may also be focused in a few key functions that can be hand-mitigated in ways that have lower performance overhead while the remainder of the application receives automatic protection.

For both limiting the scope of mitigation or manually mitigating hot functions, there needs to be some support for mixing mitigated and unmitigated code without completely defeating the mitigation. For the first use case, it would be particularly desirable that mitigated code remains safe when being called during misspeculation from unmitigated code.

For the second use case, it may be important to connect the automatic mitigation technique to explicit mitigation APIs such as what is described in <http://wg21.link/p0928> (or any other eventual API) so that there is a clean way to switch

from automatic to manual mitigation without immediately exposing a hole. However, the design for how to do this is hard to come up with until the APIs are better established. We will revisit this as those APIs mature.

4.45 Stack Safety Analysis

4.45.1 Introduction

The Stack Safety Analysis determines if stack allocated variables can be considered 'safe' from memory access bugs.

The primary purpose of the analysis is to be used by sanitizers to avoid unnecessary instrumentation of 'safe' variables. SafeStack is going to be the first user.

'safe' variables can be defined as variables that can not be used out-of-scope (e.g. use-after-return) or accessed out of bounds. In the future it can be extended to track other variable properties. E.g. we plan to extend implementation with a check to make sure that variable is always initialized before every read to optimize use-of-uninitialized-memory checks.

4.45.2 How it works

The analysis is implemented in two stages:

The intra-procedural, or 'local', stage performs a depth-first search inside functions to collect all uses of each alloca, including loads/stores and uses as arguments functions. After this stage we know which parts of the alloca are used by functions itself but we don't know what happens after it is passed as an argument to another function.

The inter-procedural, or 'global', stage, resolves what happens to allocas after they are passed as function arguments. This stage performs a depth-first search on function calls inside a single module and propagates allocas usage through functions calls.

When used with ThinLTO, the global stage performs a whole program analysis over the Module Summary Index.

4.45.3 Testing

The analysis is covered with lit tests.

We expect that users can tolerate false classification of variables as 'unsafe' when in-fact it's 'safe'. This may lead to inefficient code. However, we can't accept false 'safe' classification which may cause sanitizers to miss actual bugs in instrumented code. To avoid that we want additional validation tool.

AddressSanitizer may help with this validation. We can instrument all variables as usual but additionally store stack-safe information in the `ASanStackVariableDescription`. Then if AddressSanitizer detects a bug on a 'safe' variable we can produce an additional report to let the user know that probably Stack Safety Analysis failed and we should check for a bug in the compiler.

Writing an LLVM Pass Information on how to write LLVM transformations and analyses.

Writing an LLVM Backend Information on how to write LLVM backends for machine targets.

The LLVM Target-Independent Code Generator The design and implementation of the LLVM code generator. Useful if you are working on retargeting LLVM to a new architecture, designing a new codegen pass, or enhancing existing components.

Machine IR (MIR) Format Reference Manual A reference manual for the MIR serialization format, which is used to test LLVM's code generation passes.

TableGen Describes the TableGen tool, which is used heavily by the LLVM code generator.

LLVM Alias Analysis Infrastructure Information on how to write a new alias analysis implementation or how to use existing analyses.

MemorySSA Information about the MemorySSA utility in LLVM, as well as how to use it.

Garbage Collection with LLVM The interfaces source-language compilers should use for compiling GC'd programs.

Source Level Debugging with LLVM This document describes the design and philosophy behind the LLVM source-level debugger.

Auto-Vectorization in LLVM This document describes the current status of vectorization in LLVM.

Exception Handling in LLVM This document describes the design and implementation of exception handling in LLVM.

How To Add A Constrained Floating-Point Intrinsic Gives the steps necessary when adding a new constrained math intrinsic to LLVM.

LLVM bugpoint tool: design and usage Automatic bug finder and test-case reducer description and usage information.

LLVM Bitcode File Format This describes the file format and encoding used for LLVM "bc" files.

Support Library This document describes the LLVM Support Library (`lib/Support`) and how to keep LLVM source code portable

LLVM Link Time Optimization: Design and Implementation This document describes the interface between LLVM intermodular optimizer and the linker and its design

The LLVM gold plugin How to build your programs with link-time optimization on Linux.

Debugging JIT-ed Code With GDB How to debug JITed code with GDB.

MCJIT Design and Implementation Describes the inner workings of MCJIT execution engine.

ORC Design and Implementation Describes the design and implementation of the ORC APIs, including some usage examples, and a guide for users transitioning from ORCv1 to ORCv2.

LLVM Branch Weight Metadata Provides information about Branch Prediction Information.

LLVM Block Frequency Terminology Provides information about terminology used in the `BlockFrequencyInfo` analysis pass.

Segmented Stacks in LLVM This document describes segmented stacks and how they are used in LLVM.

LLVM's Optional Rich Disassembly Output This document describes the optional rich disassembly output syntax.

How To Use Attributes Answers some questions about the new Attributes infrastructure.

User Guide for NVPTX Back-end This document describes using the NVPTX backend to compile GPU kernels.

User Guide for AMDGPU Backend This document describes using the AMDGPU backend to compile GPU kernels.

Stack maps and patch points in LLVM LLVM support for mapping instruction addresses to the location of values and allowing code to be patched.

Using ARM NEON instructions in big endian mode LLVM's support for generating NEON instructions on big endian ARM targets is somewhat nonintuitive. This document explains the implementation and rationale.

LLVM Code Coverage Mapping Format This describes the format and encoding used for LLVM's code coverage mapping.

Garbage Collection Safepoints in LLVM This describes a set of experimental extensions for garbage collection support.

MergeFunctions pass, how it works Describes functions merging optimization.

Design and Usage of the InAlloca Attribute Description of the `inalloca` argument attribute.

FaultMaps and implicit checks LLVM support for folding control flow into faulting machine instructions.

Compiling CUDA with clang LLVM support for CUDA.

Coroutines in LLVM LLVM support for coroutines.

Global Instruction Selection This describes the prototype instruction selection replacement, GlobalISel.

XRay Instrumentation High-level documentation of how to use XRay in LLVM.

Debugging with XRay An example of how to debug an application with XRay.

The Microsoft PDB File Format A detailed description of the Microsoft PDB (Program Database) file format.

Control Flow Verification Tool Design Document A description of the verification tool for Control Flow Integrity.

Speculative Load Hardening A description of the Speculative Load Hardening mitigation for Spectre v1.

Stack Safety Analysis This document describes the design of the stack safety analysis of local variables.

DEVELOPMENT PROCESS DOCUMENTATION

Information about LLVM's development process.

5.1 Contributing to LLVM

Thank you for your interest in contributing to LLVM! There are multiple ways to contribute, and we appreciate all contributions. In case you have questions, you can either use the [Developer's List \(llvm-dev\)](#) or the #llvm channel on [irc.oftc.net](#).

If you want to contribute code, please familiarize yourself with the [LLVM Developer Policy](#).

- *Ways to Contribute*
 - *Bug Reports*
 - *Bug Fixes*
 - *Bigger Pieces of Work*
- *How to Submit a Patch*
- *Helpful Information About LLVM*

5.1.1 Ways to Contribute

Bug Reports

If you are working with LLVM and run into a bug, we definitely want to know about it. Please let us know and follow the instructions in [How to submit an LLVM bug report](#) to create a bug report.

Bug Fixes

If you are interested in contributing code to LLVM, bugs labeled with the [beginner keyword](#) in the [bug tracker](#) are a good way to get familiar with the code base. If you are interested in fixing a bug, please create an account for the bug tracker and assign it to yourself, to let people know you are working on it.

Then try to reproduce and fix the bug with upstream LLVM. Start by building LLVM from source as described in [Getting Started with the LLVM System](#) and use the built binaries to reproduce the failure described in the bug. Use a debug build (`-DCMAKE_BUILD_TYPE=Debug`) or a build with assertions (`-DLLVM_ENABLE_ASSERTIONS=On`, enabled for Debug builds).

Bigger Pieces of Work

In case you are interested in taking on a bigger piece of work, a list of interesting projects is maintained at the [LLVM's Open Projects](#) page. In case you are interested in working on any of these projects, please send a mail to the [LLVM Developer's mailing list](#), so that we know the project is being worked on.

5.1.2 How to Submit a Patch

Once you have a patch ready, it is time to submit it. The patch should:

- include a small unit test
- conform to the [LLVM Coding Standards](#). You can use the [clang-format-diff.py](#) or [git-clang-format](#) tools to automatically format your patch properly.
- not contain any unrelated changes
- be an isolated change. Independent changes should be submitted as separate patches as this makes reviewing easier.

To get a patch accepted, it has to be reviewed by the LLVM community. This can be done using [LLVM's Phabricator](#) or the `llvm-commits` mailing list. Please follow [Phabricator#requesting-a-review-via-the-web-interface](#) to request a review using Phabricator.

To make sure the right people see your patch, please select suitable reviewers and add them to your patch when requesting a review. Suitable reviewers are the code owner (see `CODE_OWNERS.txt`) and other people doing work in the area your patch touches. If you are using Phabricator, add them to the *Reviewers* field when creating a review and if you are using *llvm-commits*, add them to the CC of your email.

A reviewer may request changes or ask questions during the review. If you are uncertain on how to provide test cases, documentation, etc., feel free to ask for guidance during the review. Please address the feedback and re-post an updated version of your patch. This cycle continues until all requests and comments have been addressed and a reviewer accepts the patch with a *Looks good to me* or *LGTM*. Once that is done the change can be committed. If you do not have commit access, please let people know during the review and someone should commit it on your behalf.

If you have received no comments on your patch for a week, you can request a review by 'ping'ing a patch by responding to the email thread containing the patch, or the Phabricator review with "Ping." The common courtesy 'ping' rate is once a week. Please remember that you are asking for valuable time from other professional developers.

5.1.3 Helpful Information About LLVM

LLVM's documentation provides a wealth of information about LLVM's internals as well as various user guides. The pages listed below should provide a good overview of LLVM's high-level design, as well as its internals:

Getting Started with the LLVM System Discusses how to get up and running quickly with the LLVM infrastructure. Everything from unpacking and compilation of the distribution to execution of some tools.

LLVM Language Reference Manual Defines the LLVM intermediate representation.

LLVM Programmer's Manual Introduction to the general layout of the LLVM sourcebase, important classes and APIs, and some tips & tricks.

Subsystem Documentation A collection of pages documenting various subsystems of LLVM.

LLVM for Grad Students This is an introduction to the LLVM infrastructure by Adrian Sampson. While it has been written for grad students, it provides a good, compact overview of LLVM's architecture, LLVM's IR and how to write a new pass.

Intro to LLVM Book chapter providing a compiler hacker's introduction to LLVM.

5.2 LLVM Developer Policy

- *Copyright, License, and Patents*
 - *Copyright*
 - *Relicensing*

- *New LLVM Project License Framework*
- *Patents*
- *Legacy License Structure*

5.2.1 Introduction

This document contains the LLVM Developer Policy which defines the project's policy towards developers and their contributions. The intent of this policy is to eliminate miscommunication, rework, and confusion that might arise from the distributed nature of LLVM's development. By stating the policy in clear terms, we hope each developer can know ahead of time what to expect when making LLVM contributions. This policy covers all [llvm.org](#) subprojects, including Clang, LLDB, libc++, etc.

This policy is also designed to accomplish the following objectives:

1. Attract both users and developers to the LLVM project.
2. Make life as simple and easy for contributors as possible.
3. Keep the top of tree as stable as possible.
4. Establish awareness of the project's *copyright, license, and patent policies* with contributors to the project.

This policy is aimed at frequent contributors to LLVM. People interested in contributing one-off patches can do so in an informal way by sending them to the [llvm-commits mailing list](#) and engaging another developer to see it through the process.

5.2.2 Developer Policies

This section contains policies that pertain to frequent LLVM developers. We always welcome *one-off patches* from people who do not routinely contribute to LLVM, but we expect more from frequent contributors to keep the system as efficient as possible for everyone. Frequent LLVM contributors are expected to meet the following requirements in order for LLVM to maintain a high standard of quality.

Stay Informed

Developers should stay informed by reading at least the "dev" mailing list for the projects you are interested in, such as [llvm-dev](#) for LLVM, [cfe-dev](#) for Clang, or [lldb-dev](#) for LLDB. If you are doing anything more than just casual work on LLVM, it is suggested that you also subscribe to the "commits" mailing list for the subproject you're interested in, such as [llvm-commits](#), [cfe-commits](#), or [lldb-commits](#). Reading the "commits" list and paying attention to changes being made by others is a good way to see what other people are interested in and watching the flow of the project as a whole.

We recommend that active developers register an email account with [LLVM Bugzilla](#) and preferably subscribe to the [llvm-bugs](#) email list to keep track of bugs and enhancements occurring in LLVM. We really appreciate people who are proactive at catching incoming bugs in their components and dealing with them promptly.

Please be aware that all public LLVM mailing lists are public and archived, and that notices of confidentiality or non-disclosure cannot be respected.

Making and Submitting a Patch

When making a patch for review, the goal is to make it as easy for the reviewer to read it as possible. As such, we recommend that you:

1. Make your patch against git master, not a branch, and not an old version of LLVM. This makes it easy to apply the patch. For information on how to clone from git, please see the *Getting Started Guide*.
2. Similarly, patches should be submitted soon after they are generated. Old patches may not apply correctly if the underlying code changes between the time the patch was created and the time it is applied.
3. Patches should be made with `git format-patch`, or similar. If you use a different tool, make sure it uses the `diff -u` format and that it doesn't contain clutter which makes it hard to read.

Once your patch is ready, submit it by emailing it to the appropriate project's commit mailing list (or commit it directly if applicable). Alternatively, some patches get sent to the project's development list or component of the LLVM bug tracker, but the commit list is the primary place for reviews and should generally be preferred.

When sending a patch to a mailing list, it is a good idea to send it as an *attachment* to the message, not embedded into the text of the message. This ensures that your mailer will not mangle the patch when it sends it (e.g. by making whitespace changes or by wrapping lines).

For Thunderbird users: Before submitting a patch, please open *Preferences > Advanced > General > Config Editor*, find the key `mail.content_disposition_type`, and set its value to 1. Without this setting, Thunderbird sends your attachment using `Content-Disposition: inline` rather than `Content-Disposition: attachment`. Apple Mail gamely displays such a file inline, making it difficult to work with for reviewers using that program.

When submitting patches, please do not add confidentiality or non-disclosure notices to the patches themselves. These notices conflict with the LLVM licensing terms and may result in your contribution being excluded.

Code Reviews

LLVM has a code review policy. Code review is one way to increase the quality of software. We generally follow these policies:

1. All developers are required to have significant changes reviewed before they are committed to the repository.
2. Code reviews are conducted by email on the relevant project's commit mailing list, or alternatively on the project's development list or bug tracker.
3. Code can be reviewed either before it is committed or after. We expect major changes to be reviewed before being committed, but smaller changes (or changes where the developer owns the component) can be reviewed after commit.
4. The developer responsible for a code change is also responsible for making all necessary review-related changes.
5. Code review can be an iterative process, which continues until the patch is ready to be committed. Specifically, once a patch is sent out for review, it needs an explicit "looks good" before it is submitted. Do not assume silent approval, or request active objections to the patch with a deadline.

Sometimes code reviews will take longer than you would hope for, especially for larger features. Accepted ways to speed up review times for your patches are:

- Review other people's patches. If you help out, everybody will be more willing to do the same for you; goodwill is our currency.
- Ping the patch. If it is urgent, provide reasons why it is important to you to get this patch landed and ping it every couple of days. If it is not urgent, the common courtesy ping rate is one week. Remember that you're asking for valuable time from other professional developers.

- Ask for help on IRC. Developers on IRC will be able to either help you directly, or tell you who might be a good reviewer.
- Split your patch into multiple smaller patches that build on each other. The smaller your patch, the higher the probability that somebody will take a quick look at it.

Developers should participate in code reviews as both reviewers and reviewees. If someone is kind enough to review your code, you should return the favor for someone else. Note that anyone is welcome to review and give feedback on a patch, but only people with Subversion write access can approve it.

There is a web based code review tool that can optionally be used for code reviews. See [Code Reviews with Phabricator](#).

Code Owners

The LLVM Project relies on two features of its process to maintain rapid development in addition to the high quality of its source base: the combination of code review plus post-commit review for trusted maintainers. Having both is a great way for the project to take advantage of the fact that most people do the right thing most of the time, and only commit patches without pre-commit review when they are confident they are right.

The trick to this is that the project has to guarantee that all patches that are committed are reviewed after they go in: you don't want everyone to assume someone else will review it, allowing the patch to go unreviewed. To solve this problem, we have a notion of an 'owner' for a piece of the code. The sole responsibility of a code owner is to ensure that a commit to their area of the code is appropriately reviewed, either by themselves or by someone else. The list of current code owners can be found in the file [CODE_OWNERS.TXT](#) in the root of the LLVM source tree.

Note that code ownership is completely different than reviewers: anyone can review a piece of code, and we welcome code review from anyone who is interested. Code owners are the "last line of defense" to guarantee that all patches that are committed are actually reviewed.

Being a code owner is a somewhat unglamorous position, but it is incredibly important for the ongoing success of the project. Because people get busy, interests change, and unexpected things happen, code ownership is purely opt-in, and anyone can choose to resign their "title" at any time. For now, we do not have an official policy on how one gets elected to be a code owner.

Test Cases

Developers are required to create test cases for any bugs fixed and any new features added. Some tips for getting your testcase approved:

- All feature and regression test cases are added to the `llvm/test` directory. The appropriate sub-directory should be selected (see the [Testing Guide](#) for details).
- Test cases should be written in *LLVM assembly language*.
- Test cases, especially for regressions, should be reduced as much as possible, by [bugpoint](#) or manually. It is unacceptable to place an entire failing program into `llvm/test` as this creates a *time-to-test* burden on all developers. Please keep them short.

Note that `llvm/test` and `clang/test` are designed for regression and small feature tests only. More extensive test cases (e.g., entire applications, benchmarks, etc) should be added to the `llvm-test` test suite. The `llvm-test` suite is for coverage (correctness, performance, etc) testing, not feature or regression testing.

Quality

The minimum quality standards that any change must satisfy before being committed to the main development branch are:

1. Code must adhere to the [LLVM Coding Standards](#).
2. Code must compile cleanly (no errors, no warnings) on at least one platform.
3. Bug fixes and new features should *include a testcase* so we know if the fix/feature ever regresses in the future.
4. Code must pass the `llvm/test` test suite.
5. The code must not cause regressions on a reasonable subset of `llvm-test`, where "reasonable" depends on the contributor's judgement and the scope of the change (more invasive changes require more testing). A reasonable subset might be something like `"llvm-test/MultiSource/Benchmarks"`.

Additionally, the committer is responsible for addressing any problems found in the future that the change is responsible for. For example:

- The code should compile cleanly on all supported platforms.
- The changes should not cause any correctness regressions in the `llvm-test` suite and must not cause any major performance regressions.
- The change set should not cause performance or correctness regressions for the LLVM tools.
- The changes should not cause performance or correctness regressions in code compiled by LLVM on all applicable targets.
- You are expected to address any [Bugzilla bugs](#) that result from your change.

We prefer for this to be handled before submission but understand that it isn't possible to test all of this for every submission. Our build bots and nightly testing infrastructure normally finds these problems. A good rule of thumb is to check the nightly testers for regressions the day after your change. Build bots will directly email you if a group of commits that included yours caused a failure. You are expected to check the build bot messages to see if they are your fault and, if so, fix the breakage.

Commits that violate these quality standards (e.g. are very broken) may be reverted. This is necessary when the change blocks other developers from making progress. The developer is welcome to re-commit the change after the problem has been fixed.

Commit messages

Although we don't enforce the format of commit messages, we prefer that you follow these guidelines to help review, search in logs, email formatting and so on. These guidelines are very similar to rules used by other open source projects.

Most importantly, the contents of the message should be carefully written to convey the rationale of the change (without delving too much in detail). It also should avoid being vague or overly specific. For example, "bits were not set right" will leave the reviewer wondering about which bits, and why they weren't right, while "Correctly set overflow bits in `TargetInfo`" conveys almost all there is to the change.

Below are some guidelines about the format of the message itself:

- Separate the commit message into title, body and, if you're not the original author, a "Patch by" attribution line (see below).
- The title should be concise. Because all commits are emailed to the list with the first line as the subject, long titles are frowned upon. Short titles also look better in *git log*.

- When the changes are restricted to a specific part of the code (e.g. a back-end or optimization pass), it is customary to add a tag to the beginning of the line in square brackets. For example, "[SCEV] ..." or "[OpenMP] ...". This helps email filters and searches for post-commit reviews.
- The body, if it exists, should be separated from the title by an empty line.
- The body should be concise, but explanatory, including a complete reasoning. Unless it is required to understand the change, examples, code snippets and gory details should be left to bug comments, web review or the mailing list.
- If the patch fixes a bug in bugzilla, please include the PR# in the message.
- *Attribution of Changes* should be in a separate line, after the end of the body, as simple as "Patch by John Doe.". This is how we officially handle attribution, and there are automated processes that rely on this format.
- Text formatting and spelling should follow the same rules as documentation and in-code comments, ex. capitalization, full stop, etc.
- If the commit is a bug fix on top of another recently committed patch, or a revert or reapply of a patch, include the svn revision number of the prior related commit. This could be as simple as "Revert rNNNN because it caused PR#".

For minor violations of these recommendations, the community normally favors reminding the contributor of this policy over reverting. Minor corrections and omissions can be handled by sending a reply to the commits mailing list.

Obtaining Commit Access

We grant commit access to contributors with a track record of submitting high quality patches. If you would like commit access, please send an email to [Chris](#) with the following information:

1. The user name you want to commit with, e.g. "hacker".
2. The full name and email address you want message to llvm-commits to come from, e.g. "J. Random Hacker <hacker@yoyodyne.com>".
3. A "password hash" of the password you want to use, e.g. "2ACR96qjUqsyM". Note that you don't ever tell us what your password is; you just give it to us in an encrypted form. To get this, run "htpasswd" (a utility that comes with apache) in *crypt* mode (often enabled with "-d"), or find a web page that will do it for you. Note that our system does not work with MD5 hashes. These are significantly longer than a crypt hash - e.g. "\$apr1\$vea6bBV2\$Z8IFx.AfeD8Lhq1ZFqJer0", we only accept the shorter crypt hash.

Once you've been granted commit access, you should be able to check out an LLVM tree with an SVN URL of "[https://username@llvm.org/...](https://username@llvm.org/)" instead of the normal anonymous URL of "[http://llvm.org/...](http://llvm.org/)". The first time you commit you'll have to type in your password. Note that you may get a warning from SVN about an untrusted key; you can ignore this. To verify that your commit access works, please do a test commit (e.g. change a comment or add a blank line). Your first commit to a repository may require the autogenerated email to be approved by a moderator of the mailing list. This is normal and will be done when the mailing list owner has time.

If you have recently been granted commit access, these policies apply:

1. You are granted *commit-after-approval* to all parts of LLVM. To get approval, submit a *patch* to [llvm-commits](#). When approved, you may commit it yourself.
2. You are allowed to commit patches without approval which you think are obvious. This is clearly a subjective decision --- we simply expect you to use good judgement. Examples include: fixing build breakage, reverting obviously broken patches, documentation/comment changes, any other minor changes. Avoid committing formatting- or whitespace-only changes outside of code you plan to make subsequent changes to. Also, try to separate formatting or whitespace changes from functional changes, either by correcting the format first (ideally) or afterward. Such changes should be highly localized and the commit message should clearly state that the commit is not intended to change functionality, usually by stating it is *NFC*.

3. You are allowed to commit patches without approval to those portions of LLVM that you have contributed or maintain (i.e., have been assigned responsibility for), with the proviso that such commits must not break the build. This is a "trust but verify" policy, and commits of this nature are reviewed after they are committed.
4. Multiple violations of these policies or a single egregious violation may cause commit access to be revoked.

In any case, your changes are still subject to *code review* (either before or after they are committed, depending on the nature of the change). You are encouraged to review other peoples' patches as well, but you aren't required to do so.

Making a Major Change

When a developer begins a major new project with the aim of contributing it back to LLVM, they should inform the community with an email to the [llvm-dev](#) email list, to the extent possible. The reason for this is to:

1. keep the community informed about future changes to LLVM,
2. avoid duplication of effort by preventing multiple parties working on the same thing and not knowing about it, and
3. ensure that any technical issues around the proposed work are discussed and resolved before any significant work is done.

The design of LLVM is carefully controlled to ensure that all the pieces fit together well and are as consistent as possible. If you plan to make a major change to the way LLVM works or want to add a major new extension, it is a good idea to get consensus with the development community before you start working on it.

Once the design of the new feature is finalized, the work itself should be done as a series of *incremental changes*, not as a long-term development branch.

Incremental Development

In the LLVM project, we do all significant changes as a series of incremental patches. We have a strong dislike for huge changes or long-term development branches. Long-term development branches have a number of drawbacks:

1. Branches must have mainline merged into them periodically. If the branch development and mainline development occur in the same pieces of code, resolving merge conflicts can take a lot of time.
2. Other people in the community tend to ignore work on branches.
3. Huge changes (produced when a branch is merged back onto mainline) are extremely difficult to *code review*.
4. Branches are not routinely tested by our nightly tester infrastructure.
5. Changes developed as monolithic large changes often don't work until the entire set of changes is done. Breaking it down into a set of smaller changes increases the odds that any of the work will be committed to the main repository.

To address these problems, LLVM uses an incremental development style and we require contributors to follow this practice when making a large/invasive change. Some tips:

- Large/invasive changes usually have a number of secondary changes that are required before the big change can be made (e.g. API cleanup, etc). These sorts of changes can often be done before the major change is done, independently of that work.
- The remaining inter-related work should be decomposed into unrelated sets of changes if possible. Once this is done, define the first increment and get consensus on what the end goal of the change is.
- Each change in the set can be stand alone (e.g. to fix a bug), or part of a planned series of changes that works towards the development goal.

- Each change should be kept as small as possible. This simplifies your work (into a logical progression), simplifies code review and reduces the chance that you will get negative feedback on the change. Small increments also facilitate the maintenance of a high quality code base.
- Often, an independent precursor to a big change is to add a new API and slowly migrate clients to use the new API. Each change to use the new API is often "obvious" and can be committed without review. Once the new API is in place and used, it is much easier to replace the underlying implementation of the API. This implementation change is logically separate from the API change.

If you are interested in making a large change, and this scares you, please make sure to first *discuss the change/gather consensus* then ask about the best way to go about making the change.

Attribution of Changes

When contributors submit a patch to an LLVM project, other developers with commit access may commit it for the author once appropriate (based on the progression of code review, etc.). When doing so, it is important to retain correct attribution of contributions to their contributors. However, we do not want the source code to be littered with random attributions "this code written by J. Random Hacker" (this is noisy and distracting). In practice, the revision control system keeps a perfect history of who changed what, and the CREDITS.txt file describes higher-level contributions. If you commit a patch for someone else, please follow the attribution of changes in the simple manner as outlined by the *commit messages* section. Overall, please do not add contributor names to the source code.

Also, don't commit patches authored by others unless they have submitted the patch to the project or you have been authorized to submit them on their behalf (you work together and your company authorized you to contribute the patches, etc.). The author should first submit them to the relevant project's commit list, development list, or LLVM bug tracker component. If someone sends you a patch privately, encourage them to submit it to the appropriate list first.

IR Backwards Compatibility

When the IR format has to be changed, keep in mind that we try to maintain some backwards compatibility. The rules are intended as a balance between convenience for llvm users and not imposing a big burden on llvm developers:

- The textual format is not backwards compatible. We don't change it too often, but there are no specific promises.
- Additions and changes to the IR should be reflected in `test/Bitcode/compatibility.ll`.
- The current LLVM version supports loading any bitcode since version 3.0.
- After each X.Y release, `compatibility.ll` must be copied to `compatibility-X.Y.ll`. The corresponding bitcode file should be assembled using the X.Y build and committed as `compatibility-X.Y.ll.bc`.
- Newer releases can ignore features from older releases, but they cannot miscompile them. For example, if `nsw` is ever replaced with something else, dropping it would be a valid way to upgrade the IR.
- Debug metadata is special in that it is currently dropped during upgrades.
- Non-debug metadata is defined to be safe to drop, so a valid way to upgrade it is to drop it. That is not very user friendly and a bit more effort is expected, but no promises are made.

C API Changes

- **Stability Guarantees:** The C API is, in general, a "best effort" for stability. This means that we make every attempt to keep the C API stable, but that stability will be limited by the abstractness of the interface and the stability of the C++ API that it wraps. In practice, this means that things like "create debug info" or "create this type of instruction" are likely to be less stable than "take this IR file and JIT it for my current machine".
- **Release stability:** We won't break the C API on the release branch with patches that go on that branch, with the exception that we will fix an unintentional C API break that will keep the release consistent with both the previous and next release.
- **Testing:** Patches to the C API are expected to come with tests just like any other patch.
- **Including new things into the API:** If an LLVM subcomponent has a C API already included, then expanding that C API is acceptable. Adding C API for subcomponents that don't currently have one needs to be discussed on the mailing list for design and maintainability feedback prior to implementation.
- **Documentation:** Any changes to the C API are required to be documented in the release notes so that it's clear to external users who do not follow the project how the C API is changing and evolving.

New Targets

LLVM is very receptive to new targets, even experimental ones, but a number of problems can appear when adding new large portions of code, and back-ends are normally added in bulk. We have found that landing large pieces of new code and then trying to fix emergent problems in-tree is problematic for a variety of reasons.

For these reasons, new targets are *always* added as *experimental* until they can be proven stable, and later moved to non-experimental. The difference between both classes is that experimental targets are not built by default (need to be added to `-DLLVM_TARGETS_TO_BUILD` at CMake time).

The basic rules for a back-end to be upstreamed in **experimental** mode are:

- Every target must have a *code owner*. The `CODE_OWNERS.TXT` file has to be updated as part of the first merge. The code owner makes sure that changes to the target get reviewed and steers the overall effort.
- There must be an active community behind the target. This community will help maintain the target by providing buildbots, fixing bugs, answering the LLVM community's questions and making sure the new target doesn't break any of the other targets, or generic code. This behavior is expected to continue throughout the lifetime of the target's code.
- The code must be free of contentious issues, for example, large changes in how the IR behaves or should be formed by the front-ends, unless agreed by the majority of the community via refactoring of the (*IR standard*) **before** the merge of the new target changes, following the *IR Backwards Compatibility*.
- The code conforms to all of the policies laid out in this developer policy document, including license, patent, and coding standards.
- The target should have either reasonable documentation on how it works (ISA, ABI, etc.) or a publicly available simulator/hardware (either free or cheap enough) - preferably both. This allows developers to validate assumptions, understand constraints and review code that can affect the target.

In addition, the rules for a back-end to be promoted to **official** are:

- The target must have addressed every other minimum requirement and have been stable in tree for at least 3 months. This cool down period is to make sure that the back-end and the target community can endure continuous upstream development for the foreseeable future.
- The target's code must have been completely adapted to this policy as well as the *coding standards*. Any exceptions that were made to move into experimental mode must have been fixed **before** becoming official.

- The test coverage needs to be broad and well written (small tests, well documented). The build target `check-all` must pass with the new target built, and where applicable, the `test-suite` must also pass without errors, in at least one configuration (publicly demonstrated, for example, via buildbots).
- Public buildbots need to be created and actively maintained, unless the target requires no additional buildbots (ex. `check-all` covers all tests). The more relevant and public the new target's CI infrastructure is, the more the LLVM community will embrace it.

To **continue** as a supported and official target:

- The maintainer(s) must continue following these rules throughout the lifetime of the target. Continuous violations of aforementioned rules and policies could lead to complete removal of the target from the code base.
- Degradation in support, documentation or test coverage will make the target as nuisance to other targets and be considered a candidate for deprecation and ultimately removed.

In essences, these rules are necessary for targets to gain and retain their status, but also markers to define bit-rot, and will be used to clean up the tree from unmaintained targets.

Updating Toolchain Requirements

We intend to require newer toolchains as time goes by. This means LLVM's codebase can use newer versions of C++ as they get standardized. Requiring newer toolchains to build LLVM can be painful for those building LLVM; therefore, it will only be done through the following process:

- Generally, try to support LLVM and GCC versions from the last 3 years at a minimum. This time-based guideline is not strict: we may support much older compilers, or decide to support fewer versions.
- An RFC is sent to the [llvm-dev mailing list](#)
 - Detail upsides of the version increase (e.g. which newer C++ language or library features LLVM should use; avoid miscompiles in particular compiler versions, etc).
 - Detail downsides on important platforms (e.g. Ubuntu LTS status).
- Once the RFC reaches consensus, update the CMake toolchain version checks as well as the [getting started](#) guide. We want to soft-error when developers compile LLVM. We say "soft-error" because the error can be turned into a warning using a CMake flag. This is an important step: LLVM still doesn't have code which requires the new toolchains, but it soon will. If you compile LLVM but don't read the mailing list, we should tell you!
- Ensure that at least one LLVM release has had this soft-error. Not all developers compile LLVM top-of-tree. These release-bound developers should also be told about upcoming changes.
- Turn the soft-error into a hard-error after said LLVM release has branched.
- Update the [coding standards](#) to allow the new features we've explicitly approved in the RFC.
- Start using the new features in LLVM's codebase.

Here's a [sample RFC](#) and the [corresponding change](#).

5.2.3 Copyright, License, and Patents

Note: This section deals with legal matters but does not provide legal advice. We are not lawyers --- please seek legal counsel from a licensed attorney.

This section addresses the issues of copyright, license and patents for the LLVM project. The copyright for the code is held by the contributors of the code. The code is licensed under permissive *open source licensing terms*, namely the Apache 2 license, which includes a copyright and *patent license*. When you contribute code to the LLVM project, you license it under these terms.

If you have questions or comments about these topics, please contact the [LLVM Developer's Mailing List](#). However, please realize that most compiler developers are not lawyers, and therefore you will not be getting official legal advice.

Copyright

The LLVM project does not collect copyright assignments, which means that the copyright for the code in the project is held by the respective contributors. Because you (or your company) retain ownership of the code you contribute, you know it may only be used under the terms of the open source license you contributed it under: the license for your contributions cannot be changed in the future without your approval.

Because the LLVM project does not require copyright assignments, changing the LLVM license requires tracking down the contributors to LLVM and getting them to agree that a license change is acceptable for their contributions. We feel that a high burden for relicensing is good for the project, because contributors do not have to fear that their code will be used in a way with which they disagree.

Relicensing

The last paragraph notwithstanding, the LLVM Project is in the middle of a large effort to change licenses, which aims to solve several problems:

- The old licenses made it difficult to move code from (e.g.) the compiler to runtime libraries, because runtime libraries used a different license from the rest of the compiler.
- Some contributions were not submitted to LLVM due to concerns that the patent grant required by the project was overly broad.
- The patent grant was unique to the LLVM Project, not written by a lawyer, and was difficult to determine what protection was provided (if any).

The scope of relicensing is all code that is considered part of the LLVM project, including the main LLVM repository, runtime libraries (compiler_rt, OpenMP, etc), Polly, and all other subprojects. There are a few exceptions:

- Code imported from other projects (e.g. Google Test, Autoconf, etc) will remain as it is. This code isn't developed as part of the LLVM project, it is used by LLVM.
- Some subprojects are impractical or uninteresting to relicense (e.g. llvm-gcc and dragonegg). These will be split off from the LLVM project (e.g. to separate Github projects), allowing interested people to continue their development elsewhere.

To relicense LLVM, we will be seeking approval from all of the copyright holders of code in the repository, or potentially remove/rewrite code if we cannot. This is a large and challenging project which will take a significant amount of time to complete. In the interim, **all contributions to the project will be made under the terms of both the new license and the legacy license scheme** (each of which is described below). The exception to this is the legacy patent grant, which will not be required for new contributions.

When all of the code in the project has been converted to the new license or removed, we will drop the requirement to contribute under the legacy license. This will achieve the goal of having a single standardized license for the entire codebase.

If you are a prior contributor to LLVM and have not done so already, please do *TODO* to allow us to use your code. *Add a link to a separate page here, which is probably a click through web form or something like that. Details to be determined later.*

New LLVM Project License Framework

Contributions to LLVM are licensed under the [Apache License, Version 2.0](#), with two limited exceptions intended to ensure that LLVM is very permissively licensed. Collectively, the name of this license is "Apache 2.0 License with LLVM exceptions". The exceptions read:

```
---- LLVM Exceptions to the Apache 2.0 License ----
```

As an exception, **if, as** a result of your compiling your source code, portions of this Software are embedded into an Object form of such source code, you may redistribute such embedded portions **in** such Object form without complying **with** the conditions of Sections 4(a), 4(b) **and** 4(d) of the License.

In addition, **if** you combine **or** link compiled forms of this Software **with** software that **is** licensed under the GPLv2 ("Combined Software") **and if** a court of competent jurisdiction determines that the patent provision (Section 3), the indemnity provision (Section 9) **or** other Section of the License conflicts **with** the conditions of the GPLv2, you may retroactively **and** prospectively choose to deem waived **or** otherwise exclude such Section(s) of the License, but only **in** their entirety **and** only **with** respect to the Combined Software.

We intend to keep LLVM perpetually open source and available under a permissive license - this fosters the widest adoption of LLVM by **allowing commercial products to be derived from LLVM** with few restrictions and without a requirement for making any derived works also open source. In particular, LLVM's license is not a "copyleft" license like the GPL.

The "Apache 2.0 License with LLVM exceptions" allows you to:

- freely download and use LLVM (in whole or in part) for personal, internal, or commercial purposes.
- include LLVM in packages or distributions you create.
- combine LLVM with code licensed under every other major open source license (including BSD, MIT, GPLv2, GPLv3...).
- make changes to LLVM code without being required to contribute it back to the project - contributions are appreciated though!

However, it imposes these limitations on you:

- You must retain the copyright notice if you redistribute LLVM: You cannot strip the copyright headers off or replace them with your own.
- Binaries that include LLVM must reproduce the copyright notice (e.g. in an included README file or in an "About" box), unless the LLVM code was added as a by-product of compilation. For example, if an LLVM runtime library like `compiler_rt` or `libc++` was automatically included into your application by the compiler, you do not need to attribute it.
- You can't use our names to promote your products (LLVM derived or not) - though you can make truthful statements about your use of the LLVM code, without implying our sponsorship.

- There's no warranty on LLVM at all.

We want LLVM code to be widely used, and believe that this provides a model that is great for contributors and users of the project. For more information about the Apache 2.0 License, please see the [Apache License FAQ](#), maintained by the Apache Project.

Note: The LLVM Project includes some really old subprojects (dragonegg, llvm-gcc-4.0, and llvm-gcc-4.2), which are licensed under **GPL licenses**. This code is not actively maintained - it does not even build successfully. This code is cleanly separated into distinct SVN repositories from the rest of LLVM, and the LICENSE.txt files specifically indicate that they contain GPL code. When LLVM transitions from SVN to Git, we plan to drop these code bases from the new repository structure.

Patents

Section 3 of the Apache 2.0 license is a patent grant under which contributors of code to the project contribute the rights to use any of their patents that would otherwise be infringed by that code contribution (protecting uses of that code). Further, the patent grant is revoked from anyone who files a patent lawsuit about code in LLVM - this protects the community by providing a "patent commons" for the code base and reducing the odds of patent lawsuits in general.

The license specifically scopes which patents are included with code contributions. To help explain this, the [Apache License FAQ](#) explains this scope using some questions and answers, which we reproduce here for your convenience (for reference, the "ASF" is the Apache Software Foundation, the guidance still holds though):

Q1: If I own a patent and contribute to a Work, and, at the time my contribution is included in that Work, none of my patent's claims are subject to Apache's Grant of Patent License, is there a way any of those claims would later become subject to the Grant of Patent License solely due to subsequent contributions by other parties who are not licensees of that patent.

A1: No.

Q2: If at any time after my contribution, I am able to license other patent claims that would have been subject to Apache's Grant of Patent License if they were licenseable by me at the time of my contribution, do those other claims become subject to the Grant of Patent License?

A2: Yes.

Q3: If I own or control a licensable patent and contribute code to a specific Apache product, which of my patent claims are subject to Apache's Grant of Patent License?

A3: The only patent claims that are licensed to the ASF are those you own or have the right to license that read on your contribution or on the combination of your contribution with the specific Apache product to which you contributed as it existed at the time of your contribution. No additional patent claims become licensed as a result of subsequent combinations of your contribution with any other software. Note, however, that licensable patent claims include those that you acquire in the future, as long as they read on your original contribution as made at the original time. Once a patent claim is subject to Apache's Grant of Patent License, it is licensed under the terms of that Grant to the ASF and to recipients of any software distributed by the ASF for any Apache software product whatsoever.

Legacy License Structure

Note: The code base was previously licensed under the Terms described here. We are in the middle of relicensing to a new approach (described above), but until this effort is complete, the code is also still available under these terms. Once we finish the relicensing project, new versions of the code will not be available under these terms. However, nothing takes away your right to use old versions under the licensing terms under which they were originally released.

We intend to keep LLVM perpetually open source and to use a permissive open source license. The code in LLVM is available under the [University of Illinois/NCSA Open Source License](#), which boils down to this:

- You can freely distribute LLVM.
- You must retain the copyright notice if you redistribute LLVM.
- Binaries derived from LLVM must reproduce the copyright notice (e.g. in an included README file).
- You can't use our names to promote your LLVM derived products.
- There's no warranty on LLVM at all.

We believe this fosters the widest adoption of LLVM because it **allows commercial products to be derived from LLVM** with few restrictions and without a requirement for making any derived works also open source (i.e. LLVM's license is not a "copyleft" license like the GPL). We suggest that you read the [License](#) if further clarification is needed.

In addition to the UIUC license, the runtime library components of LLVM (**compiler_rt**, **libc++**, and **libclc**) are also licensed under the [MIT License](#), which does not contain the binary redistribution clause. As a user of these runtime libraries, it means that you can choose to use the code under either license (and thus don't need the binary redistribution clause), and as a contributor to the code that you agree that any contributions to these libraries be licensed under both licenses. We feel that this is important for runtime libraries, because they are implicitly linked into applications and therefore should not subject those applications to the binary redistribution clause. This also means that it is ok to move code from (e.g.) libc++ to the LLVM core without concern, but that code cannot be moved from the LLVM core to libc++ without the copyright owner's permission.

5.3 Creating an LLVM Project

- *Overview*
- *Source Tree Layout*
- *Writing LLVM Style Makefiles*
 - *Required Variables*
 - *Variables for Building Subdirectories*
 - *Variables for Building Libraries*
 - *Variables for Building Programs*
 - *Miscellaneous Variables*
- *Placement of Object Code*
- *Further Help*

5.3.1 Overview

The LLVM build system is designed to facilitate the building of third party projects that use LLVM header files, libraries, and tools. In order to use these facilities, a `Makefile` from a project must do the following things:

- Set `make` variables. There are several variables that a `Makefile` needs to set to use the LLVM build system:
 - `PROJECT_NAME` - The name by which your project is known.
 - `LLVM_SRC_ROOT` - The root of the LLVM source tree.
 - `LLVM_OBJ_ROOT` - The root of the LLVM object tree.
 - `PROJ_SRC_ROOT` - The root of the project's source tree.
 - `PROJ_OBJ_ROOT` - The root of the project's object tree.
 - `PROJ_INSTALL_ROOT` - The root installation directory.
 - `LEVEL` - The relative path from the current directory to the project's root (`$PROJ_OBJ_ROOT`).
- Include `Makefile.config` from `$(LLVM_OBJ_ROOT)`.
- Include `Makefile.rules` from `$(LLVM_SRC_ROOT)`.

There are two ways that you can set all of these variables:

- You can write your own `Makefiles` which hard-code these values.
- You can use the pre-made LLVM sample project. This sample project includes `Makefiles`, a configure script that can be used to configure the location of LLVM, and the ability to support multiple object directories from a single source directory.

If you want to devise your own build system, studying other projects and LLVM `Makefiles` will probably provide enough information on how to write your own `Makefiles`.

5.3.2 Source Tree Layout

In order to use the LLVM build system, you will want to organize your source code so that it can benefit from the build system's features. Mainly, you want your source tree layout to look similar to the LLVM source tree layout.

Underneath your top level directory, you should have the following directories:

lib

This subdirectory should contain all of your library source code. For each library that you build, you will have one directory in **lib** that will contain that library's source code.

Libraries can be object files, archives, or dynamic libraries. The **lib** directory is just a convenient place for libraries as it places them all in a directory from which they can be linked later.

include

This subdirectory should contain any header files that are global to your project. By global, we mean that they are used by more than one library or executable of your project.

By placing your header files in **include**, they will be found automatically by the LLVM build system. For example, if you have a file `include/jazz/note.h`, then your source files can include it simply with `#include "jazz/note.h"`.

tools

This subdirectory should contain all of your source code for executables. For each program that you build, you will have one directory in **tools** that will contain that program's source code.

test

This subdirectory should contain tests that verify that your code works correctly. Automated tests are especially useful.

Currently, the LLVM build system provides basic support for tests. The LLVM system provides the following:

- LLVM contains regression tests in `llvm/test`. These tests are run by the *Lit* testing tool. This test procedure uses `RUN` lines in the actual test case to determine how to run the test. See the *LLVM Testing Infrastructure Guide* for more details.
- LLVM contains an optional package called `llvm-test`, which provides benchmarks and programs that are known to compile with the Clang front end. You can use these programs to test your code, gather statistical information, and compare it to the current LLVM performance statistics.

Currently, there is no way to hook your tests directly into the `llvm/test` testing harness. You will simply need to find a way to use the source provided within that directory on your own.

Typically, you will want to build your **lib** directory first followed by your **tools** directory.

5.3.3 Writing LLVM Style Makefiles

The LLVM build system provides a convenient way to build libraries and executables. Most of your project Makefiles will only need to define a few variables. Below is a list of the variables one can set and what they can do:

Required Variables

LEVEL

This variable is the relative path from this Makefile to the top directory of your project's source code. For example, if your source code is in `/tmp/src`, then the Makefile in `/tmp/src/jump/high` would set `LEVEL` to `"../.."`.

Variables for Building Subdirectories

DIRS

This is a space separated list of subdirectories that should be built. They will be built, one at a time, in the order specified.

PARALLEL_DIRS

This is a list of directories that can be built in parallel. These will be built after the directories in `DIRS` have been built.

OPTIONAL_DIRS

This is a list of directories that can be built if they exist, but will not cause an error if they do not exist. They are built serially in the order in which they are listed.

Variables for Building Libraries

LIBRARYNAME

This variable contains the base name of the library that will be built. For example, to build a library named `libsampl.e.a`, `LIBRARYNAME` should be set to `sample`.

BUILD_ARCHIVE

By default, a library is a `.o` file that is linked directly into a program. To build an archive (also known as a static library), set the `BUILD_ARCHIVE` variable.

SHARED_LIBRARY

If `SHARED_LIBRARY` is defined in your Makefile, a shared (or dynamic) library will be built.

Variables for Building Programs

TOOLNAME

This variable contains the name of the program that will be built. For example, to build an executable named `sample`, `TOOLNAME` should be set to `sample`.

USEDLIBS

This variable holds a space separated list of libraries that should be linked into the program. These libraries must be libraries that come from your `lib` directory. The libraries must be specified without their `lib` prefix. For example, to link `libsampl.e.a`, you would set `USEDLIBS` to `sample.a`.

Note that this works only for statically linked libraries.

LLVMLIBS

This variable holds a space separated list of libraries that should be linked into the program. These libraries must be LLVM libraries. The libraries must be specified without their `lib` prefix. For example, to link with a driver that performs an IR transformation you might set `LLVMLIBS` to this minimal set of libraries `LLVMSupport.a LLVMCore.a LLVMBitReader.a LLVMAsmParser.a LLVMAnalysis.a LLVMTransformUtils.a LLVMScalarOpts.a LLVMTarget.a`.

Note that this works only for statically linked libraries. LLVM is split into a large number of static libraries, and the list of libraries you require may be much longer than the list above. To see a full list of libraries use: `llvm-config --libs all`. Using `LINK_COMPONENTS` as described below, obviates the need to set `LLVMLIBS`.

LINK_COMPONENTS

This variable holds a space separated list of components that the LLVM Makefiles pass to the `llvm-config` tool to generate a link line for the program. For example, to link with all LLVM libraries use `LINK_COMPONENTS = all`.

LIBS

To link dynamic libraries, add `-l<library base name>` to the `LIBS` variable. The LLVM build system will look in the same places for dynamic libraries as it does for static libraries.

For example, to link `libsampl.e.so`, you would have the following line in your Makefile:

```
LIBS += -lsample
```

Note that `LIBS` must occur in the Makefile after the inclusion of `Makefile.common`.

Miscellaneous Variables

CFLAGS & CPPFLAGS

This variable can be used to add options to the C and C++ compiler, respectively. It is typically used to add options that tell the compiler the location of additional directories to search for header files.

It is highly suggested that you append to `CFLAGS` and `CPPFLAGS` as opposed to overwriting them. The master Makefiles may already have useful options in them that you may not want to overwrite.

5.3.4 Placement of Object Code

The final location of built libraries and executables will depend upon whether you do a `Debug`, `Release`, or `Profile` build.

Libraries

All libraries (static and dynamic) will be stored in `PROJ_OBJ_ROOT/<type>/lib`, where *type* is `Debug`, `Release`, or `Profile` for a debug, optimized, or profiled build, respectively.

Executables

All executables will be stored in `PROJ_OBJ_ROOT/<type>/bin`, where *type* is `Debug`, `Release`, or `Profile` for a debug, optimized, or profiled build, respectively.

5.3.5 Further Help

If you have any questions or need any help creating an LLVM project, the LLVM team would be more than happy to help. You can always post your questions to the [LLVM Developers Mailing List](#).

5.4 LLVMBuild Guide

- *Introduction*
- *Project Organization*
- *Build Integration*
- *Component Overview*
- *LLVMBuild Format Reference*

5.4.1 Introduction

This document describes the `LLVMBuild` organization and files which we use to describe parts of the LLVM ecosystem. For description of specific LLVMBuild related tools, please see the command guide.

LLVM is designed to be a modular set of libraries which can be flexibly mixed together in order to build a variety of tools, like compilers, JITs, custom code generators, optimization passes, interpreters, and so on. Related projects in the LLVM system like Clang and LLDB also tend to follow this philosophy.

In order to support this usage style, LLVM has a fairly strict structure as to how the source code and various components are organized. The `LLVMBuild.txt` files are the explicit specification of that structure, and are used by the build systems and other tools in order to develop the LLVM project.

5.4.2 Project Organization

The source code for LLVM projects using the LLVMBuild system (LLVM, Clang, and LLDB) is organized into *components*, which define the separate pieces of functionality that make up the project. These projects may consist of many libraries, associated tools, build tools, or other utility tools (for example, testing tools).

For the most part, the project contents are organized around defining one main component per each subdirectory. Each such directory contains an `LLVMBuild.txt` which contains the component definitions.

The component descriptions for the project as a whole are automatically gathered by the LLVMBuild tools. The tools automatically traverse the source directory structure to find all of the component description files. NOTE: For performance/sanity reasons, we only traverse into subdirectories when the parent itself contains an `LLVMBuild.txt` description file.

5.4.3 Build Integration

The LLVMBuild files themselves are just a declarative way to describe the project structure. The actual building of the LLVM project is handled by another build system (See: [CMake](#)).

The build system implementation will load the relevant contents of the LLVMBuild files and use that to drive the actual project build. Typically, the build system will only need to load this information at "configure" time, and use it to generate native information. Build systems will also handle automatically reconfiguring their information when the contents of the `LLVMBuild.txt` files change.

Developers generally are not expected to need to be aware of the details of how the LLVMBuild system is integrated into their build. Ideally, LLVM developers who are not working on the build system would only ever need to modify the contents of the `LLVMBuild.txt` description files (although we have not reached this goal yet).

For more information on the utility tool we provide to help interfacing with the build system, please see the [llvm-build](#) documentation.

5.4.4 Component Overview

As mentioned earlier, LLVM projects are organized into logical *components*. Every component is typically grouped into its own subdirectory. Generally, a component is organized around a coherent group of sources which have some kind of clear API separation from other parts of the code.

LLVM primarily uses the following types of components:

- *Libraries* - Library components define a distinct API which can be independently linked into LLVM client applications. Libraries typically have private and public header files, and may specify a link of required libraries that they build on top of.
- *Build Tools* - Build tools are applications which are designed to be run as part of the build process (typically to generate other source files). Currently, LLVM uses one main build tool called [TableGen](#) to generate a variety of source files.
- *Tools* - Command line applications which are built using the LLVM component libraries. Most LLVM tools are small and are primarily frontends to the library interfaces.

Components are described using `LLVMBuild.txt` files in the directories that define the component. See the [LLVM-Build Format Reference](#) section for information on the exact format of these files.

5.4.5 LLVMBuild Format Reference

LLVMBuild files are written in a simple variant of the INI or configuration file format ([Wikipedia entry](#)). The format defines a list of sections each of which may contain some number of properties. A simple example of the file format is below:

```
; Comments start with a semi-colon.

; Sections are declared using square brackets.
[component_0]

; Properties are declared using '=' and are contained in the previous section.
;
; We support simple string and boolean scalar values and list values, where
; items are separated by spaces. There is no support for quoting, and so
; property values may not contain spaces.
property_name = property_value
list_property_name = value_1 value_2 ... value_n
boolean_property_name = 1 (or 0)
```

LLVMBuild files are expected to define a strict set of sections and properties. A typical component description file for a library component would look like the following example:

```
[component_0]
type = Library
name = Linker
parent = Libraries
required_libraries = Archive BitReader Core Support TransformUtils
```

A full description of the exact sections and properties which are allowed follows.

Each file may define exactly one common component, named `common`. The common component may define the following properties:

- `subdirectories` **[optional]**

If given, a list of the names of the subdirectories from the current subpath to search for additional LLVMBuild files.

Each file may define multiple components. Each component is described by a section whose name starts with `component`. The remainder of the section name is ignored, but each section name must be unique. Typically components are just number in order for files with multiple components (`component_0`, `component_1`, and so on).

Warning: Section names not matching this format (or the `common` section) are currently unused and are disallowed.

Every component is defined by the properties in the section. The exact list of properties that are allowed depends on the component type. Components **may not** define any properties other than those expected by the component type.

Every component must define the following properties:

- `type` **[required]**

The type of the component. Supported component types are detailed below. Most components will define additional properties which may be required or optional.

- `name` **[required]**

The name of the component. Names are required to be unique across the entire project.

- **parent [required]**

The name of the logical parent of the component. Components are organized into a logical tree to make it easier to navigate and organize groups of components. The parents have no semantics as far as the project build is concerned, however. Typically, the parent will be the main component of the parent directory.

Components may reference the root pseudo component using `$ROOT` to indicate they should logically be grouped at the top-level.

Components may define the following properties:

- **dependencies [optional]**

If specified, a list of names of components which *must* be built prior to this one. This should only be exactly those components which produce some tool or source code required for building the component.

Note: `Group` and `LibraryGroup` components have no semantics for the actual build, and are not allowed to specify dependencies.

The following section lists the available component types, as well as the properties which are associated with that component.

- `type = Group`

`Group` components exist purely to allow additional arbitrary structuring of the logical components tree. For example, one might define a `Libraries` group to hold all of the root library components.

`Group` components have no additionally properties.

- `type = Library`

`Library` components define an individual library which should be built from the source code in the component directory.

Components with this type use the following properties:

- **library_name [optional]**

If given, the name to use for the actual library file on disk. If not given, the name is derived from the component name itself.

- **required_libraries [optional]**

If given, a list of the names of `Library` or `LibraryGroup` components which must also be linked in whenever this library is used. That is, the link time dependencies for this component. When tools are built, the build system will include the transitive closure of all `required_libraries` for the components the tool needs.

- **add_to_library_groups [optional]**

If given, a list of the names of `LibraryGroup` components which this component is also part of. This allows nesting groups of components. For example, the `X86` target might define a library group for all of the `X86` components. That library group might then be included in the `all-targets` library group.

- **installed [optional] [boolean]**

Whether this library is installed. Libraries that are not installed are only reported by `llvm-config` when it is run as part of a development directory.

- `type = LibraryGroup`

`LibraryGroup` components are a mechanism to allow easy definition of useful sets of related components. In particular, we use them to easily specify things like "all targets", or "all assembly printers".

Components with this type use the following properties:

- `required_libraries` **[optional]**
See the `Library` type for a description of this property.
- `add_to_library_groups` **[optional]**
See the `Library` type for a description of this property.

- `type = TargetGroup`

`TargetGroup` components are an extension of `LibraryGroups`, specifically for defining LLVM targets (which are handled specially in a few places).

The name of the component should always be the name of the target.

Components with this type use the `LibraryGroup` properties in addition to:

- `has_asmparser` **[optional] [boolean]**
Whether this target defines an assembly parser.
- `has_asmprinter` **[optional] [boolean]**
Whether this target defines an assembly printer.
- `has_disassembler` **[optional] [boolean]**
Whether this target defines a disassembler.
- `has_jit` **[optional] [boolean]**
Whether this target supports JIT compilation.

- `type = Tool`

`Tool` components define standalone command line tools which should be built from the source code in the component directory and linked.

Components with this type use the following properties:

- `required_libraries` **[optional]**
If given, a list of the names of `Library` or `LibraryGroup` components which this tool is required to be linked with.

Note: The values should be the component names, which may not always match up with the actual library names on disk.

Build systems are expected to properly include all of the libraries required by the linked components (i.e., the transitive closure of `required_libraries`).

Build systems are also expected to understand that those library components must be built prior to linking -- they do not also need to be listed under dependencies.

- `type = BuildTool`

`BuildTool` components are like `Tool` components, except that the tool is supposed to be built for the platform where the build is running (instead of that platform being targeted). Build systems are expected to handle the fact that required libraries may need to be built for multiple platforms in order to be able to link this tool.

`BuildTool` components currently use the exact same properties as `Tool` components, the type distinction is only used to differentiate what the tool is built for.

5.5 How To Release LLVM To The Public

5.5.1 Introduction

This document contains information about successfully releasing LLVM --- including sub-projects: e.g., `clang` and `compiler-rt` --- to the public. It is the Release Manager's responsibility to ensure that a high quality build of LLVM is released.

If you're looking for the document on how to test the release candidates and create the binary packages, please refer to the [How To Validate a New Release](#) instead.

5.5.2 Release Timeline

LLVM is released on a time based schedule --- with major releases roughly every 6 months. In between major releases there may be dot releases. The release manager will determine if and when to make a dot release based on feedback from the community. Typically, dot releases should be made if there are large number of bug-fixes in the stable branch or a critical bug has been discovered that affects a large number of users.

Unless otherwise stated, dot releases will follow the same procedure as major releases.

The release process is roughly as follows:

- Set code freeze and branch creation date for 6 months after last code freeze date. Announce release schedule to the LLVM community and update the website.
- Create release branch and begin release process.
- Send out release candidate sources for first round of testing. Testing lasts 7-10 days. During the first round of testing, any regressions found should be fixed. Patches are merged from mainline into the release branch. Also, all features need to be completed during this time. Any features not completed at the end of the first round of testing will be removed or disabled for the release.
- Generate and send out the second release candidate sources. Only *critical* bugs found during this testing phase will be fixed. Any bugs introduced by merged patches will be fixed. If so a third round of testing is needed.
- The release notes are updated.
- Finally, release!

The release process will be accelerated for dot releases. If the first round of testing finds no critical bugs and no regressions since the last major release, then additional rounds of testing will not be required.

5.5.3 Release Process

- *Release Administrative Tasks*
 - *Create Release Branch*
 - *Update LLVM Version*
 - *Tagging the LLVM Release Candidates*

- *Build Clang Binary Distribution*
- *Release Qualification Criteria*
- *Official Testing*
- *Community Testing*
- *Reporting Regressions*
- *Merge Requests*
- *Release Patch Rules*
 - *Merging Patches*
- *Release Final Tasks*
 - *Update Documentation*
 - *Tag the LLVM Final Release*
- *Update the LLVM Demo Page*
 - *Update the LLVM Website*
 - *Announce the Release*

Release Administrative Tasks

This section describes a few administrative tasks that need to be done for the release process to begin. Specifically, it involves:

- Creating the release branch,
- Setting version numbers, and
- Tagging release candidates for the release team to begin testing.

Create Release Branch

Branch the Subversion trunk using the following procedure:

1. Remind developers that the release branching is imminent and to refrain from committing patches that might break the build. E.g., new features, large patches for works in progress, an overhaul of the type system, an exciting new TableGen feature, etc.
2. Verify that the current Subversion trunk is in decent shape by examining nightly tester and buildbot results.
3. Create the release branch for `llvm`, `clang`, and other sub-projects, from the last known good revision. The branch's name is `release_XY`, where `X` is the major and `Y` the minor release numbers. Use `utils/release/tag.sh` to tag the release.
4. Advise developers that they may now check their patches into the Subversion tree again.
5. The Release Manager should switch to the release branch, because all changes to the release will now be done in the branch. The easiest way to do this is to grab a working copy using the following commands:

```
$ svn co https://llvm.org/svn/llvm-project/llvm/branches/release_XY llvm-X.Y
$ svn co https://llvm.org/svn/llvm-project/cfe/branches/release_XY clang-X.Y
```

(continues on next page)

(continued from previous page)

```
$ svn co https://llvm.org/svn/llvm-project/test-suite/branches/release_XY test-
↪suite-X.Y
```

Update LLVM Version

After creating the LLVM release branch, update the release branches' `CMakeLists.txt` versions from `'X.Ysvn'` to `'X.Y'`. Update it on mainline as well to be the next version (`'X.Y+1svn'`).

In addition, the version numbers of all the Bugzilla components must be updated for the next release.

Tagging the LLVM Release Candidates

Tag release candidates using the `tag.sh` script in `utils/release`.

```
$ ./tag.sh -release X.Y.Z -rc $RC
```

The Release Manager may supply pre-packaged source tarballs for users. This can be done with the `export.sh` script in `utils/release`.

```
$ ./export.sh -release X.Y.Z -rc $RC
```

This will generate source tarballs for each LLVM project being validated, which can be uploaded to the website for further testing.

Build Clang Binary Distribution

Creating the `clang` binary distribution requires following the instructions [here](#).

That process will perform both Release+Asserts and Release builds but only pack the Release build for upload. You should use the Release+Asserts sysroot, normally under `final/Phase3/Release+Asserts/llvmCore-3.8.1-RCn.install/`, for test-suite and run-time benchmarks, to make sure nothing serious has passed through the net. For compile-time benchmarks, use the Release version.

The minimum required version of the tools you'll need are [here](#)

Release Qualification Criteria

A release is qualified when it has no regressions from the previous release (or baseline). Regressions are related to correctness first and performance second. (We may tolerate some minor performance regressions if they are deemed necessary for the general quality of the compiler.)

More specifically, Clang/LLVM is qualified when it has a clean test with all supported sub-projects included (`make check-all`), per target, and it has no regressions with the `test-suite` in relation to the previous release.

Regressions are new failures in the set of tests that are used to qualify each product and only include things on the list. Every release will have some bugs in it. It is the reality of developing a complex piece of software. We need a very concrete and definitive release criteria that ensures we have monotonically improving quality on some metric. The metric we use is described below. This doesn't mean that we don't care about other criteria, but these are the criteria which we found to be most important and which must be satisfied before a release can go out.

Official Testing

A few developers in the community have dedicated time to validate the release candidates and volunteered to be the official release testers for each architecture.

These will be the ones testing, generating and uploading the official binaries to the server, and will be the minimum tests *necessary* for the release to proceed.

This will obviously not cover all OSs and distributions, so additional community validation is important. However, if community input is not reached before the release is out, all bugs reported will have to go on the next stable release.

The official release managers are:

- Major releases (X.0): Hans Wennborg
- Stable releases (X.n): Tom Stellard

The official release testers are volunteered from the community and have consistently validated and released binaries for their targets/OSs. To contact them, you should email the `release-testers@lists.llvm.org` mailing list.

The official testers list is in the file `RELEASE_TESTERS.TXT`, in the LLVM repository.

Community Testing

Once all testing has been completed and appropriate bugs filed, the release candidate tarballs are put on the website and the LLVM community is notified.

We ask that all LLVM developers test the release in any the following ways:

1. Download `llvm-X.Y`, `llvm-test-X.Y`, and the appropriate `clang` binary. Build LLVM. Run `make check` and the full LLVM test suite (`make TEST=nightly report`).
2. Download `llvm-X.Y`, `llvm-test-X.Y`, and the `clang` sources. Compile everything. Run `make check` and the full LLVM test suite (`make TEST=nightly report`).
3. Download `llvm-X.Y`, `llvm-test-X.Y`, and the appropriate `clang` binary. Build whole programs with it (ex. Chromium, Firefox, Apache) for your platform.
4. Download `llvm-X.Y`, `llvm-test-X.Y`, and the appropriate `clang` binary. Build *your* programs with it and check for conformance and performance regressions.
5. Run the *release process*, if your platform is *different* than that which is officially supported, and report back errors only if they were not reported by the official release tester for that architecture.

We also ask that the OS distribution release managers test their packages with the first candidate of every release, and report any *new* errors in Bugzilla. If the bug can be reproduced with an unpatched upstream version of the release candidate (as opposed to the distribution's own build), the priority should be release blocker.

During the first round of testing, all regressions must be fixed before the second release candidate is tagged.

In the subsequent stages, the testing is only to ensure that bug fixes previously merged in have not created new major problems. *This is not the time to solve additional and unrelated bugs!* If no patches are merged in, the release is determined to be ready and the release manager may move onto the next stage.

Reporting Regressions

Every regression that is found during the tests (as per the criteria above), should be filled in a bug in Bugzilla with the priority *release blocker* and blocking a specific release.

To help manage all the bugs reported and which ones are blockers or not, a new "[meta]" bug should be created and all regressions *blocking* that Meta. Once all blockers are done, the Meta can be closed.

If a bug can't be reproduced, or stops being a blocker, it should be removed from the Meta and its priority decreased to *normal*. Debugging can continue, but on trunk.

Merge Requests

You can use any of the following methods to request that a revision from trunk be merged into a release branch:

1. Use the `utils/release/merge-request.sh` script which will automatically file a [bug](#) requesting that the patch be merged. e.g. To request revision 12345 be merged into the branch for the 5.0.1 release: `llvm.src/utils/release/merge-request.sh -stable-version 5.0 -r 12345 -user bugzilla@example.com`
2. Manually file a [bug](#) with the subject: "Merge r12345 into the X.Y branch", enter the commit(s) that you want merged in the "Fixed by Commit(s)" and mark it as a blocker of the current release bug. Release bugs are given aliases in the form of release-x.y.z, so to mark a bug as a blocker for the 5.0.1 release, just enter release-5.0.1 in the "Blocks" field.
3. Reply to the commit email on `llvm-commits` for the revision to merge and cc the release manager.

Release Patch Rules

Below are the rules regarding patching the release branch:

1. Patches applied to the release branch may only be applied by the release manager, the official release testers or the code owners with approval from the release manager.
2. During the first round of testing, patches that fix regressions or that are small and relatively risk free (verified by the appropriate code owner) are applied to the branch. Code owners are asked to be very conservative in approving patches for the branch. We reserve the right to reject any patch that does not fix a regression as previously defined.
3. During the remaining rounds of testing, only patches that fix critical regressions may be applied.
4. For dot releases all patches must maintain both API and ABI compatibility with the previous major release. Only bug-fixes will be accepted.

Merging Patches

The `utils/release/merge.sh` script can be used to merge individual revisions into any one of the LLVM projects. To merge revision `$N` into project `$PROJ`, do:

1. `svn co https://llvm.org/svn/llvm-project/$PROJ/branches/release_XX $PROJ.src`
2. `$PROJ.src/utils/release/merge.sh --proj $PROJ --rev $N`
3. Run regression tests.
4. `cd $PROJ.src`. Run the `svn commit` command printed out by `merge.sh` in step 2.

Release Final Tasks

The final stages of the release process involves tagging the "final" release branch, updating documentation that refers to the release, and updating the demo page.

Update Documentation

Review the documentation and ensure that it is up to date. The "Release Notes" must be updated to reflect new features, bug fixes, new known issues, and changes in the list of supported platforms. The "Getting Started Guide" should be updated to reflect the new release version number tag available from Subversion and changes in basic system requirements. Merge both changes from mainline into the release branch.

Tag the LLVM Final Release

Tag the final release sources using the `tag.sh` script in `utils/release`.

```
$ ./tag.sh -release X.Y.Z -final
```

Update the LLVM Demo Page

The LLVM demo page must be updated to use the new release. This consists of using the new `clang` binary and building LLVM.

Update the LLVM Website

The website must be updated before the release announcement is sent out. Here is what to do:

1. Check out the `www` module from Subversion.
2. Create a new sub-directory `X.Y` in the `releases` directory.
3. Commit the `llvm`, `test-suite`, `clang` source and binaries in this new directory.
4. Copy and commit the `llvm/docs` and `LICENSE.txt` files into this new directory. The docs should be built with `BUILD_FOR_WEBSITE=1`.
5. Commit the `index.html` to the `release/X.Y` directory to redirect (use from previous release).
6. Update the `releases/download.html` file with the new release.
7. Update the `releases/index.html` with the new release and link to release documentation.
8. Finally, update the main page (`index.html` and sidebar) to point to the new release and release announcement. Make sure this all gets committed back into Subversion.

Announce the Release

Send an email to the list announcing the release, pointing people to all the relevant documentation, download pages and bugs fixed.

5.6 Advice on Packaging LLVM

- *Overview*
- *Compile Flags*
- *C++ Features*
- *Shared Library*
- *Dependencies*

5.6.1 Overview

LLVM sets certain default configure options to make sure our developers don't break things for constrained platforms. These settings are not optimal for most desktop systems, and we hope that packagers (e.g., Redhat, Debian, MacPorts, etc.) will tweak them. This document lists settings we suggest you tweak.

LLVM's API changes with each release, so users are likely to want, for example, both LLVM-2.6 and LLVM-2.7 installed at the same time to support apps developed against each.

5.6.2 Compile Flags

LLVM runs much more quickly when it's optimized and assertions are removed. However, such a build is currently incompatible with users who build without defining `NDEBUG`, and the lack of assertions makes it hard to debug problems in user code. We recommend allowing users to install both optimized and debug versions of LLVM in parallel. The following configure flags are relevant:

- disable-assertions** Builds LLVM with `NDEBUG` defined. Changes the LLVM ABI. Also available by setting `DISABLE_ASSERTIONS=0|1` in make's environment. This defaults to enabled regardless of the optimization setting, but it slows things down.
- enable-debug-symbols** Builds LLVM with `-g`. Also available by setting `DEBUG_SYMBOLS=0|1` in make's environment. This defaults to disabled when optimizing, so you should turn it back on to let users debug their programs.
- enable-optimized** (For svn checkouts) Builds LLVM with `-O2` and, by default, turns off debug symbols. Also available by setting `ENABLE_OPTIMIZED=0|1` in make's environment. This defaults to enabled when not in a checkout.

5.6.3 C++ Features

RTTI LLVM disables RTTI by default. Add `REQUIRES_RTTI=1` to your environment while running `make` to re-enable it. This will allow users to build with RTTI enabled and still inherit from LLVM classes.

5.6.4 Shared Library

Configure with `--enable-shared` to build `libLLVM-<major>.<minor>.(so|dylib)` and link the tools against it. This saves lots of binary size at the cost of some startup time.

5.6.5 Dependencies

`--enable-libffi` Depend on `libffi` to allow the LLVM interpreter to call external functions.

`--with-oprofile`

Depend on `libopagent` (`>=version 0.9.4`) to let the LLVM JIT tell oprofile about function addresses and line numbers.

5.7 How To Validate a New Release

- *Introduction*
- *Scripts*
- *Test Suite*
- *Pre-Release Process*
- *Release Process*
- *Bug Reporting Process*

5.7.1 Introduction

This document contains information about testing the release candidates that will ultimately be the next LLVM release. For more information on how to manage the actual release, please refer to *[How To Release LLVM To The Public](#)*.

Overview of the Release Process

Once the release process starts, the Release Manager will ask for volunteers, and it'll be the role of each volunteer to:

- Test and benchmark the previous release
- Test and benchmark each release candidate, comparing to the previous release and candidates
- Identify, reduce and report every regression found during tests and benchmarks
- Make sure the critical bugs get fixed and merged to the next release candidate

Not all bugs or regressions are show-stoppers and it's a bit of a grey area what should be fixed before the next candidate and what can wait until the next release.

It'll depend on:

- The severity of the bug, how many people it affects and if it's a regression or a known bug. Known bugs are "unsupported features" and some bugs can be disabled if they have been implemented recently.
- The stage in the release. Less critical bugs should be considered to be fixed between RC1 and RC2, but not so much at the end of it.
- If it's a correctness or a performance regression. Performance regression tends to be taken more lightly than correctness.

5.7.2 Scripts

The scripts are in the `utils/release` directory.

test-release.sh

This script will check-out, configure and compile LLVM+Clang (+ most add-ons, like `compiler-rt`, `libcxx`, `libomp` and `clang-extra-tools`) in three stages, and will test the final stage. It'll have installed the final binaries on the `Phase3/Releasei(+Asserts)` directory, and that's the one you should use for the test-suite and other external tests.

To run the script on a specific release candidate run:

```
./test-release.sh \
  -release 3.3 \
  -rc 1 \
  -no-64bit \
  -test-asserts \
  -no-compare-files
```

Each system will require different options. For instance, `x86_64` will obviously not need `-no-64bit` while 32-bit systems will, or the script will fail.

The important flags to get right are:

- On the pre-release, you should change `-rc 1` to `-final`. On RC2, change it to `-rc 2` and so on.
- On non-release testing, you can use `-final` in conjunction with `-no-checkout`, but you'll have to create the `final` directory by hand and link the correct source dir to `final/llvm.src`.
- For release candidates, you need `-test-asserts`, or it won't create a "Release+Asserts" directory, which is needed for release testing and benchmarking. This will take twice as long.
- On the final candidate you just need Release builds, and that's the binary directory you'll have to pack.

This script builds three phases of Clang+LLVM twice each (Release and Release+Asserts), so use `screen` or `nohup` to avoid headaches, since it'll take a long time.

Use the `--help` option to see all the options and chose it according to your needs.

findRegressions-nightly.py

TODO

5.7.3 Test Suite

Follow the [LNT Quick Start Guide](#) link on how to set-up the test-suite

The binary location you'll have to use for testing is inside the `rcN/Phase3/Release+Asserts/llvmCore-REL-RC.install`. Link that directory to an easier location and run the test-suite.

An example on the run command line, assuming you created a link from the correct install directory to `~/devel/llvm/install`:

```
./sandbox/bin/python sandbox/bin/lnt runtest \  
  nt \  
  -j4 \  
  --sandbox sandbox \  
  --test-suite ~/devel/llvm/test/test-suite \  
  --cc ~/devel/llvm/install/bin/clang \  
  --cxx ~/devel/llvm/install/bin/clang++
```

It should have no new regressions, compared to the previous release or release candidate. You don't need to fix all the bugs in the test-suite, since they're not necessarily meant to pass on all architectures all the time. This is due to the nature of the result checking, which relies on direct comparison, and most of the time, the failures are related to bad output checking, rather than bad code generation.

If the errors are in LLVM itself, please report every single regression found as blocker, and all the other bugs as important, but not necessarily blocking the release to proceed. They can be set as "known failures" and to be fix on a future date.

5.7.4 Pre-Release Process

When the release process is announced on the mailing list, you should prepare for the testing, by applying the same testing you'll do on the release candidates, on the previous release.

You should:

- Download the previous release sources from <http://llvm.org/releases/download.html>.
- Run the `test-release.sh` script on final mode (change `-rc 1` to `-final`).
- Once all three stages are done, it'll test the final stage.
- Using the `Phase3/Release+Asserts/llvmCore-MAJ.MIN-final.install` base, run the test-suite.

If the final phase's `make check-all` failed, it's a good idea to also test the intermediate stages by going on the `obj` directory and running `make check-all` to find if there's at least one stage that passes (helps when reducing the error for bug report purposes).

5.7.5 Release Process

When the Release Manager sends you the release candidate, download all sources, unzip on the same directory (there will be sym-links from the appropriate places to them), and run the release test as above.

You should:

- Download the current candidate sources from where the release manager points you (ex. <http://llvm.org/pre-releases/3.3/rc1/>).
- Repeat the steps above with `-rc 1`, `-rc 2` etc modes and run the test-suite the same way.
- Compare the results, report all errors on Bugzilla and publish the binary blob where the release manager can grab it.

Once the release manager announces that the latest candidate is the good one, you have to pack the Release (no Asserts) install directory on Phase3 and that will be the official binary.

- Rename (or link) `clang+llvm-REL-ARCH-ENV` to the `.install` directory
- Tar that into the same name with `.tar.gz` extension from outside the directory
- Make it available for the release manager to download

5.7.6 Bug Reporting Process

If you found regressions or failures when comparing a release candidate with the previous release, follow the rules below:

- Critical bugs on compilation should be fixed as soon as possible, possibly before releasing the binary blobs.
- Check-all tests should be fixed before the next release candidate, but can wait until the test-suite run is finished.
- Bugs in the test suite or unimportant check-all tests can be fixed in between release candidates.
- New features or recent big changes, when close to the release, should have done in a way that it's easy to disable. If they misbehave, prefer disabling them than releasing an unstable (but untested) binary package.

5.8 LLVM Bug Life Cycle

- *Introduction - Achieving consistency in how we deal with bug reports*
- *Reporting bugs*
- *Triaging bugs*
- *Actively working on fixing bugs*
- *Resolving/Closing bugs*
- *Maintenance of products/components metadata*
- *Maintenance of cc-by-default settings*

5.8.1 Introduction - Achieving consistency in how we deal with bug reports

We aim to achieve a basic level of consistency in how reported bugs evolve from being reported, to being worked on, and finally getting closed out. The consistency helps reporters, developers and others to gain a better understanding of what a particular bug state actually means and what to expect might happen next.

At the same time, we aim to not over-specify the life cycle of bugs in the [the LLVM Bug Tracking System](#), as the overall goal is to make it easier to work with and understand the bug reports.

The main parts of the life cycle documented here are:

1. *Reporting*
2. *Triaging*
3. *Actively working on fixing*
4. *Closing*

Furthermore, some of the metadata in the bug tracker, such as who to notify on newly reported bugs or what the breakdown into products & components is we use, needs to be maintained. See the following for details:

1. *Maintenance of Bug products/component metadata*
2. *Maintenance of cc-by-default settings*

5.8.2 Reporting bugs

See [How to submit an LLVM bug report](#) on further details on how to submit good bug reports.

Make sure that you have one or more people on cc on the bug report that you think will react to it. We aim to automatically add specific people on cc for most products/components, but may not always succeed in doing so.

If you know the area of LLVM code the root cause of the bug is in, good candidates to add as cc may be the same people you'd ask for a code review in that area. See [Finding potential reviewers](#) for more details.

5.8.3 Triaging bugs

Bugs with status NEW indicate that they still need to be triaged. When triage is complete, the status of the bug is moved to CONFIRMED.

The goal of triaging a bug is to make sure a newly reported bug ends up in a good, actionable, state. Try to answer the following questions while triaging.

- Is the reported behavior actually wrong?
 - E.g. does a miscompile example depend on undefined behavior?
- Can you easily reproduce the bug?
 - If not, are there reasonable excuses why it cannot easily be reproduced?
- Is it related to an already reported bug?
 - Use the "See also"/"depends on"/"blocks" fields if so.
 - Close it as a duplicate if so, pointing to the issue it duplicates.
- Are the following fields filled in correctly?
 - Product
 - Component

- Title
- CC others not already cc'ed that you happen to know would be good to pull in.
- Add the "beginner" keyword if you think this would be a good bug to be fixed by someone new to LLVM.

5.8.4 Actively working on fixing bugs

Please remember to assign the bug to yourself if you're actively working on fixing it and to unassign it when you're no longer actively working on it. You unassign a bug by setting the Assignee field to "unassignedbugs@nondot.org".

5.8.5 Resolving/Closing bugs

For simplicity, we only have 1 status for all resolved or closed bugs: RESOLVED.

Resolving bugs is good! Make sure to properly record the reason for resolving. Examples of reasons for resolving are:

- Revision NNNNNN fixed the bug.
- The bug cannot be reproduced with revision NNNNNN.
- The circumstances for the bug don't apply anymore.
- There is a sound reason for not fixing it (WONTFIX).
- There is a specific and plausible reason to think that a given bug is otherwise inapplicable or obsolete.
 - One example is an old open bug that doesn't contain enough information to clearly understand the problem being reported (e.g. not reproducible). It is fine to resolve such a bug e.g. with resolution WORKSFORME and leaving a comment to encourage the reporter to reopen the bug with more information if it's still reproducible on their end.

If a bug is resolved, please fill in the revision number it was fixed in in the "Fixed by Commit(s)" field.

5.8.6 Maintenance of products/components metadata

Please raise a bug against "Bugzilla Admin"/"Products" to request any changes to be made to the breakdown of products & components modeled in Bugzilla.

5.8.7 Maintenance of cc-by-default settings

Please raise a bug against "Bugzilla Admin"/"Products" to request any changes to be made to the cc-by-default settings for specific components.

Contributing to LLVM An overview on how to contribute to LLVM.

LLVM Developer Policy The LLVM project's policy towards developers and their contributions.

Creating an LLVM Project How-to guide and templates for new projects that *use* the LLVM infrastructure. The templates (directory organization, Makefiles, and test tree) allow the project code to be located outside (or inside) the LLVM/ tree, while using LLVM header files and libraries.

LLVMBuild Guide Describes the LLVMBuild organization and files used by LLVM to specify component descriptions.

How To Release LLVM To The Public This is a guide to preparing LLVM releases. Most developers can ignore it.

How To Validate a New Release This is a guide to validate a new release, during the release process. Most developers can ignore it.

Advice on Packaging LLVM Advice on packaging LLVM into a distribution.

Code Reviews with Phabricator Describes how to use the Phabricator code review tool hosted on <http://reviews.llvm.org/> and its command line interface, Arcanist.

LLVM Bug Life Cycle Describes how bugs are reported, triaged and closed.

COMMUNITY

LLVM has a thriving community of friendly and helpful developers. The two primary communication mechanisms in the LLVM community are mailing lists and IRC.

6.1 Mailing Lists

If you can't find what you need in these docs, try consulting the mailing lists.

Developer's List (llvm-dev) This list is for people who want to be included in technical discussions of LLVM. People post to this list when they have questions about writing code for or using the LLVM tools. It is relatively low volume.

Commits Archive (llvm-commits) This list contains all commit messages that are made when LLVM developers commit code changes to the repository. It also serves as a forum for patch review (i.e. send patches here). It is useful for those who want to stay on the bleeding edge of LLVM development. This list is very high volume.

Bugs & Patches Archive (llvm-bugs) This list gets emailed every time a bug is opened and closed. It is higher volume than the LLVM-dev list.

Test Results Archive (llvm-testresults) A message is automatically sent to this list by every active nightly tester when it completes. As such, this list gets email several times each day, making it a high volume list.

LLVM Announcements List (llvm-announce) This is a low volume list that provides important announcements regarding LLVM. It gets email about once a month.

6.2 IRC

Users and developers of the LLVM project (including subprojects such as Clang) can be found in #llvm on irc.oftc.net.

This channel has several bots.

- Buildbot reporters
 - llvmbb - Bot for the main LLVM buildbot master. <http://lab.llvm.org:8011/console>
 - smooshlab - Apple's internal buildbot master.
- robot - Bugzilla linker. %bug <number>
- clang-bot - A [geordi](http://geordi.llvm.org) instance running near-trunk clang instead of gcc.

6.3 Meetups and social events

6.3.1 How to start LLVM Social in your town

Here are several ideas you can take into account when designing your specific LLVM Social.

Before you start, it is essential to make sure that the meetup is as welcoming as any other event related to LLVM. Therefore you shall follow LLVM's [Code of Conduct](#).

Other than that - your mileage may vary. Please adapt your social to what works best for your specific situation.

General suggestions

- We highly recommend that you join the official LLVM meetup organization. In addition to covering the cost of the meetup, all LLVM meetups are advertised together and easily found by potential attendees. Please contact arnaud.degrandmaison@llvm.org for more details.
- Beware of cultural differences: what works well in one region may not work in other part of the world.
- Do not be alone to organize the meetup. Try to work with a couple other organizers. This is more motivating as an organizer, and this makes the meetup more resilient over time.
- Each event can have a different form such as a social event, or a hackathon/workshop, or a 'mini-conference' with one or more talks. You do not have to stick to one format forever.
- Whatever format you choose, [LLVM Weekly](#) is an excellent topic starter: go through the 3-4 recent LLVM Weekly posts and prepare a list of the most interesting/notable news and discuss them with the group.

Advertisement

- Try to advertise via similar meetups/user groups
- Advertise your meetup on the mailing lists (llvm-dev, cfe-dev, lldb-dev, ...). Feel free to post to all of them, or at least to llvm-dev. But as these mailing lists have high traffic and some LLVM developers are not very active on them, you may reach more interested people using the mailing feature from meetup.com.
- Advertise the meetup on Twitter and mention [@llvmweekly](#) and [@llvmorg](#).
- Announce the next meetup in advance, and remind in one week or so.

Tech talks

- It's a great idea to have several talks scheduled for several upcoming meetups to get the ball rolling.
- Keep looking for speakers far in advance, ideally you should have 2-3 speakers ready in the pipeline.
- Try to record the talks if possible. It adds visibility to the meetup and just a good idea in general. Any modern smartphone or tablet should work, but you can also get a camera. Though, it is recommended to get an external microphone for better sound.

Where to host the meetup?

- Look around for bars/café with projectors.
- Talk to tech companies in the area.
- Some co-working spaces provide their facilities for non-profit (i.e., you do not charge attendees any fees) meetups.
- Ask nearby universities or university departments.

How to pick the date?

- Make sure you do not clash with the similar meetups in the city (e.g., C++ user groups).
- Prefer not to have a meetup the same week when the other similar meetups happen (e.g., it's not a good idea to have LLVM meetup on Thursday after C++ meetup on Wednesday).
- Meetups on weekends may attract people who live far away from the city, but the people who live in the city may not attend.
- Make a poll, but beware that not every responder will join (we had ~20 votes on the poll, while only ~8 people attended).

Besides developer [meetings and conferences](#), there are several user groups called [LLVM Socials](#). We greatly encourage you to join one in your city. Or start a new one if there is none:

[How to start LLVM Social in your town](#)

6.4 Community wide proposals

Proposals for massive changes in how the community behaves and how the work flow can be better.

6.4.1 Moving LLVM Projects to GitHub

Current Status

We are planning to complete the transition to GitHub by Oct 21, 2019. See the GitHub migration [status page](#) for the latest updates and instructions for how to migrate your workflows.

Introduction

This is a proposal to move our current revision control system from our own hosted Subversion to GitHub. Below are the financial and technical arguments as to why we are proposing such a move and how people (and validation infrastructure) will continue to work with a Git-based LLVM.

What This Proposal is *Not* About

Changing the development policy.

This proposal relates only to moving the hosting of our source-code repository from SVN hosted on our own servers to Git hosted on GitHub. We are not proposing using GitHub's issue tracker, pull-requests, or code-review.

Contributors will continue to earn commit access on demand under the Developer Policy, except that that a GitHub account will be required instead of SVN username/password-hash.

Why Git, and Why GitHub?

Why Move At All?

This discussion began because we currently host our own Subversion server and Git mirror on a voluntary basis. The LLVM Foundation sponsors the server and provides limited support, but there is only so much it can do.

Volunteers are not sysadmins themselves, but compiler engineers that happen to know a thing or two about hosting servers. We also don't have 24/7 support, and we sometimes wake up to see that continuous integration is broken because the SVN server is either down or unresponsive.

We should take advantage of one of the services out there (GitHub, GitLab, and BitBucket, among others) that offer better service (24/7 stability, disk space, Git server, code browsing, forking facilities, etc) for free.

Why Git?

Many new coders nowadays start with Git, and a lot of people have never used SVN, CVS, or anything else. Websites like GitHub have changed the landscape of open source contributions, reducing the cost of first contribution and fostering collaboration.

Git is also the version control many LLVM developers use. Despite the sources being stored in a SVN server, these developers are already using Git through the Git-SVN integration.

Git allows you to:

- Commit, squash, merge, and fork locally without touching the remote server.
- Maintain local branches, enabling multiple threads of development.
- Collaborate on these branches (e.g. through your own fork of llvm on GitHub).
- Inspect the repository history (blame, log, bisect) without Internet access.
- Maintain remote forks and branches on Git hosting services and integrate back to the main repository.

In addition, because Git seems to be replacing many OSS projects' version control systems, there are many tools that are built over Git. Future tooling may support Git first (if not only).

Why GitHub?

GitHub, like GitLab and BitBucket, provides free code hosting for open source projects. Any of these could replace the code-hosting infrastructure that we have today.

These services also have a dedicated team to monitor, migrate, improve and distribute the contents of the repositories depending on region and load.

GitHub has one important advantage over GitLab and BitBucket: it offers read-write **SVN** access to the repository (<https://github.com/blog/626-announcing-svn-support>). This would enable people to continue working post-migration as though our code were still canonically in an SVN repository.

In addition, there are already multiple LLVM mirrors on GitHub, indicating that part of our community has already settled there.

On Managing Revision Numbers with Git

The current SVN repository hosts all the LLVM sub-projects alongside each other. A single revision number (e.g. r123456) thus identifies a consistent version of all LLVM sub-projects.

Git does not use sequential integer revision number but instead uses a hash to identify each commit.

The loss of a sequential integer revision number has been a sticking point in past discussions about Git:

- "The 'branch' I most care about is mainline, and losing the ability to say 'fixed in r1234' (with some sort of monotonically increasing number) would be a tragic loss." [[LattnerRevNum](#)]
- "I like those results sorted by time and the chronology should be obvious, but timestamps are incredibly cumbersome and make it difficult to verify that a given checkout matches a given set of results." [[TrickRevNum](#)]
- "There is still the major regression with unreadable version numbers. Given the amount of Bugzilla traffic with 'Fixed in...', that's a non-trivial issue." [[JSonnRevNum](#)]
- "Sequential IDs are important for LNT and llvmlab bisection tool." [[MatthewsRevNum](#)].

However, Git can emulate this increasing revision number: `git rev-list --count <commit-hash>`. This identifier is unique only within a single branch, but this means the tuple (*num*, *branch-name*) uniquely identifies a commit.

We can thus use this revision number to ensure that e.g. `clang -v` reports a user-friendly revision number (e.g. *master-12345* or *4.0-5321*), addressing the objections raised above with respect to this aspect of Git.

What About Branches and Merges?

In contrast to SVN, Git makes branching easy. Git's commit history is represented as a DAG, a departure from SVN's linear history. However, we propose to mandate making merge commits illegal in our canonical Git repository.

Unfortunately, GitHub does not support server side hooks to enforce such a policy. We must rely on the community to avoid pushing merge commits.

GitHub offers a feature called *Status Checks*: a branch protected by *status checks* requires commits to be whitelisted before the push can happen. We could supply a pre-push hook on the client side that would run and check the history, before whitelisting the commit being pushed [[statuschecks](#)]. However this solution would be somewhat fragile (how do you update a script installed on every developer machine?) and prevents SVN access to the repository.

What About Commit Emails?

We will need a new bot to send emails for each commit. This proposal leaves the email format unchanged besides the commit URL.

Straw Man Migration Plan

Step #1 : Before The Move

1. Update docs to mention the move, so people are aware of what is going on.
2. Set up a read-only version of the GitHub project, mirroring our current SVN repository.
3. Add the required bots to implement the commit emails, as well as the umbrella repository update (if the multi-repo is selected) or the read-only Git views for the sub-projects (if the monorepo is selected).

Step #2 : Git Move

4. Update the buildbots to pick up updates and commits from the GitHub repository. Not all bots have to migrate at this point, but it'll help provide infrastructure testing.
5. Update Phabricator to pick up commits from the GitHub repository.
6. LNT and llvmlab have to be updated: they rely on unique monotonically increasing integer across branch [MatthewsRevNum].
7. Instruct downstream integrators to pick up commits from the GitHub repository.
8. Review and prepare an update for the LLVM documentation.

Until this point nothing has changed for developers, it will just boil down to a lot of work for buildbot and other infrastructure owners.

The migration will pause here until all dependencies have cleared, and all problems have been solved.

Step #3: Write Access Move

9. Collect developers' GitHub account information, and add them to the project.
10. Switch the SVN repository to read-only and allow pushes to the GitHub repository.
11. Update the documentation.
12. Mirror Git to SVN.

Step #4 : Post Move

13. Archive the SVN repository.
14. Update links on the LLVM website pointing to viewvc/klaus/phab etc. to point to GitHub instead.

Github Repository Description

Monorepo

The LLVM git repository hosted at <https://github.com/llvm/llvm-project> contains all sub-projects in a single source tree. It is often referred to as a monorepo and mimics an export of the current SVN repository, with each sub-project having its own top-level directory. Not all sub-projects are used for building toolchains. For example, `www/` and `test-suite/` are not part of the monorepo.

Putting all sub-projects in a single checkout makes cross-project refactoring naturally simple:

- New sub-projects can be trivially split out for better reuse and/or layering (e.g., to allow `libSupport` and/or `LIT` to be used by runtimes without adding a dependency on LLVM).
- Changing an API in LLVM and upgrading the sub-projects will always be done in a single commit, designing away a common source of temporary build breakage.
- Moving code across sub-project (during refactoring for instance) in a single commit enables accurate *git blame* when tracking code change history.
- Tooling based on *git grep* works natively across sub-projects, allowing to easier find refactoring opportunities across projects (for example reusing a datastructure initially in LLDB by moving it into `libSupport`).
- Having all the sources present encourages maintaining the other sub-projects when changing API.

Finally, the monorepo maintains the property of the existing SVN repository that the sub-projects move synchronously, and a single revision number (or commit hash) identifies the state of the development across all projects.

Building a single sub-project

Even though there is a single source tree, you are not required to build all sub-projects together. It is trivial to configure builds for a single sub-project.

For example:

```
mkdir build && cd build
# Configure only LLVM (default)
cmake path/to/monorepo
# Configure LLVM and lld
cmake path/to/monorepo -DLLVM_ENABLE_PROJECTS=lld
# Configure LLVM and clang
cmake path/to/monorepo -DLLVM_ENABLE_PROJECTS=clang
```

Outstanding Questions

Read-only sub-project mirrors

With the Monorepo, it is undecided whether the existing single-subproject mirrors (e.g. <https://git.llvm.org/git/compiler-rt.git>) will continue to be maintained.

Read/write SVN bridge

GitHub supports a read/write SVN bridge for its repositories. However, there have been issues with this bridge working correctly in the past, so it's not clear if this is something that will be supported going forward.

Monorepo Drawbacks

- Using the monolithic repository may add overhead for those contributing to a standalone sub-project, particularly on runtimes like `libcxx` and `compiler-rt` that don't rely on LLVM; currently, a fresh clone of `libcxx` is only 15MB (vs. 1GB for the monorepo), and the commit rate of LLVM may cause more frequent *git push* collisions when upstreaming. Affected contributors may be able to use the SVN bridge or the single-subproject Git mirrors. However, it's undecided if these projects will continue to be maintained.
- Using the monolithic repository may add overhead for those *integrating* a standalone sub-project, even if they aren't contributing to it, due to the same disk space concern as the point above. The availability of the sub-project Git mirrors would address this.
- Preservation of the existing read/write SVN-based workflows relies on the GitHub SVN bridge, which is an extra dependency. Maintaining this locks us into GitHub and could restrict future workflow changes.

Workflows

- *Checkout/Clone a Single Project, without Commit Access.*
- *Checkout/Clone Multiple Projects, with Commit Access.*
- *Commit an API Change in LLVM and Update the Sub-projects.*
- *Branching/Stashing/Updating for Local Development or Experiments.*
- *Bisecting.*

Workflow Before/After

This section goes through a few examples of workflows, intended to illustrate how end-users or developers would interact with the repository for various use-cases.

Checkout/Clone a Single Project, with Commit Access

Currently

```
# direct SVN checkout
svn co https://user@llvm.org/svn/llvm-project/llvm/trunk llvm
# or using the read-only Git view, with git-svn
git clone http://llvm.org/git/llvm.git
cd llvm
git svn init https://llvm.org/svn/llvm-project/llvm/trunk --username=<username>
git config svn-remote.svn.fetch :refs/remotes/origin/master
git svn rebase -l # -l avoids fetching ahead of the git mirror.
```

Commits are performed using *svn commit* or with the sequence *git commit* and *git svn dcommit*.

Monorepo Variant

With the monorepo variant, there are a few options, depending on your constraints. First, you could just clone the full repository:

```
git clone https://github.com/llvm/llvm-project.git
```

At this point you have every sub-project (llvm, clang, lld, lldb, ...), which *doesn't imply you have to build all of them*. You can still build only compiler-rt for instance. In this way it's not different from someone who would check out all the projects with SVN today.

If you want to avoid checking out all the sources, you can hide the other directories using a Git sparse checkout:

```
git config core.sparseCheckout true
echo /compiler-rt > .git/info/sparse-checkout
git read-tree -mu HEAD
```

The data for all sub-projects is still in your `.git` directory, but in your checkout, you only see *compiler-rt*. Before you push, you'll need to fetch and rebase (*git pull --rebase*) as usual.

Note that when you fetch you'll likely pull in changes to sub-projects you don't care about. If you are using sparse checkout, the files from other projects won't appear on your disk. The only effect is that your commit hash changes.

You can check whether the changes in the last fetch are relevant to your commit by running:

```
git log origin/master@{1}..origin/master -- libcxx
```

This command can be hidden in a script so that *git llvmpush* would perform all these steps, fail only if such a dependent change exists, and show immediately the change that prevented the push. An immediate repeat of the command would (almost) certainly result in a successful push. Note that today with SVN or git-svn, this step is not possible since the "rebase" implicitly happens while committing (unless a conflict occurs).

Checkout/Clone Multiple Projects, with Commit Access

Let's look how to assemble llvm+clang+libcxx at a given revision.

Currently

```
svn co http://llvm.org/svn/llvm-project/llvm/trunk llvm -r $REVISION
cd llvm/tools
svn co http://llvm.org/svn/llvm-project/clang/trunk clang -r $REVISION
cd ../projects
svn co http://llvm.org/svn/llvm-project/libcxx/trunk libcxx -r $REVISION
```

Or using git-svn:

```
git clone http://llvm.org/git/llvm.git
cd llvm/
git svn init https://llvm.org/svn/llvm-project/llvm/trunk --username=<username>
git config svn-remote.svn.fetch :refs/remotes/origin/master
git svn rebase -l
git checkout `git svn find-rev -B r258109`
cd tools
git clone http://llvm.org/git/clang.git
cd clang/
```

(continues on next page)

(continued from previous page)

```
git svn init https://llvm.org/svn/llvm-project/clang/trunk --username=<username>
git config svn-remote.svn.fetch :refs/remotes/origin/master
git svn rebase -l
git checkout `git svn find-rev -B r258109`
cd ../../projects/
git clone http://llvm.org/git/libcxx.git
cd libcxx
git svn init https://llvm.org/svn/llvm-project/libcxx/trunk --username=<username>
git config svn-remote.svn.fetch :refs/remotes/origin/master
git svn rebase -l
git checkout `git svn find-rev -B r258109`
```

Note that the list would be longer with more sub-projects.

Monorepo Variant

The repository contains natively the source for every sub-projects at the right revision, which makes this straightforward:

```
git clone https://github.com/llvm/llvm-project.git
cd llvm-projects
git checkout $REVISION
```

As before, at this point clang, llvm, and libcxx are stored in directories alongside each other.

Commit an API Change in LLVM and Update the Sub-projects

Today this is possible, even though not common (at least not documented) for subversion users and for git-svn users. For example, few Git users try to update LLD or Clang in the same commit as they change an LLVM API.

The multirepo variant does not address this: one would have to commit and push separately in every individual repository. It would be possible to establish a protocol whereby users add a special token to their commit messages that causes the umbrella repo's updater bot to group all of them into a single revision.

The monorepo variant handles this natively.

Branching/Stashing/Updating for Local Development or Experiments

Currently

SVN does not allow this use case, but developers that are currently using git-svn can do it. Let's look in practice what it means when dealing with multiple sub-projects.

To update the repository to tip of trunk:

```
git pull
cd tools/clang
git pull
cd ../../projects/libcxx
git pull
```

To create a new branch:

```
git checkout -b MyBranch
cd tools/clang
git checkout -b MyBranch
cd ../../projects/libcxx
git checkout -b MyBranch
```

To switch branches:

```
git checkout AnotherBranch
cd tools/clang
git checkout AnotherBranch
cd ../../projects/libcxx
git checkout AnotherBranch
```

Monorepo Variant

Regular Git commands are sufficient, because everything is in a single repository:

To update the repository to tip of trunk:

```
git pull
```

To create a new branch:

```
git checkout -b MyBranch
```

To switch branches:

```
git checkout AnotherBranch
```

Bisecting

Assuming a developer is looking for a bug in clang (or lld, or lldb, ...).

Currently

SVN does not have builtin bisection support, but the single revision across sub-projects makes it possible to script around.

Using the existing Git read-only view of the repositories, it is possible to use the native Git bisection script over the llvm repository, and use some scripting to synchronize the clang repository to match the llvm revision.

Monorepo Variant

Bisecting on the monorepo is straightforward, and very similar to the above, except that the bisection script does not need to include the *git submodule update* step.

The same example, finding which commit introduces a regression where clang-3.9 crashes but not clang-3.8 passes, will look like:

```
git bisect start releases/3.9.x releases/3.8.x
git bisect run ./bisect_script.sh
```

With the *bisect_script.sh* script being:

```
#!/bin/sh
cd $BUILD_DIR

ninja clang || exit 125    # an exit code of 125 asks "git bisect"
                          # to "skip" the current commit

./bin/clang some_crash_test.cpp
```

Also, since the monorepo handles commits update across multiple projects, you're less like to encounter a build failure where a commit change an API in LLVM and another later one "fixes" the build in clang.

Moving Local Branches to the Monorepo

Suppose you have been developing against the existing LLVM git mirrors. You have one or more git branches that you want to migrate to the "final monorepo".

The simplest way to migrate such branches is with the `migrate-downstream-fork.py` tool at <https://github.com/jyknight/llvm-git-migration>.

Basic migration

Basic instructions for `migrate-downstream-fork.py` are in the Python script and are expanded on below to a more general recipe:

```
# Make a repository which will become your final local mirror of the
# monorepo.
mkdir my-monorepo
git -C my-monorepo init

# Add a remote to the monorepo.
git -C my-monorepo remote add upstream/monorepo https://github.com/llvm/llvm-project.
↪git

# Add remotes for each git mirror you use, from upstream as well as
# your local mirror. All projects are listed here but you need only
# import those for which you have local branches.
my_projects=( clang
               clang-tools-extra
               compiler-rt
               debuginfo-tests
               libcxx
               libcxxabi
               libunwind
               lld
               lldb
               llvm
               openmp
               polly )
for p in ${my_projects[@]}; do
  git -C my-monorepo remote add upstream/split/${p} https://github.com/llvm-mirror/$
↪{p}.git
  git -C my-monorepo remote add local/split/${p} https://my.local.mirror.org/${p}.git
done
```

(continues on next page)

(continued from previous page)

```

# Pull in all the commits.
git -C my-monorepo fetch --all

# Run migrate-downstream-fork to rewrite local branches on top of
# the upstream monorepo.
(
  cd my-monorepo
  migrate-downstream-fork.py \
    refs/remotes/local \
    refs/tags \
    --new-repo-prefix=refs/remotes/upstream/monorepo \
    --old-repo-prefix=refs/remotes/upstream/split \
    --source-kind=split \
    --revmap-out=monorepo-map.txt
)

# Octopus-merge the resulting local split histories to unify them.

# Assumes local work on local split mirrors is on master (and
# upstream is presumably represented by some other branch like
# upstream/master).
my_local_branch="master"

git -C my-monorepo branch --no-track local/octopus/master \
  $(git -C my-monorepo merge-base refs/remotes/upstream/monorepo/master \
    refs/remotes/local/split/llvm/${my_local_branch})
git -C my-monorepo checkout local/octopus/${my_local_branch}

subproject_branches=()
for p in ${my_projects[@]}; do
  subproject_branch=${p}/local/monorepo/${my_local_branch}
  git -C my-monorepo branch ${subproject_branch} \
    refs/remotes/local/split/${p}/${my_local_branch}
  if [[ "${p}" != "llvm" ]]; then
    subproject_branches+=( ${subproject_branch} )
  fi
done

git -C my-monorepo merge ${subproject_branches[@]}

for p in ${my_projects[@]}; do
  subproject_branch=${p}/local/monorepo/${my_local_branch}
  git -C my-monorepo branch -d ${subproject_branch}
done

# Create local branches for upstream monorepo branches.
for ref in $(git -C my-monorepo for-each-ref --format="% (refname) " \
  refs/remotes/upstream/monorepo); do
  upstream_branch=${ref#refs/remotes/upstream/monorepo/}
  git -C my-monorepo branch upstream/${upstream_branch} ${ref}
done

```

The above gets you to a state like the following:

```

U1 - U2 - U3 <- upstream/master
 \   \   \

```

(continues on next page)

(continued from previous page)

```

      \      \      - Llld1 - Llld2 -
      \      \      \
      \      \      - Lclang1 - Lclang2-- Lmerge <- local/octopus/master
      \      \      /
      - Lllvm1 - Lllvm2-----

```

Each branched component has its branch rewritten on top of the monorepo and all components are unified by a giant octopus merge.

If additional active local branches need to be preserved, the above operations following the assignment to `my_local_branch` should be done for each branch. Ref paths will need to be updated to map the local branch to the corresponding upstream branch. If local branches have no corresponding upstream branch, then the creation of `local/octopus/<local branch>` need not use `git-merge-base` to pinpoint its root commit; it may simply be branched from the appropriate component branch (say, `llvm/local_release_X`).

Zippping local history

The octopus merge is suboptimal for many cases, because walking back through the history of one component leaves the other components fixed at a history that likely makes things unbuildable.

Some downstream users track the order commits were made to subprojects with some kind of "umbrella" project that imports the project git mirrors as submodules, similar to the multirepo umbrella proposed above. Such an umbrella repository looks something like this:

```

UM1 ---- UM2 -- UM3 -- UM4 ---- UM5 ---- UM6 ---- UM7 ---- UM8 <- master
|         |         |         |         |         |         |
Lllvm1    Llld1          Lclang1  Lclang2  Lllvm2    Llld2      Lmyproj1

```

The vertical bars represent submodule updates to a particular local commit in the project mirror. UM3 in this case is a commit of some local umbrella repository state that is not a submodule update, perhaps a README or project build script update. Commit UM8 updates a submodule of local project `myproj1`.

The tool `zip-downstream-fork.py` at <https://github.com/greened/llvm-git-migration/tree/zip> can be used to convert the umbrella history into a monorepo-based history with commits in the order implied by submodule updates:

```

U1 - U2 - U3 <- upstream/master
\      \      \
\      \      \
- Lllvm1 - Llld1 - UM3 - Lclang1 - Lclang2 - Lllvm2 - Llld2 - Lmyproj1 <- '
                                local/zip--

```

The `U*` commits represent upstream commits to the monorepo master branch. Each submodule update in the local `UM*` commits brought in a subproject tree at some local commit. The trees in the `L*` commits represent merges from upstream. These result in edges from the `U*` commits to their corresponding rewritten `L*` commits. The `L*2` commits did not do any merges from upstream.

Note that the merge from `U2` to `Lclang1` appears redundant, but if, say, `U3` changed some files in upstream clang, the `Lclang1` commit appearing after the `Llld1` commit would actually represent a clang tree *earlier* in the upstream clang history. We want the `local/zip` branch to accurately represent the state of our umbrella history and so the edge `U2 -> Lclang1` is a visual reminder of what clang's tree actually looks like in `Lclang1`.

Even so, the edge `U3 -> Llld1` could be problematic for future merges from upstream. `git` will think that we've already merged from `U3`, and we have, except for the state of the clang tree. One possible mitigation strategy is to manually diff clang between `U2` and `U3` and apply those updates to `local/zip`. Another, possibly simpler strategy is to freeze local work on downstream branches and merge all submodules from the latest upstream before running `zip-downstream-fork.py`. If downstream merged each project from upstream in lockstep without any

intervening local commits, then things should be fine without any special action. We anticipate this to be the common case.

The tree for `Lclang1` outside of `clang` will represent the state of things at `U3` since all of the upstream projects not participating in the umbrella history should be in a state respecting the commit `U3`. The trees for `llvm` and `lld` should correctly represent commits `L11vm1` and `L11d1`, respectively.

Commit `UM3` changed files not related to submodules and we need somewhere to put them. It is not safe in general to put them in the monorepo root directory because they may conflict with files in the monorepo. Let's assume we want them in a directory `local` in the monorepo.

Example 1: Umbrella looks like the monorepo

For this example, we'll assume that each subproject appears in its own top-level directory in the umbrella, just as they do in the monorepo. Let's also assume that we want the files in directory `myproj` to appear in `local/myproj`.

Given the above run of `migrate-downstream-fork.py`, a recipe to create the zipped history is below:

```
# Import any non-LLVM repositories the umbrella references.
git -C my-monorepo remote add localrepo \
    https://my.local.mirror.org/localrepo.git
git fetch localrepo

subprojects=( clang clang-tools-extra compiler-rt debuginfo-tests libclc
    libcxx libcxxabi libunwind lld lldb llgo llvm openmp
    parallel-libs polly pstl )

# Import histories for upstream split projects (this was probably
# already done for the ``migrate-downstream-fork.py`` run).
for project in ${subprojects[@]}; do
    git remote add upstream/split/${project} \
        https://github.com/llvm-mirror/${subproject}.git
    git fetch umbrella/split/${project}
done

# Import histories for downstream split projects (this was probably
# already done for the ``migrate-downstream-fork.py`` run).
for project in ${subprojects[@]}; do
    git remote add local/split/${project} \
        https://my.local.mirror.org/${subproject}.git
    git fetch local/split/${project}
done

# Import umbrella history.
git -C my-monorepo remote add umbrella \
    https://my.local.mirror.org/umbrella.git
git fetch umbrella

# Put myproj in local/myproj
echo "myproj local/myproj" > my-monorepo/submodule-map.txt

# Rewrite history
(
    cd my-monorepo
    zip-downstream-fork.py \
        refs/remotes/umbrella \
        --new-repo-prefix=refs/remotes/upstream/monorepo \
        --old-repo-prefix=refs/remotes/upstream/split \
        --revmap-in=monorepo-map.txt \
```

(continues on next page)

(continued from previous page)

```

--revmap-out=zip-map.txt \
--subdir=local \
--submodule-map=submodule-map.txt \
--update-tags
)

# Create the zip branch (assuming umbrella master is wanted).
git -C my-monorepo branch --no-track local/zip/master refs/remotes/umbrella/master

```

Note that if the umbrella has submodules to non-LLVM repositories, `zip-downstream-fork.py` needs to know about them to be able to rewrite commits. That is why the first step above is to fetch commits from such repositories.

With `--update-tags` the tool will migrate annotated tags pointing to submodule commits that were inlined into the zipped history. If the umbrella pulled in an upstream commit that happened to have a tag pointing to it, that tag will be migrated, which is almost certainly not what is wanted. The tag can always be moved back to its original commit after rewriting, or the `--update-tags` option may be discarded and any local tags would then be migrated manually.

Example 2: Nested sources layout

The tool handles nested submodules (e.g. `llvm` is a submodule in `umbrella` and `clang` is a submodule in `llvm`). The file `submodule-map.txt` is a list of pairs, one per line. The first pair item describes the path to a submodule in the umbrella repository. The second pair item describes the path where trees for that submodule should be written in the zipped history.

Let's say your umbrella repository is actually the `llvm` repository and it has submodules in the "nested sources" layout (`clang` in `tools/clang`, etc.). Let's also say `projects/myproj` is a submodule pointing to some downstream repository. The submodule map file should look like this (we still want `myproj` mapped the same way as previously):

```

tools/clang clang
tools/clang/tools/extra clang-tools-extra
projects/compiler-rt compiler-rt
projects/debuginfo-tests debuginfo-tests
projects/libclc libclc
projects/libcxx libcxx
projects/libcxxabi libcxxabi
projects/libunwind libunwind
tools/lld lld
tools/lldb lldb
projects/openmp openmp
tools/polly polly
projects/myproj local/myproj

```

If a submodule path does not appear in the map, the tool assumes it should be placed in the same place in the monorepo. That means if you use the "nested sources" layout in your umbrella, you *must* provide map entries for all of the projects in your umbrella (except `llvm`). Otherwise trees from submodule updates will appear underneath `llvm` in the zipped history.

Because `llvm` is itself the umbrella, we use `--subdir` to write its content into `llvm` in the zipped history:

```

# Import any non-LLVM repositories the umbrella references.
git -C my-monorepo remote add localrepo \
    https://my.local.mirror.org/localrepo.git
git fetch localrepo

subprojects=( clang clang-tools-extra compiler-rt debuginfo-tests libclc
    libcxx libcxxabi libunwind lld lldb llgo llvm openmp
    parallel-libs polly pstl )

```

(continues on next page)

(continued from previous page)

```

# Import histories for upstream split projects (this was probably
# already done for the ``migrate-downstream-fork.py`` run).
for project in ${subprojects[@]}; do
    git remote add upstream/split/${project} \
        https://github.com/llvm-mirror/${subproject}.git
    git fetch umbrella/split/${project}
done

# Import histories for downstream split projects (this was probably
# already done for the ``migrate-downstream-fork.py`` run).
for project in ${subprojects[@]}; do
    git remote add local/split/${project} \
        https://my.local.mirror.org/${subproject}.git
    git fetch local/split/${project}
done

# Import umbrella history. We want this under a different refs spec
# so zip-downstream-fork.py knows what it is.
git -C my-monorepo remote add umbrella \
    https://my.local.mirror.org/llvm.git
git fetch umbrella

# Create the submodule map.
echo "tools/clang clang" > my-monorepo/submodule-map.txt
echo "tools/clang/tools/extra clang-tools-extra" >> my-monorepo/submodule-map.txt
echo "projects/compiler-rt compiler-rt" >> my-monorepo/submodule-map.txt
echo "projects/debuginfo-tests debuginfo-tests" >> my-monorepo/submodule-map.txt
echo "projects/libclc libclc" >> my-monorepo/submodule-map.txt
echo "projects/libcxx libcxx" >> my-monorepo/submodule-map.txt
echo "projects/libcxxabi libcxxabi" >> my-monorepo/submodule-map.txt
echo "projects/libunwind libunwind" >> my-monorepo/submodule-map.txt
echo "tools/lld lld" >> my-monorepo/submodule-map.txt
echo "tools/lldb lldb" >> my-monorepo/submodule-map.txt
echo "projects/openmp openmp" >> my-monorepo/submodule-map.txt
echo "tools/polly polly" >> my-monorepo/submodule-map.txt
echo "projects/myproj local/myproj" >> my-monorepo/submodule-map.txt

# Rewrite history
(
    cd my-monorepo
    zip-downstream-fork.py \
        refs/remotes/umbrella \
        --new-repo-prefix=refs/remotes/upstream/monorepo \
        --old-repo-prefix=refs/remotes/upstream/split \
        --revmap-in=monorepo-map.txt \
        --revmap-out=zip-map.txt \
        --subdir=llvm \
        --submodule-map=submodule-map.txt \
        --update-tags
)

# Create the zip branch (assuming umbrella master is wanted).
git -C my-monorepo branch --no-track local/zip/master refs/remotes/umbrella/master

```

Comments at the top of `zip-downstream-fork.py` describe in more detail how the tool works and various implications of its operation.

Importing local repositories

You may have additional repositories that integrate with the LLVM ecosystem, essentially extending it with new tools. If such repositories are tightly coupled with LLVM, it may make sense to import them into your local mirror of the monorepo.

If such repositories participated in the umbrella repository used during the zipping process above, they will automatically be added to the monorepo. For downstream repositories that don't participate in an umbrella setup, the `import-downstream-repo.py` tool at <https://github.com/greened/llvm-git-migration/tree/import> can help with getting them into the monorepo. A recipe follows:

```
# Import downstream repo history into the monorepo.
git -C my-monorepo remote add myrepo https://my.local.mirror.org/myrepo.git
git fetch myrepo

my_local_tags=( refs/tags/release
                refs/tags/hotfix )

(
  cd my-monorepo
  import-downstream-repo.py \
    refs/remotes/myrepo \
    ${my_local_tags[@]} \
    --new-repo-prefix=refs/remotes/upstream/monorepo \
    --subdir=myrepo \
    --tag-prefix="myrepo-"
)

# Preserve release branches.
for ref in $(git -C my-monorepo for-each-ref --format="%(%(refname)s)" \
            refs/remotes/myrepo/release); do
  branch=${ref#refs/remotes/myrepo/}
  git -C my-monorepo branch --no-track myrepo/${branch} ${ref}
done

# Preserve master.
git -C my-monorepo branch --no-track myrepo/master refs/remotes/myrepo/master

# Merge master.
git -C my-monorepo checkout local/zip/master # Or local/octopus/master
git -C my-monorepo merge myrepo/master
```

You may want to merge other corresponding branches, for example `myrepo` release branches if they were in lockstep with LLVM project releases.

`--tag-prefix` tells `import-downstream-repo.py` to rename annotated tags with the given prefix. Due to limitations with `fast_filter_branch.py`, unannotated tags cannot be renamed (`fast_filter_branch.py` considers them branches, not tags). Since the upstream monorepo had its tags rewritten with an "llvmorg-" prefix, name conflicts should not be an issue. `--tag-prefix` can be used to more clearly indicate which tags correspond to various imported repositories.

Given this repository history:

```
R1 - R2 - R3 <- master
      ^
      |
      |
  release/1
```

The above recipe results in a history like this:

```

U1 - U2 - U3 <- upstream/master
\      \      \
\      \      \
\      \      \
- Lllvm1 - Ll1d1 - UM3 - Lclang1 - Lclang2 - Lllvm2 - Ll1d2 - Lmyproj1 - M1 <- '
                                                    /
                                                    R1 - R2 - R3 <- .
                                                    ^
                                                    |
myrepo-release/1 |
                  |
myrepo/master--'

```

Commits R1, R2 and R3 have trees that *only* contain blobs from myrepo. If you require commits from myrepo to be interleaved with commits on local project branches (for example, interleaved with llvm1, llvm2, etc. above) and myrepo doesn't appear in an umbrella repository, a new tool will need to be developed. Creating such a tool would involve:

1. Modifying `fast_filter_branch.py` to optionally take a revlist directly rather than generating it itself
2. Creating a tool to generate an interleaved ordering of local commits based on some criteria (`zip-downstream-fork.py` uses the umbrella history as its criterion)
3. Generating such an ordering and feeding it to `fast_filter_branch.py` as a revlist

Some care will also likely need to be taken to handle merge commits, to ensure the parents of such commits migrate correctly.

Scrubbing the Local Monorepo

Once all of the migrating, zipping and importing is done, it's time to clean up. The python tools use `git-fast-import` which leaves a lot of cruft around and we want to shrink our new monorepo mirror as much as possible. Here is one way to do it:

```

git -C my-monorepo checkout master

# Delete branches we no longer need. Do this for any other branches
# you merged above.
git -C my-monorepo branch -D local/zip/master || true
git -C my-monorepo branch -D local/octopus/master || true

# Remove remotes.
git -C my-monorepo remote remove upstream/monorepo

for p in ${my_projects[@]}; do
    git -C my-monorepo remote remove upstream/split/${p}
    git -C my-monorepo remote remove local/split/${p}
done

git -C my-monorepo remote remove localrepo
git -C my-monorepo remote remove umbrella
git -C my-monorepo remote remove myrepo

# Add anything else here you don't need. refs/tags/release is
# listed below assuming tags have been rewritten with a local prefix.

```

(continues on next page)

(continued from previous page)

```
# If not, remove it from this list.
refs_to_clean=(
  refs/original
  refs/remotes
  refs/tags/backups
  refs/tags/release
)

git -C my-monorepo for-each-ref --format="% (refname)" ${refs_to_clean[@]} |
  xargs -n1 --no-run-if-empty git -C my-monorepo update-ref -d

git -C my-monorepo reflog expire --all --expire=now

# fast_filter_branch.py might have gc running in the background.
while ! git -C my-monorepo \
  -c gc.reflogExpire=0 \
  -c gc.reflogExpireUnreachable=0 \
  -c gc.rerereresolved=0 \
  -c gc.rerereunresolved=0 \
  -c gc.pruneExpire=now \
  gc --prune=now; do
  continue
done

# Takes a LOOOONG time!
git -C my-monorepo repack -A -d -f --depth=250 --window=250

git -C my-monorepo prune-packed
git -C my-monorepo prune
```

You should now have a trim monorepo. Upload it to your git server and happy hacking!

6.4.2 Test-Suite Extentions

- *Abstract*
- *Benchmarks*
- *Applications/Libraries*
- *Generic Algorithms*

Abstract

These are ideas for additional programs, benchmarks, applications and algorithms that could be added to the LLVM Test-Suite. The test-suite could be much larger than it is now, which would help us detecting compiler errors (crashes, miscompiles) during development.

Most probably, the reason why the programs below have not been added to the test-suite yet is that nobody has found time to do it. But there might be other issues as well, such as

- **Licensing (Support can still be added as external module,** like for the SPEC benchmarks)
- **Language (in particular, there is no official LLVM frontend** for FORTRAN yet)
- **Parallelism (currently, all programs in test-suite use** one thread only)

Benchmarks

SPEC CPU 2017

<https://www.spec.org/cpu2017/>

The following have not been included yet because they contain Fortran code.

In case of cactuBSSN only a small portion is Fortran. The hosts's Fortran compiler could be used for these parts.

Note that CMake's Ninja generator has difficulties with Fortran. See the [CMake documentation](#) for details.

6.4.3 Variable Names Plan

- *Too Long; Didn't Read*
- *Introduction*
- *Variable Names Coding Standard Options*
 - *Differentiating variable kinds*
- *Reducing the number of acronyms*
- *Transition Options*
 - *Keep the current coding standard*
 - *Laissez faire*
 - * *Advantages*
 - * *Disadvantages*
 - *Big bang*
 - * *Keeping git blame usable*
 - * *Minimising cost of downstream merges*
- *Provisional Plan*
- *References*

This plan is *provisional*. It is not agreed upon. It is written with the intention of capturing the desires and concerns of the LLVM community, and forming them into a plan that can be agreed upon. The original author is somewhat naïve in the ways of LLVM so there will inevitably be some details that are flawed. You can help - you can edit this page (preferably with a Phabricator review for larger changes) or reply to the [Request For Comments thread](#).

Too Long; Didn't Read

Improve the readability of LLVM code.

Introduction

The current [variable naming rule](#) states:

Variable names should be nouns (as they represent state). The name should be camel case, and start with an upper case letter (e.g. `Leader` or `Boats`).

This rule is the same as that for type names. This is a problem because the type name cannot be reused for a variable name⁰. LLVM developers tend to work around this by either prepending `The` to the type name:

⁰ In [some cases](#) the type name *is* reused as a variable name, but this shadows the type name and confuses many debuggers [[DenisovCamelBack](#)].

```
Triple TheTriple;
```

... or more commonly use an acronym, despite the coding standard stating "Avoid abbreviations unless they are well known":

```
Triple T;
```

The proliferation of acronyms leads to hard-to-read code such as [this](#):

```
InnerLoopVectorizer LB(L, PSE, LI, DT, TLI, TTI, AC, ORE, VF.Width, IC,
                      &LVL, &CM);
```

Many other coding guidelines [\[LLDB\]](#) [\[Google\]](#) [\[WebKit\]](#) [\[Qt\]](#) [\[Rust\]](#) [\[Swift\]](#) [\[Python\]](#) require that variable names begin with a lower case letter in contrast to class names which begin with a capital letter. This convention means that the most readable variable name also requires the least thought:

```
Triple triple;
```

There is some agreement that the current rule is broken [\[LattnerAgree\]](#) [\[ArsenaultAgree\]](#) [\[RobinsonAgree\]](#) and that acronyms are an obstacle to reading new code [\[MalyutinDistinguish\]](#) [\[CarruthAcronym\]](#) [\[PicusAcronym\]](#). There are some opposing views [\[ParzyszekAcronym2\]](#) [\[RicciAcronyms\]](#).

This work-in-progress proposal is to change the coding standard for variable names to require that they start with a lower case letter.

Variable Names Coding Standard Options

There are two main options for variable names that begin with a lower case letter: `camelBack` and `lower_case`. (These are also known by other names but here we use the terminology from clang-tidy).

`camelBack` is consistent with [\[WebKit\]](#), [\[Qt\]](#) and [\[Swift\]](#) while `lower_case` is consistent with [\[LLDB\]](#), [\[Google\]](#), [\[Rust\]](#) and [\[Python\]](#).

`camelBack` is already used for function names, which may be considered an advantage [\[LattnerFunction\]](#) or a disadvantage [\[CarruthFunction\]](#).

Approval for `camelBack` was expressed by [\[DenisovCamelBack\]](#) [\[LattnerFunction\]](#) [\[IvanovicDistinguish\]](#). Opposition to `camelBack` was expressed by [\[CarruthCamelBack\]](#) [\[TurnerCamelBack\]](#). Approval for `lower_case` was expressed by [\[CarruthLower\]](#) [\[CarruthCamelBack\]](#) [\[TurnerLLDB\]](#). Opposition to `lower_case` was expressed by [\[LattnerLower\]](#).

Differentiating variable kinds

An additional requested change is to distinguish between different kinds of variables [\[RobinsonDistinguish\]](#) [\[RobinsonDistinguish2\]](#) [\[JonesDistinguish\]](#) [\[IvanovicDistinguish\]](#) [\[CarruthDistinguish\]](#) [\[MalyutinDistinguish\]](#).

Others oppose this idea [\[HähnleDistinguish\]](#) [\[GreeneDistinguish\]](#) [\[HendersonPrefix\]](#).

A possibility is for member variables to be prefixed with `m_` and for global variables to be prefixed with `g_` to distinguish them from local variables. This is consistent with [\[LLDB\]](#). The `m_` prefix is consistent with [\[WebKit\]](#).

A variation is for member variables to be prefixed with `m` [\[IvanovicDistinguish\]](#) [\[BeylsDistinguish\]](#). This is consistent with [\[Mozilla\]](#).

Another option is for member variables to be suffixed with `_` which is consistent with [\[Google\]](#) and similar to [\[Python\]](#). Opposed by [\[ParzyszekDistinguish\]](#).

Reducing the number of acronyms

While switching coding standard will make it easier to use non-acronym names for new code, it doesn't improve the existing large body of code that uses acronyms extensively to the detriment of its readability. Further, it is natural and generally encouraged that new code be written in the style of the surrounding code. Therefore it is likely that much newly written code will also use acronyms despite what the coding standard says, much as it is today.

As well as changing the case of variable names, they could also be expanded to their non-acronym form e.g. `Triple T` → `Triple triple`.

There is support for expanding many acronyms [[CarruthAcronym](#)] [[PicusAcronym](#)] but there is a preference that expanding acronyms be deferred [[ParzyszekAcronym](#)] [[CarruthAcronym](#)].

The consensus within the community seems to be that at least some acronyms are valuable [[ParzyszekAcronym](#)] [[LattnerAcronym](#)]. The most commonly cited acronym is `TLI` however that is used to refer to both `TargetLowering` and `TargetLibraryInfo` [[GreeneDistinguish](#)].

The following is a list of acronyms considered sufficiently useful that the benefit of using them outweighs the cost of learning them. Acronyms that are either not on the list or are used to refer to a different type should be expanded.

Class name	Variable name
<code>DeterministicFiniteAutomaton</code>	<code>dfa</code>
<code>DominatorTree</code>	<code>dt</code>
<code>LoopInfo</code>	<code>li</code>
<code>MachineFunction</code>	<code>mf</code>
<code>MachineInstr</code>	<code>mi</code>
<code>MachineRegisterInfo</code>	<code>mri</code>
<code>ScalarEvolution</code>	<code>se</code>
<code>TargetInstrInfo</code>	<code>tii</code>
<code>TargetLibraryInfo</code>	<code>tli</code>
<code>TargetRegisterInfo</code>	<code>tri</code>

In some cases renaming acronyms to the full type name will result in overly verbose code. Unlike most classes, a variable's scope is limited and therefore some of its purpose can be implied from that scope, meaning that fewer words are necessary to give it a clear name. For example, in an optimization pass the reader can assume that a variable's purpose relates to optimization and therefore an `OptimizationRemarkEmitter` variable could be given the name `remarkEmitter` or even `remarker`.

The following is a list of longer class names and the associated shorter variable name.

Class name	Variable name
<code>BasicBlock</code>	<code>block</code>
<code>ConstantExpr</code>	<code>expr</code>
<code>ExecutionEngine</code>	<code>engine</code>
<code>MachineOperand</code>	<code>operand</code>
<code>OptimizationRemarkEmitter</code>	<code>remarker</code>
<code>PreservedAnalyses</code>	<code>analyses</code>
<code>PreservedAnalysesChecker</code>	<code>checker</code>
<code>TargetLowering</code>	<code>lowering</code>
<code>TargetMachine</code>	<code>machine</code>

Transition Options

There are three main options for transitioning:

1. Keep the current coding standard
2. Laissez faire
3. Big bang

Keep the current coding standard

Proponents of keeping the current coding standard (i.e. not transitioning at all) question whether the cost of transition outweighs the benefit [EmersonConcern] [ReamesConcern] [BradburyConcern]. The costs are that `git blame` will become less usable; and that merging the changes will be costly for downstream maintainers. See *Big bang* for potential mitigations.

Laissez faire

The coding standard could allow both `CamelCase` and `camelBack` styles for variable names [LattnerTransition].

A code review to implement this is at <https://reviews.llvm.org/D57896>.

Advantages

- Very easy to implement initially.

Disadvantages

- Leads to inconsistency [BradburyConcern] [AminiInconsistent].
- Inconsistency means it will be hard to know at a guess what name a variable will have [DasInconsistent] [CarruthInconsistent].
- Some large-scale renaming may happen anyway, leading to its disadvantages without any mitigations.

Big bang

With this approach, variables will be renamed by an automated script in a series of large commits.

The principle advantage of this approach is that it minimises the cost of inconsistency [BradburyTransition] [RobinsonTransition].

It goes against a policy of avoiding large-scale reformatting of existing code [GreeneDistinguish].

It has been suggested that LLD would be a good starter project for the renaming [Ueyama].

Keeping git blame usable

`git blame` (or `git annotate`) permits quickly identifying the commit that changed a given line in a file. After renaming variables, many lines will show as being changed by that one commit, requiring a further invocation of `git blame` to identify prior, more interesting commits [GreeneGitBlame] [RicciAcronyms].

Mitigation: `git-hyper-blame` can ignore or "look through" a given set of commits. A `.git-blame-ignore-revs` file identifying the variable renaming commits could be added to the LLVM git repository root directory. It is being investigated whether similar functionality could be added to `git blame` itself.

Minimising cost of downstream merges

There are many forks of LLVM with downstream changes. Merging a large-scale renaming change could be difficult for the fork maintainers.

Mitigation: A large-scale renaming would be automated. A fork maintainer can merge from the commit immediately before the renaming, then apply the renaming script to their own branch. They can then merge again from the renaming commit, resolving all conflicts by choosing their own version. This could be tested on the [SVE] fork.

Provisional Plan

This is a provisional plan for the *Big bang* approach. It has not been agreed.

1. Investigate improving `git blame`. The extent to which it can be made to "look through" commits may impact how big a change can be made.
2. Write a script to expand acronyms.
3. Experiment and perform dry runs of the various refactoring options. Results can be published in forks of the LLVM Git repository.
4. Consider the evidence and agree on the new policy.
5. Agree & announce a date for the renaming of the starter project (LLD).
6. Update the [policy page](#). This will explain the old and new rules and which projects each applies to.
7. Refactor the starter project in two commits:
 1. Add or change the project's `.clang-tidy` to reflect the agreed rules. (This is in a separate commit to enable the merging process described in *Minimising cost of downstream merges*). Also update the project list on the policy page.
 2. Apply `clang-tidy` to the project's files, with only the `readability-identifier-naming` rules enabled. `clang-tidy` will also reformat the affected lines according to the rules in `.clang-format`. It is anticipated that this will be a good dog-fooding opportunity for `clang-tidy`, and bugs should be fixed in the process, likely including:
 - `readability-identifier-naming` incorrectly fixes lambda capture.
 - `readability-identifier-naming` incorrectly fixes variables which become keywords.
 - `readability-identifier-naming` misses fixing member variables in destructor.
8. Gather feedback and refine the process as appropriate.
9. Apply the process to the following projects, with a suitable delay between each (at least 4 weeks after the first change, at least 2 weeks subsequently) to allow gathering further feedback. This list should exclude projects that must adhere to an externally defined standard e.g. `libcxx`. The list is roughly in chronological order of

renaming. Some items may not make sense to rename individually - it is expected that this list will change following experimentation:

- TableGen
- llvm/tools
- clang-tools-extra
- clang
- ARM backend
- AArch64 backend
- AMDGPU backend
- ARC backend
- AVR backend
- BPF backend
- Hexagon backend
- Lanai backend
- MIPS backend
- NVPTX backend
- PowerPC backend
- RISC-V backend
- Sparc backend
- SystemZ backend
- WebAssembly backend
- X86 backend
- XCore backend
- libLTO
- Debug Information
- Remainder of llvm
- compiler-rt
- libunwind
- openmp
- parallel-libs
- polly
- lldb

10. Remove the old variable name rule from the policy page.

11. Repeat many of the steps in the sequence, using a script to expand acronyms.
