
LLVM Documentation

Release 9

LLVM project

2020-06-23

CONTENTS

1	LLVM Design & Overview	3
1.1	LLVM Language Reference Manual	3
2	User Guides	313
2.1	Building LLVM with CMake	313
2.2	CMake Primer	324
2.3	Advanced Build Configurations	331
2.4	How To Build On ARM	333
2.5	How To Build Clang and LLVM with Profile-Guided Optimizations	335
2.6	How to Cross Compile Compiler-rt Builtins For Arm	337
2.7	How To Cross-Compile Clang/LLVM using Clang/LLVM	342
2.8	LLVM Command Guide	345
2.9	Getting Started with the LLVM System	460
2.10	Getting Started with the LLVM System using Microsoft Visual Studio	477
2.11	Frequently Asked Questions (FAQ)	481
2.12	The LLVM Lexicon	487
2.13	How To Add Your Build Configuration To LLVM Buildbot Infrastructure	490
2.14	yaml2obj	492
2.15	How to submit an LLVM bug report	496
2.16	Sphinx Quickstart Template	499
2.17	Markdown Quickstart Template	501
2.18	Code Reviews with Phabricator	503
2.19	LLVM Testing Infrastructure Guide	507
2.20	LLVM Tutorial: Table of Contents	524
2.21	LLVM 9.0.0 Release Notes	900
2.22	LLVM's Analysis and Transform Passes	906
2.23	YAML I/O	928
2.24	The Often Misunderstood GEP Instruction	944
2.25	Performance Tips for Frontend Authors	953
2.26	MCJIT Design and Implementation	958
2.27	ORC Design and Implementation	964
2.28	LLVM Community Code of Conduct	973
2.29	Compiling CUDA with clang	975
2.30	Reporting Guide	983
2.31	Benchmarking tips	985
2.32	A guide to Dockerfiles for building LLVM	987
2.33	Building a Distribution of LLVM	990
2.34	Remarks	993
3	Programming Documentation	999

3.1	LLVM Atomic Instructions and Concurrency Guide	999
3.2	LLVM Coding Standards	1008
3.3	CommandLine 2.0 Library Manual	1034
3.4	Architecture & Platform Information for Compiler Writers	1058
3.5	Extending LLVM: Adding instructions, intrinsics, types, etc.	1062
3.6	How to set up LLVM-style RTTI for your class hierarchy	1066
3.7	LLVM Programmer's Manual	1072
3.8	LLVM Extensions	1133
3.9	libFuzzer – a library for coverage-guided fuzz testing.	1142
3.10	Fuzzing LLVM libraries and tools	1155
3.11	Scudo Hardened Allocator	1159
3.12	Using -opt-bisect-limit to debug optimization errors	1163
4	Subsystem Documentation	1167
4.1	LLVM Alias Analysis Infrastructure	1167
4.2	MemorySSA	1179
4.3	LLVM Bitcode File Format	1184
4.4	LLVM Block Frequency Terminology	1206
4.5	LLVM Branch Weight Metadata	1209
4.6	LLVM bugpoint tool: design and usage	1211
4.7	The LLVM Target-Independent Code Generator	1215
4.8	Exception Handling in LLVM	1251
4.9	How To Add A Constrained Floating-Point Intrinsic	1264
4.10	LLVM Link Time Optimization: Design and Implementation	1266
4.11	Segmented Stacks in LLVM	1271
4.12	TableGen Fundamentals	1272
4.13	TableGen	1272
4.14	Debugging JIT-ed Code With GDB	1307
4.15	The LLVM gold plugin	1310
4.16	LLVM's Optional Rich Disassembly Output	1312
4.17	System Library	1314
4.18	Support Library	1314
4.19	Source Level Debugging with LLVM	1318
4.20	Auto-Vectorization in LLVM	1352
4.21	Writing an LLVM Backend	1364
4.22	Garbage Collection with LLVM	1396
4.23	Writing an LLVM Pass	1411
4.24	How To Use Attributes	1432
4.25	User Guide for NVPTX Back-end	1433
4.26	User Guide for AMDGPU Backend	1449
4.27	Stack maps and patch points in LLVM	1882
4.28	Design and Usage of the InAlloca Attribute	1890
4.29	Using ARM NEON instructions in big endian mode	1892
4.30	LLVM Code Coverage Mapping Format	1899
4.31	Garbage Collection Safepoints in LLVM	1908
4.32	MergeFunctions pass, how it works	1922
4.33	Type Metadata	1934
4.34	Code Transformation Metadata	1937
4.35	FaultMaps and implicit checks	1944
4.36	Machine IR (MIR) Format Reference Manual	1946
4.37	Coroutines in LLVM	1957
4.38	Global Instruction Selection	1979
4.39	XRay Instrumentation	1991
4.40	Debugging with XRay	1996

4.41	XRay Flight Data Recorder Trace Format	2003
4.42	The PDB File Format	2009
4.43	Control Flow Verification Tool Design Document	2043
4.44	Speculative Load Hardening	2045
4.45	Stack Safety Analysis	2062
5	Development Process Documentation	2065
5.1	Contributing to LLVM	2065
5.2	LLVM Developer Policy	2067
5.3	Creating an LLVM Project	2080
5.4	LLVMBuild Guide	2084
5.5	How To Release LLVM To The Public	2089
5.6	Advice on Packaging LLVM	2095
5.7	How To Validate a New Release	2096
5.8	LLVM Bug Life Cycle	2099
6	Community	2103
6.1	Mailing Lists	2103
6.2	IRC	2103
6.3	Meetups and social events	2104
6.4	Community wide proposals	2105
7	Indices and tables	2137
	Bibliography	2139

The LLVM compiler infrastructure supports a wide range of projects, from industrial strength compilers to specialized JIT applications to small research projects.

Similarly, documentation is broken down into several high-level groupings targeted at different audiences:

LLVM DESIGN & OVERVIEW

Several introductory papers and presentations.

1.1 LLVM Language Reference Manual

- *Abstract*
- *Introduction*
 - *Well-Formedness*
- *Identifiers*
- *High Level Structure*
 - *Module Structure*
 - *Linkage Types*
 - *Calling Conventions*
 - *Visibility Styles*
 - *DLL Storage Classes*
 - *Thread Local Storage Models*
 - *Runtime Preemption Specifiers*
 - *Structure Types*
 - *Non-Integral Pointer Type*
 - *Global Variables*
 - *Functions*
 - *Aliases*

1.1.1 Abstract

This document is a reference manual for the LLVM assembly language. LLVM is a Static Single Assignment (SSA) based representation that provides type safety, low-level operations, flexibility, and the capability of representing 'all' high-level languages cleanly. It is the common code representation used throughout all phases of the LLVM compilation strategy.

1.1.2 Introduction

The LLVM code representation is designed to be used in three different forms: as an in-memory compiler IR, as an on-disk bitcode representation (suitable for fast loading by a Just-In-Time compiler), and as a human readable assembly language representation. This allows LLVM to provide a powerful intermediate representation for efficient compiler transformations and analysis, while providing a natural means to debug and visualize the transformations. The three different forms of LLVM are all equivalent. This document describes the human readable representation and notation.

The LLVM representation aims to be light-weight and low-level while being expressive, typed, and extensible at the same time. It aims to be a "universal IR" of sorts, by being at a low enough level that high-level ideas may be cleanly mapped to it (similar to how microprocessors are "universal IR's", allowing many source languages to be mapped to them). By providing type information, LLVM can be used as the target of optimizations: for example, through pointer analysis, it can be proven that a C automatic variable is never accessed outside of the current function, allowing it to be promoted to a simple SSA value instead of a memory location.

Well-Formedness

It is important to note that this document describes 'well formed' LLVM assembly language. There is a difference between what the parser accepts and what is considered 'well formed'. For example, the following instruction is syntactically okay, but not well formed:

```
%x = add i32 1, %x
```

because the definition of %x does not dominate all of its uses. The LLVM infrastructure provides a verification pass that may be used to verify that an LLVM module is well formed. This pass is automatically run by the parser after

parsing input assembly and by the optimizer before it outputs bitcode. The violations pointed out by the verifier pass indicate bugs in transformation passes or input to the parser.

1.1.3 Identifiers

LLVM identifiers come in two basic types: global and local. Global identifiers (functions, global variables) begin with the '@' character. Local identifiers (register names, types) begin with the '%' character. Additionally, there are three different formats for identifiers, for different purposes:

1. Named values are represented as a string of characters with their prefix. For example, %foo, @DivisionByZero, %a.really.long.identifier. The actual regular expression used is '[%@] [-a-zA-Z\$. _] [-a-zA-Z\$. _0-9] *'. Identifiers that require other characters in their names can be surrounded with quotes. Special characters may be escaped using "\xx" where xx is the ASCII code for the character in hexadecimal. In this way, any character can be used in a name value, even quotes themselves. The "\01" prefix can be used on global values to suppress mangling.
2. Unnamed values are represented as an unsigned numeric value with their prefix. For example, %12, @2, %44.
3. Constants, which are described in the section *Constants* below.

LLVM requires that values start with a prefix for two reasons: Compilers don't need to worry about name clashes with reserved words, and the set of reserved words may be expanded in the future without penalty. Additionally, unnamed identifiers allow a compiler to quickly come up with a temporary variable without having to avoid symbol table conflicts.

Reserved words in LLVM are very similar to reserved words in other languages. There are keywords for different opcodes ('add', 'bitcast', 'ret', etc...), for primitive type names ('void', 'i32', etc...), and others. These reserved words cannot conflict with variable names, because none of them start with a prefix character ('%' or '@').

Here is an example of LLVM code to multiply the integer variable '%X' by 8:

The easy way:

```
%result = mul i32 %X, 8
```

After strength reduction:

```
%result = shl i32 %X, 3
```

And the hard way:

```
%0 = add i32 %X, %X           ; yields i32:%0
%1 = add i32 %0, %0           ; yields i32:%1
%result = add i32 %1, %1
```

This last way of multiplying %X by 8 illustrates several important lexical features of LLVM:

1. Comments are delimited with a ';' and go until the end of line.
2. Unnamed temporaries are created when the result of a computation is not assigned to a named value.
3. Unnamed temporaries are numbered sequentially (using a per-function incrementing counter, starting with 0). Note that basic blocks and unnamed function parameters are included in this numbering. For example, if the entry basic block is not given a label name and all function parameters are named, then it will get number 0.

It also shows a convention that we follow in this document. When demonstrating instructions, we will follow an instruction with a comment that defines the type and name of value produced.

1.1.4 High Level Structure

Module Structure

LLVM programs are composed of Module's, each of which is a translation unit of the input programs. Each module consists of functions, global variables, and symbol table entries. Modules may be combined together with the LLVM linker, which merges function (and global variable) definitions, resolves forward declarations, and merges symbol table entries. Here is an example of the "hello world" module:

```
; Declare the string constant as a global constant.
@.str = private unnamed_addr constant [13 x i8] c"hello world\0A\00"

; External declaration of the puts function
declare i32 @puts(i8* nocapture) nounwind

; Definition of main function
define i32 @main() { ; i32()*
    ; Convert [13 x i8]* to i8*...
    %cast210 = getelementptr [13 x i8], [13 x i8]* @.str, i64 0, i64 0

    ; Call puts function to write out the string to stdout.
    call i32 @puts(i8* %cast210)
    ret i32 0
}

; Named metadata
!0 = !{i32 42, null, !"string"}
!foo = !{!0}
```

This example is made up of a *global variable* named ".str", an external declaration of the "puts" function, a *function definition* for "main" and *named metadata* "foo".

In general, a module is made up of a list of global values (where both functions and global variables are global values). Global values are represented by a pointer to a memory location (in this case, a pointer to an array of char, and a pointer to a function), and have one of the following *linkage types*.

Linkage Types

All Global Variables and Functions have one of the following types of linkage:

private Global values with "private" linkage are only directly accessible by objects in the current module.

In particular, linking code into a module with a private global value may cause the private to be renamed as necessary to avoid collisions. Because the symbol is private to the module, all references can be updated. This doesn't show up in any symbol table in the object file.

internal Similar to private, but the value shows as a local symbol (STB_LOCAL in the case of ELF) in the object file. This corresponds to the notion of the 'static' keyword in C.

available_externally Globals with "available_externally" linkage are never emitted into the object file corresponding to the LLVM module. From the linker's perspective, an `available_externally` global is equivalent to an external declaration. They exist to allow inlining and other optimizations to take place given knowledge of the definition of the global, which is known to be somewhere outside the module. Globals with `available_externally` linkage are allowed to be discarded at will, and allow inlining and other optimizations. This linkage type is only allowed on definitions, not declarations.

linkonce Globals with "linkonce" linkage are merged with other globals of the same name when linkage occurs. This can be used to implement some forms of inline functions, templates, or other code which must be generated

in each translation unit that uses it, but where the body may be overridden with a more definitive definition later. Unreferenced `linkonce` globals are allowed to be discarded. Note that `linkonce` linkage does not actually allow the optimizer to inline the body of this function into callers because it doesn't know if this definition of the function is the definitive definition within the program or whether it will be overridden by a stronger definition. To enable inlining and other optimizations, use `"linkonce_odr"` linkage.

weak "weak" linkage has the same merging semantics as `linkonce` linkage, except that unreferenced globals with `weak` linkage may not be discarded. This is used for globals that are declared "weak" in C source code.

common "common" linkage is most similar to "weak" linkage, but they are used for tentative definitions in C, such as `"int X;"` at global scope. Symbols with "common" linkage are merged in the same way as `weak` symbols, and they may not be deleted if unreferenced. `common` symbols may not have an explicit section, must have a zero initializer, and may not be marked '*constant*'. Functions and aliases may not have common linkage.

appending "appending" linkage may only be applied to global variables of pointer to array type. When two global variables with appending linkage are linked together, the two global arrays are appended together. This is the LLVM, typesafe, equivalent of having the system linker append together "sections" with identical names when `.o` files are linked.

Unfortunately this doesn't correspond to any feature in `.o` files, so it can only be used for variables like `llvm.global_ctors` which `llvm` interprets specially.

extern_weak The semantics of this linkage follow the ELF object file model: the symbol is weak until linked, if not linked, the symbol becomes null instead of being an undefined reference.

linkonce_odr, weak_odr Some languages allow differing globals to be merged, such as two functions with different semantics. Other languages, such as C++, ensure that only equivalent globals are ever merged (the "one definition rule" --- "ODR"). Such languages can use the `linkonce_odr` and `weak_odr` linkage types to indicate that the global will only be merged with equivalent globals. These linkage types are otherwise the same as their non-`odr` versions.

external If none of the above identifiers are used, the global is externally visible, meaning that it participates in linkage and can be used to resolve external symbol references.

It is illegal for a function *declaration* to have any linkage type other than `external` or `extern_weak`.

Calling Conventions

LLVM *functions*, *calls* and *invokes* can all have an optional calling convention specified for the call. The calling convention of any pair of dynamic caller/callee must match, or the behavior of the program is undefined. The following calling conventions are supported by LLVM, and more may be added in the future:

"ccc" - The C calling convention This calling convention (the default if no other calling convention is specified) matches the target C calling conventions. This calling convention supports `varargs` function calls and tolerates some mismatch in the declared prototype and implemented declaration of the function (as does normal C).

"fastcc" - The fast calling convention This calling convention attempts to make calls as fast as possible (e.g. by passing things in registers). This calling convention allows the target to use whatever tricks it wants to produce fast code for the target, without having to conform to an externally specified ABI (Application Binary Interface). *Tail calls can only be optimized when this, the GHC or the HiPE convention is used.* This calling convention does not support `varargs` and requires the prototype of all callees to exactly match the prototype of the function definition.

"coldcc" - The cold calling convention This calling convention attempts to make code in the caller as efficient as possible under the assumption that the call is not commonly executed. As such, these calls often preserve all registers so that the call does not break any live ranges in the caller side. This calling convention does not support `varargs` and requires the prototype of all callees to exactly match the prototype of the function definition. Furthermore the inliner doesn't consider such function calls for inlining.

"cc 10" - GHC convention This calling convention has been implemented specifically for use by the [Glasgow Haskell Compiler \(GHC\)](#). It passes everything in registers, going to extremes to achieve this by disabling callee save registers. This calling convention should not be used lightly but only for specific situations such as an alternative to the *register pinning* performance technique often used when implementing functional programming languages. At the moment only X86 supports this convention and it has the following limitations:

- On X86-32 only supports up to 4 bit type parameters. No floating-point types are supported.
- On X86-64 only supports up to 10 bit type parameters and 6 floating-point parameters.

This calling convention supports [tail call optimization](#) but requires both the caller and callee are using it.

"cc 11" - The HiPE calling convention This calling convention has been implemented specifically for use by the [High-Performance Erlang \(HiPE\)](#) compiler, the native code compiler of the [Ericsson's Open Source Erlang/OTP system](#). It uses more registers for argument passing than the ordinary C calling convention and defines no callee-saved registers. The calling convention properly supports [tail call optimization](#) but requires that both the caller and the callee use it. It uses a *register pinning* mechanism, similar to GHC's convention, for keeping frequently accessed runtime components pinned to specific hardware registers. At the moment only X86 supports this convention (both 32 and 64 bit).

"webkit_jscc" - WebKit's JavaScript calling convention This calling convention has been implemented for [WebKit FTL JIT](#). It passes arguments on the stack right to left (as cdecl does), and returns a value in the platform's customary return register.

"anyregcc" - Dynamic calling convention for code patching This is a special convention that supports patching an arbitrary code sequence in place of a call site. This convention forces the call arguments into registers but allows them to be dynamically allocated. This can currently only be used with calls to `llvm.experimental.patchpoint` because only this intrinsic records the location of its arguments in a side table. See [Stack maps and patch points in LLVM](#).

"preserve_mostcc" - The PreserveMost calling convention This calling convention attempts to make the code in the caller as unintrusive as possible. This convention behaves identically to the C calling convention on how arguments and return values are passed, but it uses a different set of caller/callee-saved registers. This alleviates the burden of saving and recovering a large register set before and after the call in the caller. If the arguments are passed in callee-saved registers, then they will be preserved by the callee across the call. This doesn't apply for values returned in callee-saved registers.

- On X86-64 the callee preserves all general purpose registers, except for R11. R11 can be used as a scratch register. Floating-point registers (XMMs/YMMs) are not preserved and need to be saved by the caller.

The idea behind this convention is to support calls to runtime functions that have a hot path and a cold path. The hot path is usually a small piece of code that doesn't use many registers. The cold path might need to call out to another function and therefore only needs to preserve the caller-saved registers, which haven't already been saved by the caller. The *PreserveMost* calling convention is very similar to the *coldcc* calling convention in terms of caller/callee-saved registers, but they are used for different types of function calls. *coldcc* is for function calls that are rarely executed, whereas *preserve_mostcc* function calls are intended to be on the hot path and definitely executed a lot. Furthermore *preserve_mostcc* doesn't prevent the inliner from inlining the function call.

This calling convention will be used by a future version of the ObjectiveC runtime and should therefore still be considered experimental at this time. Although this convention was created to optimize certain runtime calls to the ObjectiveC runtime, it is not limited to this runtime and might be used by other runtimes in the future too. The current implementation only supports X86-64, but the intention is to support more architectures in the future.

"preserve_allcc" - The PreserveAll calling convention This calling convention attempts to make the code in the caller even less intrusive than the *PreserveMost* calling convention. This calling convention also behaves identical to the C calling convention on how arguments and return values are passed, but it uses a different set of caller/callee-saved registers. This removes the burden of saving and recovering a large register set before and

after the call in the caller. If the arguments are passed in callee-saved registers, then they will be preserved by the callee across the call. This doesn't apply for values returned in callee-saved registers.

- On X86-64 the callee preserves all general purpose registers, except for R11. R11 can be used as a scratch register. Furthermore it also preserves all floating-point registers (XMMs/YMMs).

The idea behind this convention is to support calls to runtime functions that don't need to call out to any other functions.

This calling convention, like the *PreserveMost* calling convention, will be used by a future version of the ObjectiveC runtime and should be considered experimental at this time.

"cxx_fast_tlscc" - The CXX_FAST_TLS calling convention for access functions Clang generates an access function to access C++-style TLS. The access function generally has an entry block, an exit block and an initialization block that is run at the first time. The entry and exit blocks can access a few TLS IR variables, each access will be lowered to a platform-specific sequence.

This calling convention aims to minimize overhead in the caller by preserving as many registers as possible (all the registers that are preserved on the fast path, composed of the entry and exit blocks).

This calling convention behaves identical to the C calling convention on how arguments and return values are passed, but it uses a different set of caller/callee-saved registers.

Given that each platform has its own lowering sequence, hence its own set of preserved registers, we can't use the existing *PreserveMost*.

- On X86-64 the callee preserves all general purpose registers, except for RDI and RAX.

"swiftcc" - This calling convention is used for Swift language.

- On X86-64 RCX and R8 are available for additional integer returns, and XMM2 and XMM3 are available for additional FP/vector returns.
- On iOS platforms, we use AAPCS-VFP calling convention.

"cc <n>" - Numbered convention Any calling convention may be specified by number, allowing target-specific calling conventions to be used. Target specific calling conventions start at 64.

More calling conventions can be added/defined on an as-needed basis, to support Pascal conventions or any other well-known target-independent convention.

Visibility Styles

All Global Variables and Functions have one of the following visibility styles:

"default" - Default style On targets that use the ELF object file format, default visibility means that the declaration is visible to other modules and, in shared libraries, means that the declared entity may be overridden. On Darwin, default visibility means that the declaration is visible to other modules. Default visibility corresponds to "external linkage" in the language.

"hidden" - Hidden style Two declarations of an object with hidden visibility refer to the same object if they are in the same shared object. Usually, hidden visibility indicates that the symbol will not be placed into the dynamic symbol table, so no other module (executable or shared library) can reference it directly.

"protected" - Protected style On ELF, protected visibility indicates that the symbol will be placed in the dynamic symbol table, but that references within the defining module will bind to the local symbol. That is, the symbol cannot be overridden by another module.

A symbol with `internal` or `private` linkage must have `default` visibility.

DLL Storage Classes

All Global Variables, Functions and Aliases can have one of the following DLL storage class:

dllimport "dllimport" causes the compiler to reference a function or variable via a global pointer to a pointer that is set up by the DLL exporting the symbol. On Microsoft Windows targets, the pointer name is formed by combining `__imp_` and the function or variable name.

dllexport "dllexport" causes the compiler to provide a global pointer to a pointer in a DLL, so that it can be referenced with the `dllimport` attribute. On Microsoft Windows targets, the pointer name is formed by combining `__imp_` and the function or variable name. Since this storage class exists for defining a dll interface, the compiler, assembler and linker know it is externally referenced and must refrain from deleting the symbol.

Thread Local Storage Models

A variable may be defined as `thread_local`, which means that it will not be shared by threads (each thread will have a separated copy of the variable). Not all targets support thread-local variables. Optionally, a TLS model may be specified:

localdynamic For variables that are only used within the current shared library.

initialexec For variables in modules that will not be loaded dynamically.

localexec For variables defined in the executable and only used within it.

If no explicit model is given, the "general dynamic" model is used.

The models correspond to the ELF TLS models; see [ELF Handling For Thread-Local Storage](#) for more information on under which circumstances the different models may be used. The target may choose a different TLS model if the specified model is not supported, or if a better choice of model can be made.

A model can also be specified in an alias, but then it only governs how the alias is accessed. It will not have any effect in the aliasee.

For platforms without linker support of ELF TLS model, the `-femulated-tls` flag can be used to generate GCC compatible emulated TLS code.

Runtime Preemption Specifiers

Global variables, functions and aliases may have an optional runtime preemption specifier. If a preemption specifier isn't given explicitly, then a symbol is assumed to be `dso_preemptable`.

dso_preemptable Indicates that the function or variable may be replaced by a symbol from outside the linkage unit at runtime.

dso_local The compiler may assume that a function or variable marked as `dso_local` will resolve to a symbol within the same linkage unit. Direct access will be generated even if the definition is not within this compilation unit.

Structure Types

LLVM IR allows you to specify both "identified" and "literal" *structure types*. Literal types are unique structurally, but identified types are never unique. An *opaque structural type* can also be used to forward declare a type that is not yet available.

An example of an identified structure specification is:

```
%mytype = type { %mytype*, i32 }
```

Prior to the LLVM 3.0 release, identified types were structurally unique. Only literal types are unique in recent versions of LLVM.

Non-Integral Pointer Type

Note: non-integral pointer types are a work in progress, and they should be considered experimental at this time.

LLVM IR optionally allows the frontend to denote pointers in certain address spaces as "non-integral" via the *data-layout string*. Non-integral pointer types represent pointers that have an *unspecified* bitwise representation; that is, the integral representation may be target dependent or unstable (not backed by a fixed integer).

`inttoptr` instructions converting integers to non-integral pointer types are ill-typed, and so are `ptrtoint` instructions converting values of non-integral pointer types to integers. Vector versions of said instructions are ill-typed as well.

Global Variables

Global variables define regions of memory allocated at compilation time instead of run-time.

Global variable definitions must be initialized.

Global variables in other translation units can also be declared, in which case they don't have an initializer.

Either global variable definitions or declarations may have an explicit section to be placed in and may have an optional explicit alignment specified. If there is a mismatch between the explicit or inferred section information for the variable declaration and its definition the resulting behavior is undefined.

A variable may be defined as a global `constant`, which indicates that the contents of the variable will **never** be modified (enabling better optimization, allowing the global data to be placed in the read-only section of an executable, etc). Note that variables that need runtime initialization cannot be marked `constant` as there is a store to the variable.

LLVM explicitly allows *declarations* of global variables to be marked constant, even if the final definition of the global is not. This capability can be used to enable slightly better optimization of the program, but requires the language definition to guarantee that optimizations based on the 'constantness' are valid for the translation units that do not include the definition.

As SSA values, global variables define pointer values that are in scope (i.e. they dominate) all basic blocks in the program. Global variables always define a pointer to their "content" type because they describe a region of memory, and all memory objects in LLVM are accessed through pointers.

Global variables can be marked with `unnamed_addr` which indicates that the address is not significant, only the content. Constants marked like this can be merged with other constants if they have the same initializer. Note that a constant with significant address *can* be merged with a `unnamed_addr` constant, the result being a constant whose address is significant.

If the `local_unnamed_addr` attribute is given, the address is known to not be significant within the module.

A global variable may be declared to reside in a target-specific numbered address space. For targets that support them, address spaces may affect how optimizations are performed and/or what target instructions are used to access the variable. The default address space is zero. The address space qualifier must precede any other attributes.

LLVM allows an explicit section to be specified for globals. If the target supports it, it will emit globals to the section specified. Additionally, the global can be placed in a comdat if the target has the necessary support.

External declarations may have an explicit section specified. Section information is retained in LLVM IR for targets that make use of this information. Attaching section information to an external declaration is an assertion that its definition is located in the specified section. If the definition is located in a different section, the behavior is undefined.

By default, global initializers are optimized by assuming that global variables defined within the module are not modified from their initial values before the start of the global initializer. This is true even for variables potentially accessible from outside the module, including those with external linkage or appearing in `@llvm.used` or `dllexport` variables. This assumption may be suppressed by marking the variable with `externally_initialized`.

An explicit alignment may be specified for a global, which must be a power of 2. If not present, or if the alignment is set to zero, the alignment of the global is set by the target to whatever it feels convenient. If an explicit alignment is specified, the global is forced to have exactly that alignment. Targets and optimizers are not allowed to over-align the global if the global has an assigned section. In this case, the extra alignment could be observable: for example, code could assume that the globals are densely packed in their section and try to iterate over them as an array, alignment padding would break this iteration. The maximum alignment is $1 \ll 29$.

Globals can also have a *DLL storage class*, an optional *runtime preemption specifier*, an optional *global attributes* and an optional list of attached *metadata*.

Variables and aliases can have a *Thread Local Storage Model*.

Scalable vectors cannot be global variables or members of structs or arrays because their size is unknown at compile time.

Syntax:

```
@<GlobalVarName> = [Linkage] [PreemptionSpecifier] [Visibility]
                  [DLLStorageClass] [ThreadLocal]
                  [(unnamed_addr|local_unnamed_addr)] [AddrSpace]
                  [ExternallyInitialized]
                  <global | constant> <Type> [<InitializerConstant>]
                  [, section "name"] [, comdat [($name)]]
                  [, align <Alignment>] (, !name !N)*
```

For example, the following defines a global in a numbered address space with an initializer, section, and alignment:

```
@G = addrspace(5) constant float 1.0, section "foo", align 4
```

The following example just declares a global variable

```
@G = external global i32
```

The following example defines a thread-local global with the `initialexec` TLS model:

```
@G = thread_local(initialexec) global i32 0, align 4
```

Functions

LLVM function definitions consist of the "define" keyword, an optional *linkage type*, an optional *runtime preemption specifier*, an optional *visibility style*, an optional *DLL storage class*, an optional *calling convention*, an optional `unnamed_addr` attribute, a return type, an optional *parameter attribute* for the return type, a function name, a (possibly empty) argument list (each with optional *parameter attributes*), optional *function attributes*, an optional address space, an optional section, an optional alignment, an optional *comdat*, an optional *garbage collector name*, an optional *prefix*, an optional *prologue*, an optional *personality*, an optional list of attached *metadata*, an opening curly brace, a list of basic blocks, and a closing curly brace.

LLVM function declarations consist of the "declare" keyword, an optional *linkage type*, an optional *visibility style*, an optional *DLL storage class*, an optional *calling convention*, an optional `unnamed_addr` or `local_unnamed_addr` attribute, an optional address space, a return type, an optional *parameter attribute* for the return type, a function name, a possibly empty list of arguments, an optional alignment, an optional *garbage collector name*, an optional *prefix*, and an optional *prologue*.

A function definition contains a list of basic blocks, forming the CFG (Control Flow Graph) for the function. Each basic block may optionally start with a label (giving the basic block a symbol table entry), contains a list of instructions, and ends with a *terminator* instruction (such as a branch or function return). If an explicit label name is not provided, a block is assigned an implicit numbered label, using the next value from the same counter as used for unnamed temporaries (*see above*). For example, if a function entry block does not have an explicit label, it will be assigned label "%0", then the first unnamed temporary in that block will be "%1", etc. If a numeric label is explicitly specified, it must match the numeric label that would be used implicitly.

The first basic block in a function is special in two ways: it is immediately executed on entrance to the function, and it is not allowed to have predecessor basic blocks (i.e. there can not be any branches to the entry block of a function). Because the block can have no predecessors, it also cannot have any *PHI nodes*.

LLVM allows an explicit section to be specified for functions. If the target supports it, it will emit functions to the section specified. Additionally, the function can be placed in a COMDAT.

An explicit alignment may be specified for a function. If not present, or if the alignment is set to zero, the alignment of the function is set by the target to whatever it feels convenient. If an explicit alignment is specified, the function is forced to have at least that much alignment. All alignments must be a power of 2.

If the `unnamed_addr` attribute is given, the address is known to not be significant and two identical functions can be merged.

If the `local_unnamed_addr` attribute is given, the address is known to not be significant within the module.

If an explicit address space is not given, it will default to the program address space from the *data layout string*.

Syntax:

```
define [linkage] [PreemptionSpecifier] [visibility] [DLLStorageClass]
    [cconv] [ret attrs]
    <ResultType> @<FunctionName> ([argument list])
    [(unnamed_addr|local_unnamed_addr)] [AddrSpace] [fn Attrs]
    [section "name"] [comdat [($name)]] [align N] [gc] [prefix Constant]
    [prologue Constant] [personality Constant] (!name !N)* { ... }
```

The argument list is a comma separated sequence of arguments where each argument is of the following form:

Syntax:

```
<type> [parameter Attrs] [name]
```

Aliases

Aliases, unlike function or variables, don't create any new data. They are just a new symbol and metadata for an existing position.

Aliases have a name and an aliasee that is either a global value or a constant expression.

Aliases may have an optional *linkage type*, an optional *runtime preemption specifier*, an optional *visibility style*, an optional *DLL storage class* and an optional *tls model*.

Syntax:

```
@<Name> = [Linkage] [PreemptionSpecifier] [Visibility] [DLLStorageClass]_
↳ [ThreadLocal] [(unnamed_addr|local_unnamed_addr)] alias <AliaseeTy>, <AliaseeTy>* @
↳ <Aliasee>
```

The linkage must be one of `private`, `internal`, `linkonce`, `weak`, `linkonce_odr`, `weak_odr`, `external`. Note that some system linkers might not correctly handle dropping a weak symbol that is aliased.

Aliases that are not `unnamed_addr` are guaranteed to have the same address as the aliasee expression. `unnamed_addr` ones are only guaranteed to point to the same content.

If the `local_unnamed_addr` attribute is given, the address is known to not be significant within the module.

Since aliases are only a second name, some restrictions apply, of which some can only be checked when producing an object file:

- The expression defining the aliasee must be computable at assembly time. Since it is just a name, no relocations can be used.
- No alias in the expression can be weak as the possibility of the intermediate alias being overridden cannot be represented in an object file.
- No global value in the expression can be a declaration, since that would require a relocation, which is not possible.

IFuncs

IFuncs, like as aliases, don't create any new data or func. They are just a new symbol that dynamic linker resolves at runtime by calling a resolver function.

IFuncs have a name and a resolver that is a function called by dynamic linker that returns address of another function associated with the name.

IFunc may have an optional *linkage type* and an optional *visibility style*.

Syntax:

```
@<Name> = [Linkage] [Visibility] ifunc <IFuncTy>, <ResolverTy>* @<Resolver>
```

Comdats

Comdat IR provides access to COFF and ELF object file COMDAT functionality.

Comdats have a name which represents the COMDAT key. All global objects that specify this key will only end up in the final object file if the linker chooses that key over some other key. Aliases are placed in the same COMDAT that their aliasee computes to, if any.

Comdats have a selection kind to provide input on how the linker should choose between keys in two different object files.

Syntax:

```
$<Name> = comdat SelectionKind
```

The selection kind must be one of the following:

any The linker may choose any COMDAT key, the choice is arbitrary.

exactmatch The linker may choose any COMDAT key but the sections must contain the same data.

largest The linker will choose the section containing the largest COMDAT key.

noduplicates The linker requires that only section with this COMDAT key exist.

samesize The linker may choose any COMDAT key but the sections must contain the same amount of data.

Note that the Mach-O platform doesn't support COMDATs, and ELF and WebAssembly only support **any** as a selection kind.

Here is an example of a COMDAT group where a function will only be selected if the COMDAT key's section is the largest:

```
$foo = comdat largest
@foo = global i32 2, comdat($foo)

define void @bar() comdat($foo) {
    ret void
}
```

As a syntactic sugar the `$name` can be omitted if the name is the same as the global name:

```
$foo = comdat any
@foo = global i32 2, comdat
```

In a COFF object file, this will create a COMDAT section with selection kind `IMAGE_COMDAT_SELECT_LARGEST` containing the contents of the `@foo` symbol and another COMDAT section with selection kind `IMAGE_COMDAT_SELECT_ASSOCIATIVE` which is associated with the first COMDAT section and contains the contents of the `@bar` symbol.

There are some restrictions on the properties of the global object. It, or an alias to it, must have the same name as the COMDAT group when targeting COFF. The contents and size of this object may be used during link-time to determine which COMDAT groups get selected depending on the selection kind. Because the name of the object must match the name of the COMDAT group, the linkage of the global object must not be local; local symbols can get renamed if a collision occurs in the symbol table.

The combined use of COMDATS and section attributes may yield surprising results. For example:

```
$foo = comdat any
$bar = comdat any
```

(continues on next page)

(continued from previous page)

```
@g1 = global i32 42, section "sec", comdat($foo)
@g2 = global i32 42, section "sec", comdat($bar)
```

From the object file perspective, this requires the creation of two sections with the same name. This is necessary because both globals belong to different COMDAT groups and COMDATs, at the object file level, are represented by sections.

Note that certain IR constructs like global variables and functions may create COMDATs in the object file in addition to any which are specified using COMDAT IR. This arises when the code generator is configured to emit globals in individual sections (e.g. when *-data-sections* or *-function-sections* is supplied to *llc*).

Named Metadata

Named metadata is a collection of metadata. *Metadata nodes* (but not metadata strings) are the only valid operands for a named metadata.

1. Named metadata are represented as a string of characters with the metadata prefix. The rules for metadata names are the same as for identifiers, but quoted names are not allowed. "`\xx`" type escapes are still valid, which allows any character to be part of a name.

Syntax:

```
; Some unnamed metadata nodes, which are referenced by the named metadata.
!0 = !{"zero"}
!1 = !{"one"}
!2 = !{"two"}
; A named metadata.
!name = !{!0, !1, !2}
```

Parameter Attributes

The return type and each parameter of a function type may have a set of *parameter attributes* associated with them. Parameter attributes are used to communicate additional information about the result or parameters of a function. Parameter attributes are considered to be part of the function, not of the function type, so functions with different parameter attributes can have the same function type.

Parameter attributes are simple keywords that follow the type specified. If multiple parameter attributes are needed, they are space separated. For example:

```
declare i32 @printf(i8* noalias nocapture, ...)
declare i32 @atoi(i8 zeroext)
declare signext i8 @returns_signed_char()
```

Note that any attributes for the function result (*nounwind*, *readonly*) come immediately after the argument list.

Currently, only the following parameter attributes are defined:

zeroext This indicates to the code generator that the parameter or return value should be zero-extended to the extent required by the target's ABI by the caller (for a parameter) or the callee (for a return value).

signext This indicates to the code generator that the parameter or return value should be sign-extended to the extent required by the target's ABI (which is usually 32-bits) by the caller (for a parameter) or the callee (for a return value).

inreg This indicates that this parameter or return value should be treated in a special target-dependent fashion while emitting code for a function call or return (usually, by putting it in a register as opposed to memory, though some targets use it to distinguish between two different kinds of registers). Use of this attribute is target-specific.

byval or **byval (<ty>)** This indicates that the pointer parameter should really be passed by value to the function. The attribute implies that a hidden copy of the pointee is made between the caller and the callee, so the callee is unable to modify the value in the caller. This attribute is only valid on LLVM pointer arguments. It is generally used to pass structs and arrays by value, but is also valid on pointers to scalars. The copy is considered to belong to the caller not the callee (for example, `readonly` functions should not write to `byval` parameters). This is not a valid attribute for return values.

The `byval` attribute also supports an optional type argument, which must be the same as the pointee type of the argument.

The `byval` attribute also supports specifying an alignment with the `align` attribute. It indicates the alignment of the stack slot to form and the known alignment of the pointer specified to the call site. If the alignment is not specified, then the code generator makes a target-specific assumption.

inalloca

The `inalloca` argument attribute allows the caller to take the address of outgoing stack arguments. An `inalloca` argument must be a pointer to stack memory produced by an `alloca` instruction. The `alloca`, or argument allocation, must also be tagged with the `inalloca` keyword. Only the last argument may have the `inalloca` attribute, and that argument is guaranteed to be passed in memory.

An argument allocation may be used by a call at most once because the call may deallocate it. The `inalloca` attribute cannot be used in conjunction with other attributes that affect argument storage, like `inreg`, `nest`, `sret`, or `byval`. The `inalloca` attribute also disables LLVM's implicit lowering of large aggregate return values, which means that frontend authors must lower them with `sret` pointers.

When the call site is reached, the argument allocation must have been the most recent stack allocation that is still live, or the behavior is undefined. It is possible to allocate additional stack space after an argument allocation and before its call site, but it must be cleared off with [llvm.stackrestore](#).

See [Design and Usage of the InAlloca Attribute](#) for more information on how to use this attribute.

sret This indicates that the pointer parameter specifies the address of a structure that is the return value of the function in the source program. This pointer must be guaranteed by the caller to be valid: loads and stores to the structure may be assumed by the callee not to trap and to be properly aligned. This is not a valid attribute for return values.

align <n> This indicates that the pointer value may be assumed by the optimizer to have the specified alignment. If the pointer value does not have the specified alignment, behavior is undefined.

Note that this attribute has additional semantics when combined with the `byval` attribute, which are documented there.

noalias This indicates that objects accessed via pointer values *based* on the argument or return value are not also accessed, during the execution of the function, via pointer values *not based* on the argument or return value. The attribute on a return value also has additional semantics described below. The caller shares the responsibility with the callee for ensuring that these requirements are met. For further details, please see the discussion of the NoAlias response in [alias analysis](#).

Note that this definition of `noalias` is intentionally similar to the definition of `restrict` in C99 for function arguments.

For function return values, C99's `restrict` is not meaningful, while LLVM's `noalias` is. Furthermore, the semantics of the `noalias` attribute on return values are stronger than the semantics of the attribute when used on function arguments. On function return values, the `noalias` attribute indicates that the function acts like a system memory allocation function, returning a pointer to allocated storage disjoint from the storage for any other object accessible to the caller.

nocapture This indicates that the callee does not make any copies of the pointer that outlive the callee itself. This is not a valid attribute for return values. Addresses used in volatile operations are considered to be captured.

nest This indicates that the pointer parameter can be excised using the *trampoline intrinsics*. This is not a valid attribute for return values and can only be applied to one parameter.

returned This indicates that the function always returns the argument as its return value. This is a hint to the optimizer and code generator used when generating the caller, allowing value propagation, tail call optimization, and omission of register saves and restores in some cases; it is not checked or enforced when generating the callee. The parameter and the function return type must be valid operands for the *bitcast instruction*. This is not a valid attribute for return values and can only be applied to one parameter.

nonnull This indicates that the parameter or return pointer is not null. This attribute may only be applied to pointer typed parameters. This is not checked or enforced by LLVM; if the parameter or return pointer is null, the behavior is undefined.

dereferenceable(<n>) This indicates that the parameter or return pointer is dereferenceable. This attribute may only be applied to pointer typed parameters. A pointer that is dereferenceable can be loaded from speculatively without a risk of trapping. The number of bytes known to be dereferenceable must be provided in parentheses. It is legal for the number of bytes to be less than the size of the pointee type. The **nonnull** attribute does not imply dereferenceability (consider a pointer to one element past the end of an array), however **dereferenceable(<n>)** does imply **nonnull** in `addrspace(0)` (which is the default address space).

dereferenceable_or_null(<n>) This indicates that the parameter or return value isn't both non-null and non-dereferenceable (up to <n> bytes) at the same time. All non-null pointers tagged with **dereferenceable_or_null(<n>)** are **dereferenceable(<n>)**. For address space 0 **dereferenceable_or_null(<n>)** implies that a pointer is exactly one of **dereferenceable(<n>)** or **null**, and in other address spaces **dereferenceable_or_null(<n>)** implies that a pointer is at least one of **dereferenceable(<n>)** or **null** (i.e. it may be both **null** and **dereferenceable(<n>)**). This attribute may only be applied to pointer typed parameters.

swiftself This indicates that the parameter is the self/context parameter. This is not a valid attribute for return values and can only be applied to one parameter.

swifterror This attribute is motivated to model and optimize Swift error handling. It can be applied to a parameter with pointer to pointer type or a pointer-sized alloca. At the call site, the actual argument that corresponds to a **swifterror** parameter has to come from a **swifterror** alloca or the **swifterror** parameter of the caller. A **swifterror** value (either the parameter or the alloca) can only be loaded and stored from, or used as a **swifterror** argument. This is not a valid attribute for return values and can only be applied to one parameter.

These constraints allow the calling convention to optimize access to **swifterror** variables by associating them with a specific register at call boundaries rather than placing them in memory. Since this does change the calling convention, a function which uses the **swifterror** attribute on a parameter is not ABI-compatible with one which does not.

These constraints also allow LLVM to assume that a **swifterror** argument does not alias any other memory visible within a function and that a **swifterror** alloca passed as an argument does not escape.

immarg This indicates the parameter is required to be an immediate value. This must be a trivial immediate integer or floating-point constant. Undef or constant expressions are not valid. This is only valid on intrinsic declarations and cannot be applied to a call site or arbitrary function.

Garbage Collector Strategy Names

Each function may specify a garbage collector strategy name, which is simply a string:

```
define void @f() gc "name" { ... }
```

The supported values of *name* includes those *built in to LLVM* and any provided by loaded plugins. Specifying a GC strategy will cause the compiler to alter its output in order to support the named garbage collection algorithm. Note that LLVM itself does not contain a garbage collector, this functionality is restricted to generating machine code which can interoperate with a collector provided externally.

Prefix Data

Prefix data is data associated with a function which the code generator will emit immediately before the function's entrypoint. The purpose of this feature is to allow frontends to associate language-specific runtime metadata with specific functions and make it available through the function pointer while still allowing the function pointer to be called.

To access the data for a given function, a program may bitcast the function pointer to a pointer to the constant's type and dereference index -1. This implies that the IR symbol points just past the end of the prefix data. For instance, take the example of a function annotated with a single `i32`,

```
define void @f() prefix i32 123 { ... }
```

The prefix data can be referenced as,

```
%0 = bitcast void* () @f to i32*
%a = getelementptr inbounds i32, i32* %0, i32 -1
%b = load i32, i32* %a
```

Prefix data is laid out as if it were an initializer for a global variable of the prefix data's type. The function will be placed such that the beginning of the prefix data is aligned. This means that if the size of the prefix data is not a multiple of the alignment size, the function's entrypoint will not be aligned. If alignment of the function's entrypoint is desired, padding must be added to the prefix data.

A function may have prefix data but no body. This has similar semantics to the `available_externally` linkage in that the data may be used by the optimizers but will not be emitted in the object file.

Prologue Data

The `prologue` attribute allows arbitrary code (encoded as bytes) to be inserted prior to the function body. This can be used for enabling function hot-patching and instrumentation.

To maintain the semantics of ordinary function calls, the prologue data must have a particular format. Specifically, it must begin with a sequence of bytes which decode to a sequence of machine instructions, valid for the module's target, which transfer control to the point immediately succeeding the prologue data, without performing any other visible action. This allows the inliner and other passes to reason about the semantics of the function definition without needing to reason about the prologue data. Obviously this makes the format of the prologue data highly target dependent.

A trivial example of valid prologue data for the x86 architecture is `i8 144`, which encodes the `nop` instruction:

```
define void @f() prologue i8 144 { ... }
```

Generally prologue data can be formed by encoding a relative branch instruction which skips the metadata, as in this example of valid prologue data for the `x86_64` architecture, where the first two bytes encode `jmp .+10:`

```
%0 = type <{ i8, i8, i8* }>

define void @f() prologue %0 <{ i8 235, i8 8, i8* @md}> { ... }
```

A function may have prologue data but no body. This has similar semantics to the `available_externally` linkage in that the data may be used by the optimizers but will not be emitted in the object file.

Personality Function

The `personality` attribute permits functions to specify what function to use for exception handling.

Attribute Groups

Attribute groups are groups of attributes that are referenced by objects within the IR. They are important for keeping .ll files readable, because a lot of functions will use the same set of attributes. In the degenerative case of a .ll file that corresponds to a single .c file, the single attribute group will capture the important command line flags used to build that file.

An attribute group is a module-level object. To use an attribute group, an object references the attribute group's ID (e.g. #37). An object may refer to more than one attribute group. In that situation, the attributes from the different groups are merged.

Here is an example of attribute groups for a function that should always be inlined, has a stack alignment of 4, and which shouldn't use SSE instructions:

```
; Target-independent attributes:
attributes #0 = { alwaysinline alignstack=4 }

; Target-dependent attributes:
attributes #1 = { "no-sse" }

; Function @f has attributes: alwaysinline, alignstack=4, and "no-sse".
define void @f() #0 #1 { ... }
```

Function Attributes

Function attributes are set to communicate additional information about a function. Function attributes are considered to be part of the function, not of the function type, so functions with different function attributes can have the same function type.

Function attributes are simple keywords that follow the type specified. If multiple attributes are needed, they are space separated. For example:

```
define void @f() noline { ... }
define void @f() alwaysinline { ... }
define void @f() alwaysinline optsize { ... }
define void @f() optsize { ... }
```

alignstack(<n>) This attribute indicates that, when emitting the prologue and epilogue, the backend should forcibly align the stack pointer. Specify the desired alignment, which must be a power of two, in parentheses.

allocsize(<EltSizeParam>[, <NumEltsParam>]) This attribute indicates that the annotated function will always return at least a given number of bytes (or null). Its arguments are zero-indexed parameter numbers; if one argument is provided, then it's assumed that at least `CallSite.Args[EltSizeParam]`

bytes will be available at the returned pointer. If two are provided, then it's assumed that `CallSite.Args[EltSizeParam] * CallSite.Args[NumEltsParam]` bytes are available. The referenced parameters must be integer types. No assumptions are made about the contents of the returned block of memory.

alwaysinline This attribute indicates that the inliner should attempt to inline this function into callers whenever possible, ignoring any active inlining size threshold for this caller.

builtin This indicates that the callee function at a call site should be recognized as a built-in function, even though the function's declaration uses the `nobuiltin` attribute. This is only valid at call sites for direct calls to functions that are declared with the `nobuiltin` attribute.

cold This attribute indicates that this function is rarely called. When computing edge weights, basic blocks post-dominated by a cold function call are also considered to be cold; and, thus, given low weight.

convergent In some parallel execution models, there exist operations that cannot be made control-dependent on any additional values. We call such operations *convergent*, and mark them with this attribute.

The `convergent` attribute may appear on functions or call/invoke instructions. When it appears on a function, it indicates that calls to this function should not be made control-dependent on additional values. For example, the intrinsic `llvm.nvvm.barrier0` is *convergent*, so calls to this intrinsic cannot be made control-dependent on additional values.

When it appears on a call/invoke, the `convergent` attribute indicates that we should treat the call as though we're calling a convergent function. This is particularly useful on indirect calls; without this we may treat such calls as though the target is non-convergent.

The optimizer may remove the `convergent` attribute on functions when it can prove that the function does not execute any convergent operations. Similarly, the optimizer may remove `convergent` on calls/invoke when it can prove that the call/invoke cannot call a convergent function.

inaccessiblememonly This attribute indicates that the function may only access memory that is not accessible by the module being compiled. This is a weaker form of `readnone`. If the function reads or writes other memory, the behavior is undefined.

inaccessiblemem_or_argmemonly This attribute indicates that the function may only access memory that is either not accessible by the module being compiled, or is pointed to by its pointer arguments. This is a weaker form of `argmemonly`. If the function reads or writes other memory, the behavior is undefined.

inlinehint This attribute indicates that the source code contained a hint that inlining this function is desirable (such as the "inline" keyword in C/C++). It is just a hint; it imposes no requirements on the inliner.

jumpable This attribute indicates that the function should be added to a jump-instruction table at code-generation time, and that all address-taken references to this function should be replaced with a reference to the appropriate jump-instruction-table function pointer. Note that this creates a new pointer for the original function, which means that code that depends on function-pointer identity can break. So, any function annotated with `jumpable` must also be `unnamed_addr`.

minsize This attribute suggests that optimization passes and code generator passes make choices that keep the code size of this function as small as possible and perform optimizations that may sacrifice runtime performance in order to minimize the size of the generated code.

naked This attribute disables prologue / epilogue emission for the function. This can have very system-specific consequences.

no-jump-tables When this attribute is set to true, the jump tables and lookup tables that can be generated from a switch case lowering are disabled.

nobuiltin This indicates that the callee function at a call site is not recognized as a built-in function. LLVM will retain the original call and not replace it with equivalent code based on the semantics of the built-in function, unless the call site uses the `builtin` attribute. This is valid at call sites and on function declarations and definitions.

noduplicate This attribute indicates that calls to the function cannot be duplicated. A call to a `noduplicate` function may be moved within its parent function, but may not be duplicated within its parent function.

A function containing a `noduplicate` call may still be an inlining candidate, provided that the call is not duplicated by inlining. That implies that the function has internal linkage and only has one call site, so the original call is dead after inlining.

nofree This function attribute indicates that the function does not, directly or indirectly, call a memory-deallocation function (free, for example). As a result, uncaptured pointers that are known to be dereferenceable prior to a call to a function with the `nofree` attribute are still known to be dereferenceable after the call (the capturing condition is necessary in environments where the function might communicate the pointer to another thread which then deallocates the memory).

noimplicitfloat This attribute disables implicit floating-point instructions.

noinline This attribute indicates that the inliner should never inline this function in any situation. This attribute may not be used together with the `alwaysinline` attribute.

nonlazybind This attribute suppresses lazy symbol binding for the function. This may make calls to the function faster, at the cost of extra program startup time if the function is not called during program startup.

noredzone This attribute indicates that the code generator should not use a red zone, even if the target-specific ABI normally permits it.

indirect-tls-seg-refs This attribute indicates that the code generator should not use direct TLS access through segment registers, even if the target-specific ABI normally permits it.

noreturn This function attribute indicates that the function never returns normally. This produces undefined behavior at runtime if the function ever does dynamically return.

norecurse This function attribute indicates that the function does not call itself either directly or indirectly down any possible call path. This produces undefined behavior at runtime if the function ever does recurse.

willreturn This function attribute indicates that a call of this function will either exhibit undefined behavior or comes back and continues execution at a point in the existing call stack that includes the current invocation. Annotated functions may still raise an exception, i.e., `nounwind` is not implied. If an invocation of an annotated function does not return control back to a point in the call stack, the behavior is undefined.

nosync This function attribute indicates that the function does not communicate (synchronize) with another thread through memory or other well-defined means. Synchronization is considered possible in the presence of *atomic* accesses that enforce an order, thus not "unordered" and "monotonic", *volatile* accesses, as well as *convergent* function calls. Note that through *convergent* function calls non-memory communication, e.g., cross-lane operations, are possible and are also considered synchronization. However *convergent* does not contradict *nosync*. If an annotated function does ever synchronize with another thread, the behavior is undefined.

nounwind This function attribute indicates that the function never raises an exception. If the function does raise an exception, its runtime behavior is undefined. However, functions marked `nounwind` may still trap or generate asynchronous exceptions. Exception handling schemes that are recognized by LLVM to handle asynchronous exceptions, such as SEH, will still provide their implementation defined semantics.

"null-pointer-is-valid" If "null-pointer-is-valid" is set to "true", then null address in address-space 0 is considered to be a valid address for memory loads and stores. Any analysis or optimization should not treat dereferencing a pointer to null as undefined behavior in this function. Note: Comparing address of a global variable to null may still evaluate to false because of a limitation in querying this attribute inside constant expressions.

optforfuzzing This attribute indicates that this function should be optimized for maximum fuzzing signal.

optnone This function attribute indicates that most optimization passes will skip this function, with the exception of interprocedural optimization passes. Code generation defaults to the "fast" instruction selector. This at-

tribute cannot be used together with the `alwaysinline` attribute; this attribute is also incompatible with the `minsize` attribute and the `optsize` attribute.

This attribute requires the `noinline` attribute to be specified on the function as well, so the function is never inlined into any caller. Only functions with the `alwaysinline` attribute are valid candidates for inlining into the body of this function.

optsize This attribute suggests that optimization passes and code generator passes make choices that keep the code size of this function low, and otherwise do optimizations specifically to reduce code size as long as they do not significantly impact runtime performance.

"patchable-function" This attribute tells the code generator that the code generated for this function needs to follow certain conventions that make it possible for a runtime function to patch over it later. The exact effect of this attribute depends on its string value, for which there currently is one legal possibility:

- **"prologue-short-redirect"** - This style of patchable function is intended to support patching a function prologue to redirect control away from the function in a thread safe manner. It guarantees that the first instruction of the function will be large enough to accommodate a short jump instruction, and will be sufficiently aligned to allow being fully changed via an atomic compare-and-swap instruction. While the first requirement can be satisfied by inserting large enough NOP, LLVM can and will try to re-purpose an existing instruction (i.e. one that would have to be emitted anyway) as the patchable instruction larger than a short jump.

"prologue-short-redirect" is currently only supported on x86-64.

This attribute by itself does not imply restrictions on inter-procedural optimizations. All of the semantic effects the patching may have to be separately conveyed via the linkage type.

"probe-stack" This attribute indicates that the function will trigger a guard region in the end of the stack. It ensures that accesses to the stack must be no further apart than the size of the guard region to a previous access of the stack. It takes one required string value, the name of the stack probing function that will be called.

If a function that has a "probe-stack" attribute is inlined into a function with another "probe-stack" attribute, the resulting function has the "probe-stack" attribute of the caller. If a function that has a "probe-stack" attribute is inlined into a function that has no "probe-stack" attribute at all, the resulting function has the "probe-stack" attribute of the callee.

readnone On a function, this attribute indicates that the function computes its result (or decides to unwind an exception) based strictly on its arguments, without dereferencing any pointer arguments or otherwise accessing any mutable state (e.g. memory, control registers, etc) visible to caller functions. It does not write through any pointer arguments (including `byval` arguments) and never changes any state visible to callers. This means while it cannot unwind exceptions by calling the C++ exception throwing methods (since they write to memory), there may be non-C++ mechanisms that throw exceptions without writing to LLVM visible memory.

On an argument, this attribute indicates that the function does not dereference that pointer argument, even though it may read or write the memory that the pointer points to if accessed through other pointers.

If a `readnone` function reads or writes memory visible to the program, or has other side-effects, the behavior is undefined. If a function reads from or writes to a `readnone` pointer argument, the behavior is undefined.

readonly On a function, this attribute indicates that the function does not write through any pointer arguments (including `byval` arguments) or otherwise modify any state (e.g. memory, control registers, etc) visible to caller functions. It may dereference pointer arguments and read state that may be set in the caller. A `readonly` function always returns the same value (or unwinds an exception identically) when called with the same set of arguments and global state. This means while it cannot unwind exceptions by calling the C++ exception throwing methods (since they write to memory), there may be non-C++ mechanisms that throw exceptions without writing to LLVM visible memory.

On an argument, this attribute indicates that the function does not write through this pointer argument, even though it may write to the memory that the pointer points to.

If a readonly function writes memory visible to the program, or has other side-effects, the behavior is undefined.
If a function writes to a readonly pointer argument, the behavior is undefined.

"stack-probe-size" This attribute controls the behavior of stack probes: either the "probe-stack" attribute, or ABI-required stack probes, if any. It defines the size of the guard region. It ensures that if the function may use more stack space than the size of the guard region, stack probing sequence will be emitted. It takes one required integer value, which is 4096 by default.

If a function that has a "stack-probe-size" attribute is inlined into a function with another "stack-probe-size" attribute, the resulting function has the "stack-probe-size" attribute that has the lower numeric value. If a function that has a "stack-probe-size" attribute is inlined into a function that has no "stack-probe-size" attribute at all, the resulting function has the "stack-probe-size" attribute of the callee.

"no-stack-arg-probe" This attribute disables ABI-required stack probes, if any.

writeonly On a function, this attribute indicates that the function may write to but does not read from memory.

On an argument, this attribute indicates that the function may write to but does not read through this pointer argument (even though it may read from the memory that the pointer points to).

If a writeonly function reads memory visible to the program, or has other side-effects, the behavior is undefined.
If a function reads from a writeonly pointer argument, the behavior is undefined.

argmemonly This attribute indicates that the only memory accesses inside function are loads and stores from objects pointed to by its pointer-typed arguments, with arbitrary offsets. Or in other words, all memory operations in the function can refer to memory only using pointers based on its function arguments.

Note that `argmemonly` can be used together with `readonly` attribute in order to specify that function reads only from its arguments.

If an `argmemonly` function reads or writes memory other than the pointer arguments, or has other side-effects, the behavior is undefined.

returns_twice This attribute indicates that this function can return twice. The C `set jmp` is an example of such a function. The compiler disables some optimizations (like tail calls) in the caller of these functions.

safestack This attribute indicates that [SafeStack](#) protection is enabled for this function.

If a function that has a `safestack` attribute is inlined into a function that doesn't have a `safestack` attribute or which has an `ssp`, `sspstrong` or `sspreq` attribute, then the resulting function will have a `safestack` attribute.

sanitize_address This attribute indicates that AddressSanitizer checks (dynamic address safety analysis) are enabled for this function.

sanitize_memory This attribute indicates that MemorySanitizer checks (dynamic detection of accesses to uninitialized memory) are enabled for this function.

sanitize_thread This attribute indicates that ThreadSanitizer checks (dynamic thread safety analysis) are enabled for this function.

sanitize_hwaddress This attribute indicates that HWAddressSanitizer checks (dynamic address safety analysis based on tagged pointers) are enabled for this function.

sanitize_memtag This attribute indicates that MemTagSanitizer checks (dynamic address safety analysis based on Armv8 MTE) are enabled for this function.

speculative_load_hardening This attribute indicates that [Speculative Load Hardening](#) should be enabled for the function body.

Speculative Load Hardening is a best-effort mitigation against information leak attacks that make use of control flow miss-speculation - specifically miss-speculation of whether a branch is taken or not. Typically vulnera-

bilities enabling such attacks are classified as "Spectre variant #1". Notably, this does not attempt to mitigate against miss-speculation of branch target, classified as "Spectre variant #2" vulnerabilities.

When inlining, the attribute is sticky. Inlining a function that carries this attribute will cause the caller to gain the attribute. This is intended to provide a maximally conservative model where the code in a function annotated with this attribute will always (even after inlining) end up hardened.

speculatable This function attribute indicates that the function does not have any effects besides calculating its result and does not have undefined behavior. Note that `speculatable` is not enough to conclude that along any particular execution path the number of calls to this function will not be externally observable. This attribute is only valid on functions and declarations, not on individual call sites. If a function is incorrectly marked as `speculatable` and really does exhibit undefined behavior, the undefined behavior may be observed even if the call site is dead code.

ssp This attribute indicates that the function should emit a stack smashing protector. It is in the form of a "canary" --- a random value placed on the stack before the local variables that's checked upon return from the function to see if it has been overwritten. A heuristic is used to determine if a function needs stack protectors or not. The heuristic used will enable protectors for functions with:

- Character arrays larger than `ssp-buffer-size` (default 8).
- Aggregates containing character arrays larger than `ssp-buffer-size`.
- Calls to `alloca()` with variable sizes or constant sizes greater than `ssp-buffer-size`.

Variables that are identified as requiring a protector will be arranged on the stack such that they are adjacent to the stack protector guard.

If a function that has an `ssp` attribute is inlined into a function that doesn't have an `ssp` attribute, then the resulting function will have an `ssp` attribute.

sspreq This attribute indicates that the function should *always* emit a stack smashing protector. This overrides the `ssp` function attribute.

Variables that are identified as requiring a protector will be arranged on the stack such that they are adjacent to the stack protector guard. The specific layout rules are:

1. Large arrays and structures containing large arrays (\geq `ssp-buffer-size`) are closest to the stack protector.
2. Small arrays and structures containing small arrays ($<$ `ssp-buffer-size`) are 2nd closest to the protector.
3. Variables that have had their address taken are 3rd closest to the protector.

If a function that has an `sspreq` attribute is inlined into a function that doesn't have an `sspreq` attribute or which has an `ssp` or `sspstrong` attribute, then the resulting function will have an `sspreq` attribute.

sspstrong This attribute indicates that the function should emit a stack smashing protector. This attribute causes a strong heuristic to be used when determining if a function needs stack protectors. The strong heuristic will enable protectors for functions with:

- Arrays of any size and type
- Aggregates containing an array of any size and type.
- Calls to `alloca()`.
- Local variables that have had their address taken.

Variables that are identified as requiring a protector will be arranged on the stack such that they are adjacent to the stack protector guard. The specific layout rules are:

1. Large arrays and structures containing large arrays (\geq `ssp-buffer-size`) are closest to the stack protector.
2. Small arrays and structures containing small arrays ($<$ `ssp-buffer-size`) are 2nd closest to the protector.
3. Variables that have had their address taken are 3rd closest to the protector.

This overrides the `ssp` function attribute.

If a function that has an `sspstrong` attribute is inlined into a function that doesn't have an `sspstrong` attribute, then the resulting function will have an `sspstrong` attribute.

strictfp This attribute indicates that the function was called from a scope that requires strict floating-point semantics. LLVM will not attempt any optimizations that require assumptions about the floating-point rounding mode or that might alter the state of floating-point status flags that might otherwise be set or cleared by calling this function.

"thunk" This attribute indicates that the function will delegate to some other function with a tail call. The prototype of a thunk should not be used for optimization purposes. The caller is expected to cast the thunk prototype to match the thunk target prototype.

unwindtable This attribute indicates that the ABI being targeted requires that an unwind table entry be produced for this function even if we can show that no exceptions passes by it. This is normally the case for the ELF x86-64 abi, but it can be disabled for some compilation units.

nocf_check This attribute indicates that no control-flow check will be performed on the attributed entity. It disables `-fcf-protection=<>` for a specific entity to fine grain the HW control flow protection mechanism. The flag is target independent and currently appertains to a function or function pointer.

shadowcallstack This attribute indicates that the ShadowCallStack checks are enabled for the function. The instrumentation checks that the return address for the function has not changed between the function prolog and epilog. It is currently x86_64-specific.

Global Attributes

Attributes may be set to communicate additional information about a global variable. Unlike *function attributes*, attributes on a global variable are grouped into a single *attribute group*.

Operand Bundles

Operand bundles are tagged sets of SSA values that can be associated with certain LLVM instructions (currently only `calls` and `invoke`s). In a way they are like metadata, but dropping them is incorrect and will change program semantics.

Syntax:

```
operand bundle set ::= '[' operand bundle (, operand bundle ) * ']'
operand bundle ::= tag '(' [ bundle operand ] (, bundle operand ) * ')'
bundle operand ::= SSA value
tag ::= string constant
```

Operand bundles are **not** part of a function's signature, and a given function may be called from multiple places with different kinds of operand bundles. This reflects the fact that the operand bundles are conceptually a part of the `call` (or `invoke`), not the callee being dispatched to.

Operand bundles are a generic mechanism intended to support runtime-introspection-like functionality for managed languages. While the exact semantics of an operand bundle depend on the bundle tag, there are certain limitations to how much the presence of an operand bundle can influence the semantics of a program. These restrictions are described

as the semantics of an "unknown" operand bundle. As long as the behavior of an operand bundle is describable within these restrictions, LLVM does not need to have special knowledge of the operand bundle to not miscompile programs containing it.

- The bundle operands for an unknown operand bundle escape in unknown ways before control is transferred to the callee or invokee.
- Calls and invokes with operand bundles have unknown read / write effect on the heap on entry and exit (even if the call target is `readnone` or `readonly`), unless they're overridden with callsite specific attributes.
- An operand bundle at a call site cannot change the implementation of the called function. Inter-procedural optimizations work as usual as long as they take into account the first two properties.

More specific types of operand bundles are described below.

Deoptimization Operand Bundles

Deoptimization operand bundles are characterized by the "deopt" operand bundle tag. These operand bundles represent an alternate "safe" continuation for the call site they're attached to, and can be used by a suitable runtime to deoptimize the compiled frame at the specified call site. There can be at most one "deopt" operand bundle attached to a call site. Exact details of deoptimization is out of scope for the language reference, but it usually involves rewriting a compiled frame into a set of interpreted frames.

From the compiler's perspective, deoptimization operand bundles make the call sites they're attached to at least `readonly`. They read through all of their pointer typed operands (even if they're not otherwise escaped) and the entire visible heap. Deoptimization operand bundles do not capture their operands except during deoptimization, in which case control will not be returned to the compiled frame.

The inliner knows how to inline through calls that have deoptimization operand bundles. Just like inlining through a normal call site involves composing the normal and exceptional continuations, inlining through a call site with a deoptimization operand bundle needs to appropriately compose the "safe" deoptimization continuation. The inliner does this by prepending the parent's deoptimization continuation to every deoptimization continuation in the inlined body. E.g. inlining `@f` into `@g` in the following example

```
define void @f() {
  call void @x()    ;; no deopt state
  call void @y() [ "deopt" (i32 10) ]
  call void @y() [ "deopt" (i32 10), "unknown" (i8* null) ]
  ret void
}

define void @g() {
  call void @f() [ "deopt" (i32 20) ]
  ret void
}
```

will result in

```
define void @g() {
  call void @x()    ;; still no deopt state
  call void @y() [ "deopt" (i32 20, i32 10) ]
  call void @y() [ "deopt" (i32 20, i32 10), "unknown" (i8* null) ]
  ret void
}
```

It is the frontend's responsibility to structure or encode the deoptimization state in a way that syntactically prepending the caller's deoptimization state to the callee's deoptimization state is semantically equivalent to composing the caller's deoptimization continuation after the callee's deoptimization continuation.

Funclet Operand Bundles

Funclet operand bundles are characterized by the "funclet" operand bundle tag. These operand bundles indicate that a call site is within a particular funclet. There can be at most one "funclet" operand bundle attached to a call site and it must have exactly one bundle operand.

If any funclet EH pads have been "entered" but not "exited" (per the [description in the EH doc](#)), it is undefined behavior to execute a `call` or `invoke` which:

- does not have a "funclet" bundle and is not a `call` to a nounwind intrinsic, or
- has a "funclet" bundle whose operand is not the most-recently-entered not-yet-exited funclet EH pad.

Similarly, if no funclet EH pads have been entered-but-not-yet-exited, executing a `call` or `invoke` with a "funclet" bundle is undefined behavior.

GC Transition Operand Bundles

GC transition operand bundles are characterized by the "gc-transition" operand bundle tag. These operand bundles mark a call as a transition between a function with one GC strategy to a function with a different GC strategy. If coordinating the transition between GC strategies requires additional code generation at the call site, these bundles may contain any values that are needed by the generated code. For more details, see [GC Transitions](#).

Module-Level Inline Assembly

Modules may contain "module-level inline asm" blocks, which corresponds to the GCC "file scope inline asm" blocks. These blocks are internally concatenated by LLVM and treated as a single unit, but may be separated in the `.ll` file if desired. The syntax is very simple:

```
module asm "inline asm code goes here"
module asm "more can go here"
```

The strings can contain any character by escaping non-printable characters. The escape sequence used is simply `"\xx"` where `"xx"` is the two digit hex code for the number.

Note that the assembly string *must* be parseable by LLVM's integrated assembler (unless it is disabled), even when emitting a `.s` file.

Data Layout

A module may specify a target specific data layout string that specifies how data is to be laid out in memory. The syntax for the data layout is simply:

```
target datalayout = "layout specification"
```

The *layout specification* consists of a list of specifications separated by the minus sign character ('-'). Each specification starts with a letter and may include other information after the letter to define some aspect of the data layout. The specifications accepted are as follows:

- E** Specifies that the target lays out data in big-endian form. That is, the bits with the most significance have the lowest address location.
- e** Specifies that the target lays out data in little-endian form. That is, the bits with the least significance have the lowest address location.

S<size> Specifies the natural alignment of the stack in bits. Alignment promotion of stack variables is limited to the natural stack alignment to avoid dynamic stack realignment. The stack alignment must be a multiple of 8-bits. If omitted, the natural stack alignment defaults to "unspecified", which does not prevent any alignment promotions.

P<address space> Specifies the address space that corresponds to program memory. Harvard architectures can use this to specify what space LLVM should place things such as functions into. If omitted, the program memory space defaults to the default address space of 0, which corresponds to a Von Neumann architecture that has code and data in the same space.

A<address space> Specifies the address space of objects created by 'alloca'. Defaults to the default address space of 0.

p[n]:<size>:<abi>:<pref>:<idx> This specifies the *size* of a pointer and its <abi> and <pref>erred alignments for address space *n*. The fourth parameter <idx> is a size of index that used for address calculation. If not specified, the default index size is equal to the pointer size. All sizes are in bits. The address space, *n*, is optional, and if not specified, denotes the default address space 0. The value of *n* must be in the range $[1, 2^{23})$.

i<size>:<abi>:<pref> This specifies the alignment for an integer type of a given bit <size>. The value of <size> must be in the range $[1, 2^{23})$.

v<size>:<abi>:<pref> This specifies the alignment for a vector type of a given bit <size>.

f<size>:<abi>:<pref> This specifies the alignment for a floating-point type of a given bit <size>. Only values of <size> that are supported by the target will work. 32 (float) and 64 (double) are supported on all targets; 80 or 128 (different flavors of long double) are also supported on some targets.

a:<abi>:<pref> This specifies the alignment for an object of aggregate type.

F<type><abi> This specifies the alignment for function pointers. The options for <type> are:

- i: The alignment of function pointers is independent of the alignment of functions, and is a multiple of <abi>.
- n: The alignment of function pointers is a multiple of the explicit alignment specified on the function, and is a multiple of <abi>.

m:<mangling> If present, specifies that llvm names are mangled in the output. Symbols prefixed with the mangling escape character \01 are passed through directly to the assembler without the escape character. The mangling style options are

- e: ELF mangling: Private symbols get a .L prefix.
- m: Mips mangling: Private symbols get a \$ prefix.
- o: Mach-O mangling: Private symbols get L prefix. Other symbols get a _ prefix.
- x: Windows x86 COFF mangling: Private symbols get the usual prefix. Regular C symbols get a _ prefix. Functions with __stdcall, __fastcall, and __vectorcall have custom mangling that appends @N where N is the number of bytes used to pass parameters. C++ symbols starting with ? are not mangled in any way.
- w: Windows COFF mangling: Similar to x, except that normal C symbols do not receive a _ prefix.

n<size1>:<size2>:<size3>... This specifies a set of native integer widths for the target CPU in bits. For example, it might contain n32 for 32-bit PowerPC, n32:64 for PowerPC 64, or n8:16:32:64 for X86-64. Elements of this set are considered to support most general arithmetic operations efficiently.

ni:<address space0>:<address space1>:<address space2>... This specifies pointer types with the specified address spaces as *Non-Integral Pointer Type* s. The 0 address space cannot be specified as non-integral.

On every specification that takes a `<abi>:<pref>`, specifying the `<pref>` alignment is optional. If omitted, the preceding `:` should be omitted too and `<pref>` will be equal to `<abi>`.

When constructing the data layout for a given target, LLVM starts with a default set of specifications which are then (possibly) overridden by the specifications in the `data layout` keyword. The default specifications are given in this list:

- E - big endian
- `p:64:64:64` - 64-bit pointers with 64-bit alignment.
- `p[n]:64:64:64` - Other address spaces are assumed to be the same as the default address space.
- S0 - natural stack alignment is unspecified
- `i1:8:8` - i1 is 8-bit (byte) aligned
- `i8:8:8` - i8 is 8-bit (byte) aligned
- `i16:16:16` - i16 is 16-bit aligned
- `i32:32:32` - i32 is 32-bit aligned
- `i64:32:64` - i64 has ABI alignment of 32-bits but preferred alignment of 64-bits
- `f16:16:16` - half is 16-bit aligned
- `f32:32:32` - float is 32-bit aligned
- `f64:64:64` - double is 64-bit aligned
- `f128:128:128` - quad is 128-bit aligned
- `v64:64:64` - 64-bit vector is 64-bit aligned
- `v128:128:128` - 128-bit vector is 128-bit aligned
- `a:0:64` - aggregates are 64-bit aligned

When LLVM is determining the alignment for a given type, it uses the following rules:

1. If the type sought is an exact match for one of the specifications, that specification is used.
2. If no match is found, and the type sought is an integer type, then the smallest integer type that is larger than the bitwidth of the sought type is used. If none of the specifications are larger than the bitwidth then the largest integer type is used. For example, given the default specifications above, the `i7` type will use the alignment of `i8` (next largest) while both `i65` and `i256` will use the alignment of `i64` (largest specified).
3. If no match is found, and the type sought is a vector type, then the largest vector type that is smaller than the sought vector type will be used as a fall back. This happens because `<128 x double>` can be implemented in terms of `64 <2 x double>`, for example.

The function of the data layout string may not be what you expect. Notably, this is not a specification from the frontend of what alignment the code generator should use.

Instead, if specified, the target data layout is required to match what the ultimate *code generator* expects. This string is used by the mid-level optimizers to improve code, and this only works if it matches what the ultimate code generator uses. There is no way to generate IR that does not embed this target-specific detail into the IR. If you don't specify the string, the default specifications will be used to generate a Data Layout and the optimization phases will operate accordingly and introduce target specificity into the IR with respect to these default specifications.

Target Triple

A module may specify a target triple string that describes the target host. The syntax for the target triple is simply:

```
target triple = "x86_64-apple-macosx10.7.0"
```

The *target triple* string consists of a series of identifiers delimited by the minus sign character ('-'). The canonical forms are:

```
ARCHITECTURE-VENDOR-OPERATING_SYSTEM  
ARCHITECTURE-VENDOR-OPERATING_SYSTEM-ENVIRONMENT
```

This information is passed along to the backend so that it generates code for the proper architecture. It's possible to override this on the command line with the `-mtriple` command line option.

Pointer Aliasing Rules

Any memory access must be done through a pointer value associated with an address range of the memory access, otherwise the behavior is undefined. Pointer values are associated with address ranges according to the following rules:

- A pointer value is associated with the addresses associated with any value it is *based* on.
- An address of a global variable is associated with the address range of the variable's storage.
- The result value of an allocation instruction is associated with the address range of the allocated storage.
- A null pointer in the default address-space is associated with no address.
- An *undef value* in *any* address-space is associated with no address.
- An integer constant other than zero or a pointer value returned from a function not defined within LLVM may be associated with address ranges allocated through mechanisms other than those provided by LLVM. Such ranges shall not overlap with any ranges of addresses allocated by mechanisms provided by LLVM.

A pointer value is *based* on another pointer value according to the following rules:

- A pointer value formed from a scalar `getelementptr` operation is *based* on the pointer-typed operand of the `getelementptr`.
- The pointer in lane *l* of the result of a vector `getelementptr` operation is *based* on the pointer in lane *l* of the vector-of-pointers-typed operand of the `getelementptr`.
- The result value of a `bitcast` is *based* on the operand of the `bitcast`.
- A pointer value formed by an `inttoptr` is *based* on all pointer values that contribute (directly or indirectly) to the computation of the pointer's value.
- The "*based on*" relationship is transitive.

Note that this definition of "*based*" is intentionally similar to the definition of "*based*" in C99, though it is slightly weaker.

LLVM IR does not associate types with memory. The result type of a `load` merely indicates the size and alignment of the memory from which to load, as well as the interpretation of the value. The first operand type of a `store` similarly only indicates the size and alignment of the store.

Consequently, type-based alias analysis, aka TBAA, aka `-fstrict-aliasing`, is not applicable to general unadorned LLVM IR. *Metadata* may be used to encode additional information which specialized optimization passes may use to implement type-based alias analysis.

Volatile Memory Accesses

Certain memory accesses, such as *load*'s, *store*'s, and *llvm.memcpy*'s may be marked `volatile`. The optimizers must not change the number of volatile operations or change their order of execution relative to other volatile operations. The optimizers *may* change the order of volatile operations relative to non-volatile operations. This is not Java's "volatile" and has no cross-thread synchronization behavior.

A volatile load or store may have additional target-specific semantics. Any volatile operation can have side effects, and any volatile operation can read and/or modify state which is not accessible via a regular load or store in this module. Volatile operations may use addresses which do not point to memory (like MMIO registers). This means the compiler may not use a volatile operation to prove a non-volatile access to that address has defined behavior.

The allowed side-effects for volatile accesses are limited. If a non-volatile store to a given address would be legal, a volatile operation may modify the memory at that address. A volatile operation may not modify any other memory accessible by the module being compiled. A volatile operation may not call any code in the current module.

The compiler may assume execution will continue after a volatile operation, so operations which modify memory or may have undefined behavior can be hoisted past a volatile operation.

IR-level volatile loads and stores cannot safely be optimized into `llvm.memcpy` or `llvm.memmove` intrinsics even when those intrinsics are flagged volatile. Likewise, the backend should never split or merge target-legal volatile load/store instructions.

Rationale

Platforms may rely on volatile loads and stores of natively supported data width to be executed as single instruction. For example, in C this holds for an l-value of volatile primitive type with native hardware support, but not necessarily for aggregate types. The frontend upholds these expectations, which are intentionally unspecified in the IR. The rules above ensure that IR transformations do not violate the frontend's contract with the language.

Memory Model for Concurrent Operations

The LLVM IR does not define any way to start parallel threads of execution or to register signal handlers. Nonetheless, there are platform-specific ways to create them, and we define LLVM IR's behavior in their presence. This model is inspired by the C++0x memory model.

For a more informal introduction to this model, see the *LLVM Atomic Instructions and Concurrency Guide*.

We define a *happens-before* partial order as the least partial order that

- Is a superset of single-thread program order, and
- When a *synchronizes-with* b, includes an edge from a to b. *Synchronizes-with* pairs are introduced by platform-specific techniques, like pthread locks, thread creation, thread joining, etc., and by atomic instructions. (See also *Atomic Memory Ordering Constraints*).

Note that program order does not introduce *happens-before* edges between a thread and signals executing inside that thread.

Every (defined) read operation (load instructions, `memcpy`, atomic loads/read-modify-writes, etc.) R reads a series of bytes written by (defined) write operations (store instructions, atomic stores/read-modify-writes, `memcpy`, etc.). For the purposes of this section, initialized globals are considered to have a write of the initializer which is atomic and happens before any other read or write of the memory in question. For each byte of a read R, R_{byte} may see any write to the same byte, except:

- If write_1 happens before write_2 , and write_2 happens before R_{byte} , then R_{byte} does not see write_1 .
- If R_{byte} happens before write_3 , then R_{byte} does not see write_3 .

Given that definition, R_{byte} is defined as follows:

- If R is volatile, the result is target-dependent. (Volatile is supposed to give guarantees which can support `sig_atomic_t` in C/C++, and may be used for accesses to addresses that do not behave like normal memory. It does not generally provide cross-thread synchronization.)
- Otherwise, if there is no write to the same byte that happens before R_{byte} , R_{byte} returns `undef` for that byte.
- Otherwise, if R_{byte} may see exactly one write, R_{byte} returns the value written by that write.
- Otherwise, if R is atomic, and all the writes R_{byte} may see are atomic, it chooses one of the values written. See the *Atomic Memory Ordering Constraints* section for additional constraints on how the choice is made.
- Otherwise R_{byte} returns `undef`.

R returns the value composed of the series of bytes it read. This implies that some bytes within the value may be `undef` **without** the entire value being `undef`. Note that this only defines the semantics of the operation; it doesn't mean that targets will emit more than one instruction to read the series of bytes.

Note that in cases where none of the atomic intrinsics are used, this model places only one restriction on IR transformations on top of what is required for single-threaded execution: introducing a store to a byte which might not otherwise be stored is not allowed in general. (Specifically, in the case where another thread might write to and read from an address, introducing a store can change a load that may see exactly one write into a load that may see multiple writes.)

Atomic Memory Ordering Constraints

Atomic instructions (*`cmpxchg`*, *`atomicrmw`*, *`fence`*, *`atomic load`*, and *`atomic store`*) take ordering parameters that determine which other atomic instructions on the same address they *synchronize with*. These semantics are borrowed from Java and C++0x, but are somewhat more colloquial. If these descriptions aren't precise enough, check those specs (see spec references in the *atomics guide*). *`fence`* instructions treat these orderings somewhat differently since they don't take an address. See that instruction's documentation for details.

For a simpler introduction to the ordering constraints, see the *LLVM Atomic Instructions and Concurrency Guide*.

unordered The set of values that can be read is governed by the happens-before partial order. A value cannot be read unless some operation wrote it. This is intended to provide a guarantee strong enough to model Java's non-volatile shared variables. This ordering cannot be specified for read-modify-write operations; it is not strong enough to make them atomic in any interesting way.

monotonic In addition to the guarantees of **unordered**, there is a single total order for modifications by **monotonic** operations on each address. All modification orders must be compatible with the happens-before order. There is no guarantee that the modification orders can be combined to a global total order for the whole program (and this often will not be possible). The read in an atomic read-modify-write operation (*`cmpxchg`* and *`atomicrmw`*) reads the value in the modification order immediately before the value it writes. If one atomic read happens before another atomic read of the same address, the later read must see the same value or a later value in the address's modification order. This disallows reordering of **monotonic** (or stronger) operations on the same address. If an address is written **monotonic**-ally by one thread, and other threads **monotonic**-ally read that address repeatedly, the other threads must eventually see the write. This corresponds to the C++0x/C1x `memory_order_relaxed`.

acquire In addition to the guarantees of **monotonic**, a *synchronizes-with* edge may be formed with a release operation. This is intended to model C++'s `memory_order_acquire`.

release In addition to the guarantees of **monotonic**, if this operation writes a value which is subsequently read by an **acquire** operation, it *synchronizes-with* that operation. (This isn't a complete description; see the C++0x definition of a release sequence.) This corresponds to the C++0x/C1x `memory_order_release`.

acq_rel (acquire+release) Acts as both an **acquire** and **release** operation on its address. This corresponds to the C++0x/C1x `memory_order_acq_rel`.

seq_cst (sequentially consistent) In addition to the guarantees of `acq_rel` (acquire for an operation that only reads, `release` for an operation that only writes), there is a global total order on all sequentially-consistent operations on all addresses, which is consistent with the *happens-before* partial order and with the modification orders of all the affected addresses. Each sequentially-consistent read sees the last preceding write to the same address in this global order. This corresponds to the C++0x/C1x `memory_order_seq_cst` and Java `volatile`.

If an atomic operation is marked `syncscope("singlethread")`, it only *synchronizes with* and only participates in the `seq_cst` total orderings of other operations running in the same thread (for example, in signal handlers).

If an atomic operation is marked `syncscope("<target-scope>")`, where `<target-scope>` is a target specific synchronization scope, then it is target dependent if it *synchronizes with* and participates in the `seq_cst` total orderings of other operations.

Otherwise, an atomic operation that is not marked `syncscope("singlethread")` or `syncscope("<target-scope>")` *synchronizes with* and participates in the `seq_cst` total orderings of other operations that are not marked `syncscope("singlethread")` or `syncscope("<target-scope>")`.

Floating-Point Environment

The default LLVM floating-point environment assumes that floating-point instructions do not have side effects. Results assume the round-to-nearest rounding mode. No floating-point exception state is maintained in this environment. Therefore, there is no attempt to create or preserve invalid operation (SNaN) or division-by-zero exceptions.

The benefit of this exception-free assumption is that floating-point operations may be speculated freely without any other fast-math relaxations to the floating-point model.

Code that requires different behavior than this should use the *Constrained Floating-Point Intrinsics*.

Fast-Math Flags

LLVM IR floating-point operations (*fadd*, *fsub*, *fmul*, *fdiv*, *frem*, *fcmp*) and *call* may use the following flags to enable otherwise unsafe floating-point transformations.

nnan No NaNs - Allow optimizations to assume the arguments and result are not NaN. If an argument is a nan, or the result would be a nan, it produces a *poison value* instead.

ninf No Infs - Allow optimizations to assume the arguments and result are not +/-Inf. If an argument is +/-Inf, or the result would be +/-Inf, it produces a *poison value* instead.

nsz No Signed Zeros - Allow optimizations to treat the sign of a zero argument or result as insignificant.

arcp Allow Reciprocal - Allow optimizations to use the reciprocal of an argument rather than perform division.

contract Allow floating-point contraction (e.g. fusing a multiply followed by an addition into a fused multiply-and-add).

afn Approximate functions - Allow substitution of approximate calculations for functions (sin, log, sqrt, etc). See floating-point intrinsic definitions for places where this can apply to LLVM's intrinsic math functions.

reassoc Allow reassociation transformations for floating-point instructions. This may dramatically change results in floating-point.

fast This flag implies all of the others.

Use-list Order Directives

Use-list directives encode the in-memory order of each use-list, allowing the order to be recreated. `<order-indexes>` is a comma-separated list of indexes that are assigned to the referenced value's uses. The referenced value's use-list is immediately sorted by these indexes.

Use-list directives may appear at function scope or global scope. They are not instructions, and have no effect on the semantics of the IR. When they're at function scope, they must appear after the terminator of the final basic block.

If basic blocks have their address taken via `blockaddress()` expressions, `uselistorder_bb` can be used to reorder their use-lists from outside their function's scope.

Syntax

```
uselistorder <ty> <value>, { <order-indexes> }
uselistorder_bb @function, %block { <order-indexes> }
```

Examples

```
define void @foo(i32 %arg1, i32 %arg2) {
entry:
  ; ... instructions ...
bb:
  ; ... instructions ...

  ; At function scope.
  uselistorder i32 %arg1, { 1, 0, 2 }
  uselistorder label %bb, { 1, 0 }
}

; At global scope.
uselistorder i32* @global, { 1, 2, 0 }
uselistorder i32 7, { 1, 0 }
uselistorder i32 (i32) @bar, { 1, 0 }
uselistorder_bb @foo, %bb, { 5, 1, 3, 2, 0, 4 }
```

Source Filename

The *source filename* string is set to the original module identifier, which will be the name of the compiled source file when compiling from source through the clang front end, for example. It is then preserved through the IR and bitcode.

This is currently necessary to generate a consistent unique global identifier for local functions used in profile data, which prepends the source file name to the local function name.

The syntax for the source file name is simply:

```
source_filename = "/path/to/source.c"
```

1.1.5 Type System

The LLVM type system is one of the most important features of the intermediate representation. Being typed enables a number of optimizations to be performed on the intermediate representation directly, without having to do extra analyses on the side before the transformation. A strong type system makes it easier to read the generated code and enables novel analyses and transformations that are not feasible to perform on normal three address code representations.

Void Type

Overview

The void type does not represent any value and has no size.

Syntax

```
void
```

Function Type

Overview

The function type can be thought of as a function signature. It consists of a return type and a list of formal parameter types. The return type of a function type is a void type or first class type --- except for *label* and *metadata* types.

Syntax

```
<returntype> (<parameter list>)
```

...where '*<parameter list>*' is a comma-separated list of type specifiers. Optionally, the parameter list may include a type *...*, which indicates that the function takes a variable number of arguments. Variable argument functions can access their arguments with the *variable argument handling intrinsic* functions. '*<returntype>*' is any type except *label* and *metadata*.

Examples

<code>i32 (i32)</code>	function taking an <code>i32</code> , returning an <code>i32</code>
<code>float (i16, i32 *) *</code>	<i>Pointer</i> to a function that takes an <code>i16</code> and a <i>pointer</i> to <code>i32</code> , returning <code>float</code> .
<code>i32 (i8*, ...)</code>	A vararg function that takes at least one <i>pointer</i> to <code>i8</code> (char in C), which returns an integer. This is the signature for <code>printf</code> in LLVM.
<code>{i32, i32} (i32)</code>	A function taking an <code>i32</code> , returning a <i>structure</i> containing two <code>i32</code> values

First Class Types

The *first class* types are perhaps the most important. Values of these types are the only ones which can be produced by instructions.

Single Value Types

These are the types that are valid in registers from CodeGen's perspective.

Integer Type

Overview

The integer type is a very simple type that simply specifies an arbitrary bit width for the integer type desired. Any bit width from 1 bit to $2^{23}-1$ (about 8 million) can be specified.

Syntax

```
iN
```

The number of bits the integer will occupy is specified by the N value.

Examples:

i1	a single-bit integer.
i32	a 32-bit integer.
i1942652	a really big integer of over 1 million bits.

Floating-Point Types

Type	Description
half	16-bit floating-point value
float	32-bit floating-point value
double	64-bit floating-point value
fp128	128-bit floating-point value (112-bit mantissa)
x86_fp80	80-bit floating-point value (X87)
ppc_fp128	128-bit floating-point value (two 64-bits)

The binary format of half, float, double, and fp128 correspond to the IEEE-754-2008 specifications for binary16, binary32, binary64, and binary128 respectively.

X86_mmx Type

Overview

The `x86_mmx` type represents a value held in an MMX register on an x86 machine. The operations allowed on it are quite limited: parameters and return values, load and store, and bitcast. User-specified MMX instructions are represented as intrinsic or asm calls with arguments and/or results of this type. There are no arrays, vectors or constants of this type.

Syntax

```
x86_mmx
```

Pointer Type

Overview

The pointer type is used to specify memory locations. Pointers are commonly used to reference objects in memory.

Pointer types may have an optional address space attribute defining the numbered address space where the pointed-to object resides. The default address space is number zero. The semantics of non-zero address spaces are target-specific.

Note that LLVM does not permit pointers to void (`void*`) nor does it permit pointers to labels (`label*`). Use `i8*` instead.

Syntax

```
<type> *
```

Examples

<code>[4 x i32]*</code>	A <i>pointer to array</i> of four <code>i32</code> values.
<code>i32 (i32*) *</code>	A <i>pointer to a function</i> that takes an <code>i32*</code> , returning an <code>i32</code> .
<code>i32 addrspace(5) *</code>	A <i>pointer</i> to an <code>i32</code> value that resides in address space #5.

Vector Type

Overview

A vector type is a simple derived type that represents a vector of elements. Vector types are used when multiple primitive data are operated in parallel using a single instruction (SIMD). A vector type requires a size (number of elements), an underlying primitive data type, and a scalable property to represent vectors where the exact hardware vector length is unknown at compile time. Vector types are considered *first class*.

Syntax

```
< <# elements> x <elementtype> > ; Fixed-length vector  
< vscale x <# elements> x <elementtype> > ; Scalable vector
```

The number of elements is a constant integer value larger than 0; `elementtype` may be any integer, floating-point or pointer type. Vectors of size zero are not allowed. For scalable vectors, the total number of elements is a constant multiple (called `vscale`) of the specified number of elements; `vscale` is a positive integer that is unknown at compile time and the same hardware-dependent constant for all scalable vectors at run time. The size of a specific scalable vector type is thus constant within IR, even if the exact size in bytes cannot be determined until run time.

Examples

<4 x i32>	Vector of 4 32-bit integer values.
<8 x float>	Vector of 8 32-bit floating-point values.
<2 x i64>	Vector of 2 64-bit integer values.
<4 x i64*>	Vector of 4 pointers to 64-bit integer values.
<vscale x 4 x i32>	Vector with a multiple of 4 32-bit integer values.

Label Type

Overview

The label type represents code labels.

Syntax

```
label
```

Token Type

Overview

The token type is used when a value is associated with an instruction but all uses of the value must not attempt to introspect or obscure it. As such, it is not appropriate to have a *phi* or *select* of type token.

Syntax

```
token
```

Metadata Type

Overview

The metadata type represents embedded metadata. No derived types may be created from metadata except for *function* arguments.

Syntax

```
metadata
```

Aggregate Types

Aggregate Types are a subset of derived types that can contain multiple member types. *Arrays* and *structs* are aggregate types. *Vectors* are not considered to be aggregate types.

Array Type

Overview

The array type is a very simple derived type that arranges elements sequentially in memory. The array type requires a size (number of elements) and an underlying data type.

Syntax

```
[<# elements> x <elementtype>]
```

The number of elements is a constant integer value; `elementtype` may be any type with a size.

Examples

[40 x i32]	Array of 40 32-bit integer values.
[41 x i32]	Array of 41 32-bit integer values.
[4 x i8]	Array of 4 8-bit integer values.

Here are some examples of multidimensional arrays:

[3 x [4 x i32]]	3x4 array of 32-bit integer values.
[12 x [10 x float]]	12x10 array of single precision floating-point values.
[2 x [3 x [4 x i16]]]	2x3x4 array of 16-bit integer values.

There is no restriction on indexing beyond the end of the array implied by a static type (though there are restrictions on indexing beyond the bounds of an allocated object in some cases). This means that single-dimension 'variable sized array' addressing can be implemented in LLVM with a zero length array type. An implementation of 'pascal style arrays' in LLVM could use the type "{ i32, [0 x float] }", for example.

Structure Type

Overview

The structure type is used to represent a collection of data members together in memory. The elements of a structure may be any type that has a size.

Structures in memory are accessed using 'load' and 'store' by getting a pointer to a field with the 'getelementptr' instruction. Structures in registers are accessed using the 'extractvalue' and 'insertvalue' instructions.

Structures may optionally be "packed" structures, which indicate that the alignment of the struct is one byte, and that there is no padding between the elements. In non-packed structs, padding between field types is inserted as defined by the `DataLayout` string in the module, which is required to match what the underlying code generator expects.

Structures can either be "literal" or "identified". A literal structure is defined inline with other types (e.g. {i32, i32}*) whereas identified types are always defined at the top level with a name. Literal types are uniqued by their contents and can never be recursive or opaque since there is no way to write one. Identified types can be recursive, can be opaque, and are never uniqued.

Syntax

```
%T1 = type { <type list> }      ; Identified normal struct type
%T2 = type <{ <type list> }>    ; Identified packed struct type
```

Examples

<code>{ i32, i32, i32 }</code>	A triple of three <code>i32</code> values
<code>{ float, i32 (i32) * }</code>	A pair, where the first element is a <code>float</code> and the second element is a <i>pointer</i> to a <i>function</i> that takes an <code>i32</code> , returning an <code>i32</code> .
<code><{ i8, i32 }></code>	A packed struct known to be 5 bytes in size.

Opaque Structure Types

Overview

Opaque structure types are used to represent named structure types that do not have a body specified. This corresponds (for example) to the C notion of a forward declared structure.

Syntax

```
%X = type opaque
%52 = type opaque
```

Examples

<code>opaque</code>	An opaque type.
---------------------	-----------------

1.1.6 Constants

LLVM has several different basic types of constants. This section describes them all and their syntax.

Simple Constants

Boolean constants The two strings `'true'` and `'false'` are both valid constants of the `i1` type.

Integer constants Standard integers (such as `'4'`) are constants of the *integer* type. Negative numbers may be used with integer types.

Floating-point constants Floating-point constants use standard decimal notation (e.g. 123.421), exponential notation (e.g. 1.23421e+2), or a more precise hexadecimal notation (see below). The assembler requires the exact decimal value of a floating-point constant. For example, the assembler accepts 1.25 but rejects 1.3 because 1.3 is a repeating decimal in binary. Floating-point constants must have a *floating-point* type.

Null pointer constants The identifier `'null'` is recognized as a null pointer constant and must be of *pointer type*.

Token constants The identifier `'none'` is recognized as an empty token constant and must be of *token type*.

The one non-intuitive notation for constants is the hexadecimal form of floating-point constants. For example, the form `'double 0x432ff973cafa8000'` is equivalent to (but harder to read than) `'double 4.5e+15'`. The only time hexadecimal floating-point constants are required (and the only time that they are generated by the disassembler) is when a floating-point constant must be emitted but it cannot be represented as a decimal floating-point number in a reasonable number of digits. For example, NaN's, infinities, and other special values are represented in their IEEE hexadecimal format so that assembly and disassembly do not cause any bits to change in the constants.

When using the hexadecimal form, constants of types `half`, `float`, and `double` are represented using the 16-digit form shown above (which matches the IEEE754 representation for double); `half` and `float` values must, however, be exactly representable as IEEE 754 half and single precision, respectively. Hexadecimal format is always used for long double, and there are three forms of long double. The 80-bit format used by x86 is represented as `0xK` followed by 20 hexadecimal digits. The 128-bit format used by PowerPC (two adjacent doubles) is represented by `0xM` followed by

32 hexadecimal digits. The IEEE 128-bit format is represented by `0xL` followed by 32 hexadecimal digits. Long doubles will only work if they match the long double format on your target. The IEEE 16-bit format (half precision) is represented by `0xH` followed by 4 hexadecimal digits. All hexadecimal formats are big-endian (sign bit at the left).

There are no constants of type `x86_mmx`.

Complex Constants

Complex constants are a (potentially recursive) combination of simple constants and smaller complex constants.

Structure constants Structure constants are represented with notation similar to structure type definitions (a comma separated list of elements, surrounded by braces (`{}`)). For example: `{ i32 4, float 17.0, i32* @G }`, where `@G` is declared as `@G = external global i32`. Structure constants must have *structure type*, and the number and types of elements must match those specified by the type.

Array constants Array constants are represented with notation similar to array type definitions (a comma separated list of elements, surrounded by square brackets (`[]`)). For example: `[i32 42, i32 11, i32 74]`. Array constants must have *array type*, and the number and types of elements must match those specified by the type. As a special case, character array constants may also be represented as a double-quoted string using the `c` prefix. For example: `"c"Hello World\0A\00"`.

Vector constants Vector constants are represented with notation similar to vector type definitions (a comma separated list of elements, surrounded by less-than/greater-than's (`<>`)). For example: `< i32 42, i32 11, i32 74, i32 100 >`. Vector constants must have *vector type*, and the number and types of elements must match those specified by the type.

Zero initialization The string `'zeroinitializer'` can be used to zero initialize a value to zero of *any* type, including scalar and *aggregate* types. This is often used to avoid having to print large zero initializers (e.g. for large arrays) and is always exactly equivalent to using explicit zero initializers.

Metadata node A metadata node is a constant tuple without types. For example: `!{!0, !{!2, !0}, ! "test"}`. Metadata can reference constant values, for example: `!{!0, i32 0, i8* @global, i64 (i64)* @function, !"str"}`. Unlike other typed constants that are meant to be interpreted as part of the instruction stream, metadata is a place to attach additional information such as debug info.

Global Variable and Function Addresses

The addresses of *global variables* and *functions* are always implicitly valid (link-time) constants. These constants are explicitly referenced when the *identifier for the global* is used and always have *pointer* type. For example, the following is a legal LLVM file:

```
@X = global i32 17
@Y = global i32 42
@Z = global [2 x i32*] [ i32* @X, i32* @Y ]
```

Undefined Values

The string `'undef'` can be used anywhere a constant is expected, and indicates that the user of the value may receive an unspecified bit-pattern. Undefined values may be of any type (other than `'label'` or `'void'`) and be used anywhere a constant is permitted.

Undefined values are useful because they indicate to the compiler that the program is well defined no matter what value is used. This gives the compiler more freedom to optimize. Here are some examples of (potentially surprising) transformations that are valid (in pseudo IR):

```

%A = add %X, undef
%B = sub %X, undef
%C = xor %X, undef
Safe:
%A = undef
%B = undef
%C = undef

```

This is safe because all of the output bits are affected by the undef bits. Any output bit can have a zero or one depending on the input bits.

```

%A = or %X, undef
%B = and %X, undef
Safe:
%A = -1
%B = 0
Safe:
%A = %X ;; By choosing undef as 0
%B = %X ;; By choosing undef as -1
Unsafe:
%A = undef
%B = undef

```

These logical operations have bits that are not always affected by the input. For example, if %X has a zero bit, then the output of the 'and' operation will always be a zero for that bit, no matter what the corresponding bit from the 'undef' is. As such, it is unsafe to optimize or assume that the result of the 'and' is 'undef'. However, it is safe to assume that all bits of the 'undef' could be 0, and optimize the 'and' to 0. Likewise, it is safe to assume that all the bits of the 'undef' operand to the 'or' could be set, allowing the 'or' to be folded to -1.

```

%A = select undef, %X, %Y
%B = select undef, 42, %Y
%C = select %X, %Y, undef
Safe:
%A = %X      (or %Y)
%B = 42      (or %Y)
%C = %Y
Unsafe:
%A = undef
%B = undef
%C = undef

```

This set of examples shows that undefined 'select' (and conditional branch) conditions can go *either way*, but they have to come from one of the two operands. In the %A example, if %X and %Y were both known to have a clear low bit, then %A would have to have a cleared low bit. However, in the %C example, the optimizer is allowed to assume that the 'undef' operand could be the same as %Y, allowing the whole 'select' to be eliminated.

```

%A = xor undef, undef

%B = undef
%C = xor %B, %B

%D = undef
%E = icmp slt %D, 4
%F = icmp gte %D, 4

Safe:
%A = undef

```

(continues on next page)

(continued from previous page)

```
%B = undef
%C = undef
%D = undef
%E = undef
%F = undef
```

This example points out that two 'undef' operands are not necessarily the same. This can be surprising to people (and also matches C semantics) where they assume that "X^X" is always zero, even if X is undefined. This isn't true for a number of reasons, but the short answer is that an 'undef' "variable" can arbitrarily change its value over its "live range". This is true because the variable doesn't actually *have a live range*. Instead, the value is logically read from arbitrary registers that happen to be around when needed, so the value is not necessarily consistent over time. In fact, %A and %C need to have the same semantics or the core LLVM "replace all uses with" concept would not hold.

```
%A = sdiv undef, %X
%B = sdiv %X, undef
Safe:
%A = 0
b: unreachable
```

These examples show the crucial difference between an *undefined value* and *undefined behavior*. An undefined value (like 'undef') is allowed to have an arbitrary bit-pattern. This means that the %A operation can be constant folded to '0', because the 'undef' could be zero, and zero divided by any value is zero. However, in the second example, we can make a more aggressive assumption: because the undef is allowed to be an arbitrary value, we are allowed to assume that it could be zero. Since a divide by zero has *undefined behavior*, we are allowed to assume that the operation does not execute at all. This allows us to delete the divide and all code after it. Because the undefined operation "can't happen", the optimizer can assume that it occurs in dead code.

```
a: store undef -> %X
b: store %X -> undef
Safe:
a: <deleted>
b: unreachable
```

A store *of* an undefined value can be assumed to not have any effect; we can assume that the value is overwritten with bits that happen to match what was already there. However, a store *to* an undefined location could clobber arbitrary memory, therefore, it has undefined behavior.

Poison Values

In order to facilitate speculative execution, many instructions do not invoke immediate undefined behavior when provided with illegal operands, and return a poison value instead.

There is currently no way of representing a poison value in the IR; they only exist when produced by operations such as *add* with the *nsw* flag.

Poison value behavior is defined in terms of value *dependence*:

- Values other than *phi* nodes depend on their operands.
- *Phi* nodes depend on the operand corresponding to their dynamic predecessor basic block.
- Function arguments depend on the corresponding actual argument values in the dynamic callers of their functions.
- *Call* instructions depend on the *ret* instructions that dynamically transfer control back to them.

- *Invoke* instructions depend on the *ret*, *resume*, or exception-throwing call instructions that dynamically transfer control back to them.
- Non-volatile loads and stores depend on the most recent stores to all of the referenced memory addresses, following the order in the IR (including loads and stores implied by intrinsics such as *@llvm.memcpy*.)
- An instruction with externally visible side effects depends on the most recent preceding instruction with externally visible side effects, following the order in the IR. (This includes *volatile operations*.)
- An instruction *control-depends* on a *terminator instruction* if the terminator instruction has multiple successors and the instruction is always executed when control transfers to one of the successors, and may not be executed when control is transferred to another.
- Additionally, an instruction also *control-depends* on a terminator instruction if the set of instructions it otherwise depends on would be different if the terminator had transferred control to a different successor.
- Dependence is transitive.

An instruction that *depends* on a poison value, produces a poison value itself. A poison value may be relaxed into an *undef value*, which takes an arbitrary bit-pattern.

This means that immediate undefined behavior occurs if a poison value is used as an instruction operand that has any values that trigger undefined behavior. Notably this includes (but is not limited to):

- The pointer operand of a *load*, *store* or any other pointer dereferencing instruction (independent of address space).
- The divisor operand of a *udiv*, *sdiv*, *urem* or *srem* instruction.

Additionally, undefined behavior occurs if a side effect *depends* on poison. This includes side effects that are control dependent on a poisoned branch.

Here are some examples:

```
entry:
    %poison = sub nuw i32 0, 1          ; Results in a poison value.
    %still_poison = and i32 %poison, 0 ; 0, but also poison.
    %poison_yet_again = getelementptr i32, i32* @h, i32 %still_poison
    store i32 0, i32* %poison_yet_again ; Undefined behavior due to
                                         ; store to poison.

    store i32 %poison, i32* @g          ; Poison value stored to memory.
    %poison2 = load i32, i32* @g        ; Poison value loaded back from memory.

    %narrowaddr = bitcast i32* @g to i16*
    %wideaddr = bitcast i32* @g to i64*
    %poison3 = load i16, i16* %narrowaddr ; Returns a poison value.
    %poison4 = load i64, i64* %wideaddr  ; Returns a poison value.

    %cmp = icmp slt i32 %poison, 0      ; Returns a poison value.
    br i1 %cmp, label %true, label %end ; Branch to either destination.

true:
    store volatile i32 0, i32* @g      ; This is control-dependent on %cmp, so
                                         ; it has undefined behavior.

    br label %end

end:
    %p = phi i32 [ 0, %entry ], [ 1, %true ]
                                         ; Both edges into this PHI are
                                         ; control-dependent on %cmp, so this
```

(continues on next page)

(continued from previous page)

```

                                ; always results in a poison value.

store volatile i32 0, i32* @g      ; This would depend on the store in %true
                                ; if %cmp is true, or the store in %entry
                                ; otherwise, so this is undefined behavior.

br i1 %cmp, label %second_true, label %second_end
                                ; The same branch again, but this time the
                                ; true block doesn't have side effects.

second_true:
    ; No side effects!
    ret void

second_end:
    store volatile i32 0, i32* @g      ; This time, the instruction always depends
                                ; on the store in %end. Also, it is
                                ; control-equivalent to %end, so this is
                                ; well-defined (ignoring earlier undefined
                                ; behavior in this example).
```

Addresses of Basic Blocks

`blockaddress(@function, %block)`

The 'blockaddress' constant computes the address of the specified basic block in the specified function, and always has an `i8*` type. Taking the address of the entry block is illegal.

This value only has defined behavior when used as an operand to the 'indirectbr' or 'callbr' instruction, or for comparisons against null. Pointer equality tests between labels addresses results in undefined behavior --- though, again, comparison against null is ok, and no label is equal to the null pointer. This may be passed around as an opaque pointer sized value as long as the bits are not inspected. This allows `ptrtoint` and arithmetic to be performed on these values so long as the original value is reconstituted before the `indirectbr` or `callbr` instruction.

Finally, some targets may provide defined semantics when using the value as the operand to an inline assembly, but that is target specific.

Constant Expressions

Constant expressions are used to allow expressions involving other constants to be used as constants. Constant expressions may be of any *first class* type and may involve any LLVM operation that does not have side effects (e.g. load and call are not supported). The following is the syntax for constant expressions:

trunc (CST to TYPE) Perform the *trunc operation* on constants.

zext (CST to TYPE) Perform the *zext operation* on constants.

sext (CST to TYPE) Perform the *sext operation* on constants.

fptrunc (CST to TYPE) Truncate a floating-point constant to another floating-point type. The size of CST must be larger than the size of TYPE. Both types must be floating-point.

fpext (CST to TYPE) Floating-point extend a constant to another type. The size of CST must be smaller or equal to the size of TYPE. Both types must be floating-point.

fptoui (CST to TYPE) Convert a floating-point constant to the corresponding unsigned integer constant. TYPE must be a scalar or vector integer type. CST must be of scalar or vector floating-point type. Both

CST and TYPE must be scalars, or vectors of the same number of elements. If the value won't fit in the integer type, the result is a *poison value*.

fptosi (CST to TYPE) Convert a floating-point constant to the corresponding signed integer constant. TYPE must be a scalar or vector integer type. CST must be of scalar or vector floating-point type. Both CST and TYPE must be scalars, or vectors of the same number of elements. If the value won't fit in the integer type, the result is a *poison value*.

uitofp (CST to TYPE) Convert an unsigned integer constant to the corresponding floating-point constant. TYPE must be a scalar or vector floating-point type. CST must be of scalar or vector integer type. Both CST and TYPE must be scalars, or vectors of the same number of elements.

sitofp (CST to TYPE) Convert a signed integer constant to the corresponding floating-point constant. TYPE must be a scalar or vector floating-point type. CST must be of scalar or vector integer type. Both CST and TYPE must be scalars, or vectors of the same number of elements.

ptrtoint (CST to TYPE) Perform the *ptrtoint operation* on constants.

inttoptr (CST to TYPE) Perform the *inttoptr operation* on constants. This one is *really* dangerous!

bitcast (CST to TYPE) Convert a constant, CST, to another TYPE. The constraints of the operands are the same as those for the *bitcast instruction*.

addrspacecast (CST to TYPE) Convert a constant pointer or constant vector of pointer, CST, to another TYPE in a different address space. The constraints of the operands are the same as those for the *addrspacecast instruction*.

getelementptr (TY, CSTPTR, IDX0, IDX1, ...), getelementptr inbounds (TY, CSTPTR, IDX0, IDX1, ...) Perform the *getelementptr operation* on constants. As with the *getelementptr* instruction, the index list may have one or more indexes, which are required to make sense for the type of "pointer to TY".

select (COND, VAL1, VAL2) Perform the *select operation* on constants.

icmp COND (VAL1, VAL2) Perform the *icmp operation* on constants.

fcmp COND (VAL1, VAL2) Perform the *fcmp operation* on constants.

extractelement (VAL, IDX) Perform the *extractelement operation* on constants.

insertelement (VAL, ELT, IDX) Perform the *insertelement operation* on constants.

shufflevector (VEC1, VEC2, IDXMASK) Perform the *shufflevector operation* on constants.

extractvalue (VAL, IDX0, IDX1, ...) Perform the *extractvalue operation* on constants. The index list is interpreted in a similar manner as indices in a '*getelementptr*' operation. At least one index value must be specified.

insertvalue (VAL, ELT, IDX0, IDX1, ...) Perform the *insertvalue operation* on constants. The index list is interpreted in a similar manner as indices in a '*getelementptr*' operation. At least one index value must be specified.

OPCODE (LHS, RHS) Perform the specified operation of the LHS and RHS constants. OPCODE may be any of the *binary* or *bitwise binary* operations. The constraints on operands are the same as those for the corresponding instruction (e.g. no bitwise operations on floating-point values are allowed).

1.1.7 Other Values

Inline Assembler Expressions

LLVM supports inline assembler expressions (as opposed to *Module-Level Inline Assembly*) through the use of a special value. This value represents the inline assembler as a template string (containing the instructions to emit), a list of operand constraints (stored as a string), a flag that indicates whether or not the inline asm expression has side effects, and a flag indicating whether the function containing the asm needs to align its stack conservatively.

The template string supports argument substitution of the operands using "\$" followed by a number, to indicate substitution of the given register/memory location, as specified by the constraint string. "\${NUM:MODIFIER}" may also be used, where MODIFIER is a target-specific annotation for how to print the operand (See *Asm template argument modifiers*).

A literal "\$" may be included by using "\$\$" in the template. To include other special characters into the output, the usual "\\XX" escapes may be used, just as in other strings. Note that after template substitution, the resulting assembly string is parsed by LLVM's integrated assembler unless it is disabled -- even when emitting a .s file -- and thus must contain assembly syntax known to LLVM.

LLVM also supports a few more substitutions useful for writing inline assembly:

- `${:uid}`: Expands to a decimal integer unique to this inline assembly blob. This substitution is useful when declaring a local label. Many standard compiler optimizations, such as inlining, may duplicate an inline asm blob. Adding a blob-unique identifier ensures that the two labels will not conflict during assembly. This is used to implement GCC's `%=` special format string.
- `${:comment}`: Expands to the comment character of the current target's assembly dialect. This is usually `#`, but many targets use other strings, such as `;`, `//`, or `!`.
- `${:private}`: Expands to the assembler private label prefix. Labels with this prefix will not appear in the symbol table of the assembled object. Typically the prefix is `L`, but targets may use other strings. `.L` is relatively popular.

LLVM's support for inline asm is modeled closely on the requirements of Clang's GCC-compatible inline-asm support. Thus, the feature-set and the constraint and modifier codes listed here are similar or identical to those in GCC's inline asm support. However, to be clear, the syntax of the template and constraint strings described here is *not* the same as the syntax accepted by GCC and Clang, and, while most constraint letters are passed through as-is by Clang, some get translated to other codes when converting from the C source to the LLVM assembly.

An example inline assembler expression is:

```
i32 (i32) asm "bswap $0", "=r,r"
```

Inline assembler expressions may **only** be used as the callee operand of a *call* or an *invoke* instruction. Thus, typically we have:

```
%X = call i32 @asm "bswap $0", "=r,r" (i32 %Y)
```

Inline asms with side effects not visible in the constraint list must be marked as having side effects. This is done through the use of the 'sideeffect' keyword, like so:

```
call void @asm sideeffect "eieio", ""()
```

In some cases inline asms will contain code that will not work unless the stack is aligned in some way, such as calls or SSE instructions on x86, yet will not contain code that does that alignment within the asm. The compiler should make conservative assumptions about what the asm might contain and should generate its usual stack alignment code in the prologue if the 'alignstack' keyword is present:

```
call void asm alignstack "eieio", ""()
```

Inline asms also support using non-standard assembly dialects. The assumed dialect is ATT. When the 'inteldialect' keyword is present, the inline asm is using the Intel dialect. Currently, ATT and Intel are the only supported dialects. An example is:

```
call void asm inteldialect "eieio", ""()
```

If multiple keywords appear the 'sideeffect' keyword must come first, the 'alignstack' keyword second and the 'inteldialect' keyword last.

Inline Asm Constraint String

The constraint list is a comma-separated string, each element containing one or more constraint codes.

For each element in the constraint list an appropriate register or memory operand will be chosen, and it will be made available to assembly template string expansion as `$0` for the first constraint in the list, `$1` for the second, etc.

There are three different types of constraints, which are distinguished by a prefix symbol in front of the constraint code: Output, Input, and Clobber. The constraints must always be given in that order: outputs first, then inputs, then clobbers. They cannot be intermingled.

There are also three different categories of constraint codes:

- Register constraint. This is either a register class, or a fixed physical register. This kind of constraint will allocate a register, and if necessary, bitcast the argument or result to the appropriate type.
- Memory constraint. This kind of constraint is for use with an instruction taking a memory operand. Different constraints allow for different addressing modes used by the target.
- Immediate value constraint. This kind of constraint is for an integer or other immediate value which can be rendered directly into an instruction. The various target-specific constraints allow the selection of a value in the proper range for the instruction you wish to use it with.

Output constraints

Output constraints are specified by an "=" prefix (e.g. "=r"). This indicates that the assembly will write to this operand, and the operand will then be made available as a return value of the `asm` expression. Output constraints do not consume an argument from the call instruction. (Except, see below about indirect outputs).

Normally, it is expected that no output locations are written to by the assembly expression until *all* of the inputs have been read. As such, LLVM may assign the same register to an output and an input. If this is not safe (e.g. if the assembly contains two instructions, where the first writes to one output, and the second reads an input and writes to a second output), then the "&" modifier must be used (e.g. "=&r") to specify that the output is an "early-clobber" output. Marking an output as "early-clobber" ensures that LLVM will not use the same register for any inputs (other than an input tied to this output).

Input constraints

Input constraints do not have a prefix -- just the constraint codes. Each input constraint will consume one argument from the call instruction. It is not permitted for the asm to write to any input register or memory location (unless that input is tied to an output). Note also that multiple inputs may all be assigned to the same register, if LLVM can determine that they necessarily all contain the same value.

Instead of providing a Constraint Code, input constraints may also "tie" themselves to an output constraint, by providing an integer as the constraint string. Tied inputs still consume an argument from the call instruction, and take up a position in the asm template numbering as is usual -- they will simply be constrained to always use the same register as the output they've been tied to. For example, a constraint string of `"=r, 0"` says to assign a register for output, and use that register as an input as well (it being the 0'th constraint).

It is permitted to tie an input to an "early-clobber" output. In that case, no *other* input may share the same register as the input tied to the early-clobber (even when the other input has the same value).

You may only tie an input to an output which has a register constraint, not a memory constraint. Only a single input may be tied to an output.

There is also an "interesting" feature which deserves a bit of explanation: if a register class constraint allocates a register which is too small for the value type operand provided as input, the input value will be split into multiple registers, and all of them passed to the inline asm.

However, this feature is often not as useful as you might think.

Firstly, the registers are *not* guaranteed to be consecutive. So, on those architectures that have instructions which operate on multiple consecutive instructions, this is not an appropriate way to support them. (e.g. the 32-bit SparcV8 has a 64-bit load, which instruction takes a single 32-bit register. The hardware then loads into both the named register, and the next register. This feature of inline asm would not be useful to support that.)

A few of the targets provide a template string modifier allowing explicit access to the second register of a two-register operand (e.g. MIPS `L`, `M`, and `D`). On such an architecture, you can actually access the second allocated register (yet, still, not any subsequent ones). But, in that case, you're still probably better off simply splitting the value into two separate operands, for clarity. (e.g. see the description of the `A` constraint on X86, which, despite existing only for use with this feature, is not really a good idea to use)

Indirect inputs and outputs

Indirect output or input constraints can be specified by the `"*"` modifier (which goes after the `"="` in case of an output). This indicates that the asm will write to or read from the contents of an *address* provided as an input argument. (Note that in this way, indirect outputs act more like an *input* than an output: just like an input, they consume an argument of the call expression, rather than producing a return value. An indirect output constraint is an "output" only in that the asm is expected to write to the contents of the input memory location, instead of just read from it).

This is most typically used for memory constraint, e.g. `"=*m"`, to pass the address of a variable as a value.

It is also possible to use an indirect *register* constraint, but only on output (e.g. `"=*r"`). This will cause LLVM to allocate a register for an output value normally, and then, separately emit a store to the address provided as input, after the provided inline asm. (It's not clear what value this functionality provides, compared to writing the store explicitly after the asm statement, and it can only produce worse code, since it bypasses many optimization passes. I would recommend not using it.)

Clobber constraints

A clobber constraint is indicated by a "~" prefix. A clobber does not consume an input operand, nor generate an output. Clobbers cannot use any of the general constraint code letters -- they may use only explicit register constraints, e.g. "~{eax}". The one exception is that a clobber string of "~{memory}" indicates that the assembly writes to arbitrary undeclared memory locations -- not only the memory pointed to by a declared indirect output.

Note that clobbering named registers that are also present in output constraints is not legal.

Constraint Codes

After a potential prefix comes constraint code, or codes.

A Constraint Code is either a single letter (e.g. "r"), a "^" character followed by two letters (e.g. "^wC"), or "{" register-name "}" (e.g. "{eax}").

The one and two letter constraint codes are typically chosen to be the same as GCC's constraint codes.

A single constraint may include one or more than constraint code in it, leaving it up to LLVM to choose which one to use. This is included mainly for compatibility with the translation of GCC inline asm coming from clang.

There are two ways to specify alternatives, and either or both may be used in an inline asm constraint list:

- 1) Append the codes to each other, making a constraint code set. E.g. "im" or "{eax}m". This means "choose any of the options in the set". The choice of constraint is made independently for each constraint in the constraint list.
- 2) Use "|" between constraint code sets, creating alternatives. Every constraint in the constraint list must have the same number of alternative sets. With this syntax, the same alternative in *all* of the items in the constraint list will be chosen together.

Putting those together, you might have a two operand constraint string like "rm|r,ri|rm". This indicates that if operand 0 is r or m, then operand 1 may be one of r or i. If operand 0 is r, then operand 1 may be one of r or m. But, operand 0 and 1 cannot both be of type m.

However, the use of either of the alternatives features is *NOT* recommended, as LLVM is not able to make an intelligent choice about which one to use. (At the point it currently needs to choose, not enough information is available to do so in a smart way.) Thus, it simply tries to make a choice that's most likely to compile, not one that will be optimal performance. (e.g., given "rm", it'll always choose to use memory, not registers). And, if given multiple registers, or multiple register classes, it will simply choose the first one. (In fact, it doesn't currently even ensure explicitly specified physical registers are unique, so specifying multiple physical registers as alternatives, like {r11}{r12}, {r11}{r12}, will assign r11 to both operands, not at all what was intended.)

Supported Constraint Code List

The constraint codes are, in general, expected to behave the same way they do in GCC. LLVM's support is often implemented on an 'as-needed' basis, to support C inline asm code which was supported by GCC. A mismatch in behavior between LLVM and GCC likely indicates a bug in LLVM.

Some constraint codes are typically supported by all targets:

- r: A register in the target's general purpose register class.
- m: A memory address operand. It is target-specific what addressing modes are supported, typical examples are register, or register + register offset, or register + immediate offset (of some target-specific size).
- i: An integer constant (of target-specific width). Allows either a simple immediate, or a relocatable value.
- n: An integer constant -- *not* including relocatable values.

- `s`: An integer constant, but allowing *only* relocatable values.
- `X`: Allows an operand of any kind, no constraint whatsoever. Typically useful to pass a label for an asm branch or call.
- `{register-name}`: Requires exactly the named physical register.

Other constraints are target-specific:

AArch64:

- `z`: An immediate integer 0. Outputs WZR or XZR, as appropriate.
- `I`: An immediate integer valid for an ADD or SUB instruction, i.e. 0 to 4095 with optional shift by 12.
- `J`: An immediate integer that, when negated, is valid for an ADD or SUB instruction, i.e. -1 to -4095 with optional left shift by 12.
- `K`: An immediate integer that is valid for the 'bitmask immediate 32' of a logical instruction like AND, EOR, or ORR with a 32-bit register.
- `L`: An immediate integer that is valid for the 'bitmask immediate 64' of a logical instruction like AND, EOR, or ORR with a 64-bit register.
- `M`: An immediate integer for use with the MOV assembly alias on a 32-bit register. This is a superset of `K`: in addition to the bitmask immediate, also allows immediate integers which can be loaded with a single MOVZ or MOVL instruction.
- `N`: An immediate integer for use with the MOV assembly alias on a 64-bit register. This is a superset of `L`.
- `Q`: Memory address operand must be in a single register (no offsets). (However, LLVM currently does this for the `m` constraint as well.)
- `r`: A 32 or 64-bit integer register (W* or X*).
- `w`: A 32, 64, or 128-bit floating-point/SIMD register.
- `x`: A lower 128-bit floating-point/SIMD register (V0 to V15).

AMDGPU:

- `r`: A 32 or 64-bit integer register.
- `[0-9]v`: The 32-bit VGPR register, number 0-9.
- `[0-9]s`: The 32-bit SGPR register, number 0-9.

All ARM modes:

- `Q`, `Um`, `Un`, `Uq`, `Us`, `Ut`, `Uv`, `Uy`: Memory address operand. Treated the same as operand `m`, at the moment.
- `Te`: An even general-purpose 32-bit integer register: `r0`, `r2`, ..., `r12`, `r14`
- `To`: An odd general-purpose 32-bit integer register: `r1`, `r3`, ..., `r11`

ARM and ARM's Thumb2 mode:

- `j`: An immediate integer between 0 and 65535 (valid for MOVW)
- `I`: An immediate integer valid for a data-processing instruction.
- `J`: An immediate integer between -4095 and 4095.
- `K`: An immediate integer whose bitwise inverse is valid for a data-processing instruction. (Can be used with template modifier "B" to print the inverted value).
- `L`: An immediate integer whose negation is valid for a data-processing instruction. (Can be used with template modifier "n" to print the negated value).

- M: A power of two or a integer between 0 and 32.
- N: Invalid immediate constraint.
- O: Invalid immediate constraint.
- r: A general-purpose 32-bit integer register (r0-r15).
- l: In Thumb2 mode, low 32-bit GPR registers (r0-r7). In ARM mode, same as r.
- h: In Thumb2 mode, a high 32-bit GPR register (r8-r15). In ARM mode, invalid.
- w: A 32, 64, or 128-bit floating-point/SIMD register: s0-s31, d0-d31, or q0-q15.
- x: A 32, 64, or 128-bit floating-point/SIMD register: s0-s15, d0-d7, or q0-q3.
- t: A low floating-point/SIMD register: s0-s31, d0-d16, or q0-q8.

ARM's Thumb1 mode:

- I: An immediate integer between 0 and 255.
- J: An immediate integer between -255 and -1.
- K: An immediate integer between 0 and 255, with optional left-shift by some amount.
- L: An immediate integer between -7 and 7.
- M: An immediate integer which is a multiple of 4 between 0 and 1020.
- N: An immediate integer between 0 and 31.
- O: An immediate integer which is a multiple of 4 between -508 and 508.
- r: A low 32-bit GPR register (r0-r7).
- l: A low 32-bit GPR register (r0-r7).
- h: A high GPR register (r0-r7).
- w: A 32, 64, or 128-bit floating-point/SIMD register: s0-s31, d0-d31, or q0-q15.
- x: A 32, 64, or 128-bit floating-point/SIMD register: s0-s15, d0-d7, or q0-q3.
- t: A low floating-point/SIMD register: s0-s31, d0-d16, or q0-q8.

Hexagon:

- o, v: A memory address operand, treated the same as constraint m, at the moment.
- r: A 32 or 64-bit register.

MSP430:

- r: An 8 or 16-bit register.

MIPS:

- I: An immediate signed 16-bit integer.
- J: An immediate integer zero.
- K: An immediate unsigned 16-bit integer.
- L: An immediate 32-bit integer, where the lower 16 bits are 0.
- N: An immediate integer between -65535 and -1.
- O: An immediate signed 15-bit integer.
- P: An immediate integer between 1 and 65535.

- `m`: A memory address operand. In MIPS-SE mode, allows a base address register plus 16-bit immediate offset. In MIPS mode, just a base register.
- `R`: A memory address operand. In MIPS-SE mode, allows a base address register plus a 9-bit signed offset. In MIPS mode, the same as constraint `m`.
- `ZC`: A memory address operand, suitable for use in a `pref`, `ll`, or `sc` instruction on the given subtarget (details vary).
- `r`, `d`, `y`: A 32 or 64-bit GPR register.
- `f`: A 32 or 64-bit FPU register (`F0–F31`), or a 128-bit MSA register (`W0–W31`). In the case of MSA registers, it is recommended to use the `w` argument modifier for compatibility with GCC.
- `c`: A 32-bit or 64-bit GPR register suitable for indirect jump (always 25).
- `l`: The `lo` register, 32 or 64-bit.
- `x`: Invalid.

NVPTX:

- `b`: A 1-bit integer register.
- `c` or `h`: A 16-bit integer register.
- `r`: A 32-bit integer register.
- `l` or `N`: A 64-bit integer register.
- `f`: A 32-bit float register.
- `d`: A 64-bit float register.

PowerPC:

- `I`: An immediate signed 16-bit integer.
- `J`: An immediate unsigned 16-bit integer, shifted left 16 bits.
- `K`: An immediate unsigned 16-bit integer.
- `L`: An immediate signed 16-bit integer, shifted left 16 bits.
- `M`: An immediate integer greater than 31.
- `N`: An immediate integer that is an exact power of 2.
- `O`: The immediate integer constant 0.
- `P`: An immediate integer constant whose negation is a signed 16-bit constant.
- `es`, `o`, `Q`, `Z`, `Zy`: A memory address operand, currently treated the same as `m`.
- `r`: A 32 or 64-bit integer register.
- `b`: A 32 or 64-bit integer register, excluding `R0` (that is: `R1–R31`).
- `f`: A 32 or 64-bit float register (`F0–F31`), or when QPX is enabled, a 128 or 256-bit QPX register (`Q0–Q31`; aliases the `F` registers).
- `v`: For $4 \times f32$ or $4 \times f64$ types, when QPX is enabled, a 128 or 256-bit QPX register (`Q0–Q31`), otherwise a 128-bit altivec vector register (`V0–V31`).
- `y`: Condition register (`CR0–CR7`).
- `wc`: An individual CR bit in a CR register.

- *wa*, *wd*, *wf*: Any 128-bit VSX vector register, from the full VSX register set (overlapping both the floating-point and vector register files).
- *ws*: A 32 or 64-bit floating-point register, from the full VSX register set.

Sparc:

- *I*: An immediate 13-bit signed integer.
- *r*: A 32-bit integer register.
- *f*: Any floating-point register on SparcV8, or a floating-point register in the "low" half of the registers on SparcV9.
- *e*: Any floating-point register. (Same as *f* on SparcV8.)

SystemZ:

- *I*: An immediate unsigned 8-bit integer.
- *J*: An immediate unsigned 12-bit integer.
- *K*: An immediate signed 16-bit integer.
- *L*: An immediate signed 20-bit integer.
- *M*: An immediate integer 0x7ffffff.
- *Q*: A memory address operand with a base address and a 12-bit immediate unsigned displacement.
- *R*: A memory address operand with a base address, a 12-bit immediate unsigned displacement, and an index register.
- *S*: A memory address operand with a base address and a 20-bit immediate signed displacement.
- *T*: A memory address operand with a base address, a 20-bit immediate signed displacement, and an index register.
- *r* or *d*: A 32, 64, or 128-bit integer register.
- *a*: A 32, 64, or 128-bit integer address register (excludes R0, which in an address context evaluates as zero).
- *h*: A 32-bit value in the high part of a 64bit data register (LLVM-specific)
- *f*: A 32, 64, or 128-bit floating-point register.

X86:

- *I*: An immediate integer between 0 and 31.
- *J*: An immediate integer between 0 and 64.
- *K*: An immediate signed 8-bit integer.
- *L*: An immediate integer, 0xff or 0xffff or (in 64-bit mode only) 0xffffffff.
- *M*: An immediate integer between 0 and 3.
- *N*: An immediate unsigned 8-bit integer.
- *O*: An immediate integer between 0 and 127.
- *e*: An immediate 32-bit signed integer.
- *Z*: An immediate 32-bit unsigned integer.
- *o*, *v*: Treated the same as *m*, at the moment.
- *q*: An 8, 16, 32, or 64-bit register which can be accessed as an 8-bit 1 integer register. On X86-32, this is the *a*, *b*, *c*, and *d* registers, and on X86-64, it is all of the integer registers.

- `Q`: An 8, 16, 32, or 64-bit register which can be accessed as an 8-bit integer register. This is the `a`, `b`, `c`, and `d` registers.
- `r` or `l`: An 8, 16, 32, or 64-bit integer register.
- `R`: An 8, 16, 32, or 64-bit "legacy" integer register -- one which has existed since i386, and can be accessed without the REX prefix.
- `f`: A 32, 64, or 80-bit '387 FPU stack pseudo-register.
- `y`: A 64-bit MMX register, if MMX is enabled.
- `x`: If SSE is enabled: a 32 or 64-bit scalar operand, or 128-bit vector operand in a SSE register. If AVX is also enabled, can also be a 256-bit vector operand in an AVX register. If AVX-512 is also enabled, can also be a 512-bit vector operand in an AVX512 register. Otherwise, an error.
- `Y`: The same as `x`, if SSE2 is enabled, otherwise an error.
- `A`: Special case: allocates EAX first, then EDX, for a single operand (in 32-bit mode, a 64-bit integer operand will get split into two registers). It is not recommended to use this constraint, as in 64-bit mode, the 64-bit operand will get allocated only to RAX -- if two 32-bit operands are needed, you're better off splitting it yourself, before passing it to the asm statement.

XCore:

- `r`: A 32-bit integer register.

Asm template argument modifiers

In the asm template string, modifiers can be used on the operand reference, like `"${0:n}"`.

The modifiers are, in general, expected to behave the same way they do in GCC. LLVM's support is often implemented on an 'as-needed' basis, to support C inline asm code which was supported by GCC. A mismatch in behavior between LLVM and GCC likely indicates a bug in LLVM.

Target-independent:

- `c`: Print an immediate integer constant unadorned, without the target-specific immediate punctuation (e.g. no `$` prefix).
- `n`: Negate and print immediate integer constant unadorned, without the target-specific immediate punctuation (e.g. no `$` prefix).
- `l`: Print as an unadorned label, without the target-specific label punctuation (e.g. no `$` prefix).

AArch64:

- `w`: Print a GPR register with a `w*` name instead of `x*` name. E.g., instead of `x30`, print `w30`.
- `x`: Print a GPR register with a `x*` name. (this is the default, anyhow).
- `b`, `h`, `s`, `d`, `q`: Print a floating-point/SIMD register with a `b*`, `h*`, `s*`, `d*`, or `q*` name, rather than the default of `v*`.

AMDGPU:

- `r`: No effect.

ARM:

- `a`: Print an operand as an address (with `[` and `]` surrounding a register).
- `P`: No effect.
- `q`: No effect.

- `y`: Print a VFP single-precision register as an indexed double (e.g. print as `d4 [1]` instead of `s9`)
- `B`: Bitwise invert and print an immediate integer constant without `#` prefix.
- `L`: Print the low 16-bits of an immediate integer constant.
- `M`: Print as a register set suitable for `ldm/stm`. Also prints *all* register operands subsequent to the specified one (!), so use carefully.
- `Q`: Print the low-order register of a register-pair, or the low-order register of a two-register operand.
- `R`: Print the high-order register of a register-pair, or the high-order register of a two-register operand.
- `H`: Print the second register of a register-pair. (On a big-endian system, `H` is equivalent to `Q`, and on little-endian system, `H` is equivalent to `R`.)
- `e`: Print the low doubleword register of a NEON quad register.
- `f`: Print the high doubleword register of a NEON quad register.
- `m`: Print the base register of a memory operand without the `[` and `]` adornment.

Hexagon:

- `L`: Print the second register of a two-register operand. Requires that it has been allocated consecutively to the first.
- `I`: Print the letter 'i' if the operand is an integer constant, otherwise nothing. Used to print 'addi' vs 'add' instructions.

MSP430:

No additional modifiers.

MIPS:

- `X`: Print an immediate integer as hexadecimal
- `x`: Print the low 16 bits of an immediate integer as hexadecimal.
- `d`: Print an immediate integer as decimal.
- `m`: Subtract one and print an immediate integer as decimal.
- `z`: Print \$0 if an immediate zero, otherwise print normally.
- `L`: Print the low-order register of a two-register operand, or prints the address of the low-order word of a double-word memory operand.
- `M`: Print the high-order register of a two-register operand, or prints the address of the high-order word of a double-word memory operand.
- `D`: Print the second register of a two-register operand, or prints the second word of a double-word memory operand. (On a big-endian system, `D` is equivalent to `L`, and on little-endian system, `D` is equivalent to `M`.)
- `w`: No effect. Provided for compatibility with GCC which requires this modifier in order to print MSA registers (`w0-w31`) with the `f` constraint.

NVPTX:

- `r`: No effect.

PowerPC:

- `L`: Print the second register of a two-register operand. Requires that it has been allocated consecutively to the first.

- `I`: Print the letter 'i' if the operand is an integer constant, otherwise nothing. Used to print 'addi' vs 'add' instructions.
- `y`: For a memory operand, prints formatter for a two-register X-form instruction. (Currently always prints `r0, OPERAND`).
- `U`: Prints 'u' if the memory operand is an update form, and nothing otherwise. (NOTE: LLVM does not support update form, so this will currently always print nothing)
- `X`: Prints 'x' if the memory operand is an indexed form. (NOTE: LLVM does not support indexed form, so this will currently always print nothing)

Sparc:

- `r`: No effect.

SystemZ:

SystemZ implements only `n`, and does *not* support any of the other target-independent modifiers.

X86:

- `c`: Print an unadorned integer or symbol name. (The latter is target-specific behavior for this typically target-independent modifier).
- `A`: Print a register name with a '*' before it.
- `b`: Print an 8-bit register name (e.g. `al`); do nothing on a memory operand.
- `h`: Print the upper 8-bit register name (e.g. `ah`); do nothing on a memory operand.
- `w`: Print the 16-bit register name (e.g. `ax`); do nothing on a memory operand.
- `k`: Print the 32-bit register name (e.g. `eax`); do nothing on a memory operand.
- `q`: Print the 64-bit register name (e.g. `rax`), if 64-bit registers are available, otherwise the 32-bit register name; do nothing on a memory operand.
- `n`: Negate and print an unadorned integer, or, for operands other than an immediate integer (e.g. a relocatable symbol expression), print a '-' before the operand. (The behavior for relocatable symbol expressions is a target-specific behavior for this typically target-independent modifier)
- `H`: Print a memory reference with additional offset +8.
- `P`: Print a memory reference or operand for use as the argument of a call instruction. (E.g. omit `(rip)`, even though it's PC-relative.)

XCore:

No additional modifiers.

Inline Asm Metadata

The call instructions that wrap inline asm nodes may have a `!srcloc` MDNode attached to it that contains a list of constant integers. If present, the code generator will use the integer as the location cookie value when report errors through the `LLVMContext` error reporting mechanisms. This allows a front-end to correlate backend errors that occur with inline asm back to the source code that produced it. For example:

```
call void asm sideeffect "something bad", "()", !srcloc !42
...
!42 = !{ i32 1234567 }
```

It is up to the front-end to make sense of the magic numbers it places in the IR. If the MDNode contains multiple constants, the code generator will use the one that corresponds to the line of the asm that the error occurs on.

1.1.8 Metadata

LLVM IR allows metadata to be attached to instructions in the program that can convey extra information about the code to the optimizers and code generator. One example application of metadata is source-level debug information. There are two metadata primitives: strings and nodes.

Metadata does not have a type, and is not a value. If referenced from a `call` instruction, it uses the `metadata` type.

All metadata are identified in syntax by an exclamation point ('!').

Metadata Nodes and Metadata Strings

A metadata string is a string surrounded by double quotes. It can contain any character by escaping non-printable characters with `"\xx"` where `"xx"` is the two digit hex code. For example: `!"test\00"`.

Metadata nodes are represented with notation similar to structure constants (a comma separated list of elements, surrounded by braces and preceded by an exclamation point). Metadata nodes can have any values as their operand. For example:

```
!{ !"test\00", i32 10 }
```

Metadata nodes that aren't unique use the `distinct` keyword. For example:

```
!0 = distinct !{ !"test\00", i32 10 }
```

`distinct` nodes are useful when nodes shouldn't be merged based on their content. They can also occur when transformations cause uniquing collisions when metadata operands change.

A *named metadata* is a collection of metadata nodes, which can be looked up in the module symbol table. For example:

```
!foo = !{!4, !3}
```

Metadata can be used as function arguments. Here the `llvm.dbg.value` intrinsic is using three metadata arguments:

```
call void @llvm.dbg.value(metadata !24, metadata !25, metadata !26)
```

Metadata can be attached to an instruction. Here metadata `!21` is attached to the `add` instruction using the `!dbg` identifier:

```
%indvar.next = add i64 %indvar, 1, !dbg !21
```

Metadata can also be attached to a function or a global variable. Here metadata `!22` is attached to the `f1` and `f2` functions, and the globals `g1` and `g2` using the `!dbg` identifier:

```
declare !dbg !22 void @f1()
define void @f2() !dbg !22 {
    ret void
}

@g1 = global i32 0, !dbg !22
@g2 = external global i32, !dbg !22
```

A transformation is required to drop any metadata attachment that it does not know or know it can't preserve. Currently there is an exception for metadata attachment to globals for `!type` and `!absolute_symbol` which can't be unconditionally dropped unless the global is itself deleted.

Metadata attached to a module using named metadata may not be dropped, with the exception of debug metadata (named metadata with the name `!llvm.dbg.*`).

More information about specific metadata nodes recognized by the optimizers and code generator is found below.

Specialized Metadata Nodes

Specialized metadata nodes are custom data structures in metadata (as opposed to generic tuples). Their fields are labelled, and can be specified in any order.

These aren't inherently debug info centric, but currently all the specialized metadata nodes are related to debug info.

DICompileUnit

`DICompileUnit` nodes represent a compile unit. The `enums:`, `retainedTypes:`, `globals:`, `imports:` and `macros:` fields are tuples containing the debug info to be emitted along with the compile unit, regardless of code optimizations (some nodes are only emitted if there are references to them from instructions). The `debugInfoForProfiling:` field is a boolean indicating whether or not line-table discriminators are updated to provide more-accurate debug info for profiling results.

```
!0 = !DICompileUnit(language: DW_LANG_C99, file: !1, producer: "clang",
                    isOptimized: true, flags: "-O2", runtimeVersion: 2,
                    splitDebugFilename: "abc.debug", emissionKind: FullDebug,
                    enums: !2, retainedTypes: !3, globals: !4, imports: !5,
                    macros: !6, dwoId: 0x0abcd)
```

Compile unit descriptors provide the root scope for objects declared in a specific compilation unit. File descriptors are defined using this scope. These descriptors are collected by a named metadata node `!llvm.dbg.cu`. They keep track of global variables, type information, and imported entities (declarations and namespaces).

DIFile

`DIFile` nodes represent files. The `filename:` can include slashes.

```
!0 = !DIFile(filename: "path/to/file", directory: "/path/to/dir",
             checksumkind: CSK_MD5,
             checksum: "000102030405060708090a0b0c0d0e0f")
```

Files are sometimes used in `scope:` fields, and are the only valid target for `file:` fields. Valid values for `checksumkind:` field are: `{CSK_None, CSK_MD5, CSK_SHA1}`

DIBasicType

DIBasicType nodes represent primitive types, such as int, bool and float. tag: defaults to DW_TAG_base_type.

```
!0 = !DIBasicType(name: "unsigned char", size: 8, align: 8,
                  encoding: DW_ATE_unsigned_char)
!1 = !DIBasicType(tag: DW_TAG_unspecified_type, name: "decltype(nullptr)")
```

The encoding: describes the details of the type. Usually it's one of the following:

```
DW_ATE_address      = 1
DW_ATE_boolean     = 2
DW_ATE_float       = 4
DW_ATE_signed      = 5
DW_ATE_signed_char = 6
DW_ATE_unsigned    = 7
DW_ATE_unsigned_char = 8
```

DISubroutineType

DISubroutineType nodes represent subroutine types. Their types: field refers to a tuple; the first operand is the return type, while the rest are the types of the formal arguments in order. If the first operand is null, that represents a function with no return value (such as void foo() {} in C++).

```
!0 = !BasicType(name: "int", size: 32, align: 32, DW_ATE_signed)
!1 = !BasicType(name: "char", size: 8, align: 8, DW_ATE_signed_char)
!2 = !DISubroutineType(types: !{null, !0, !1}) ; void (int, char)
```

IDerivedType

IDerivedType nodes represent types derived from other types, such as qualified types.

```
!0 = !DIBasicType(name: "unsigned char", size: 8, align: 8,
                  encoding: DW_ATE_unsigned_char)
!1 = !IDerivedType(tag: DW_TAG_pointer_type, baseType: !0, size: 32,
                  align: 32)
```

The following tag: values are valid:

```
DW_TAG_member      = 13
DW_TAG_pointer_type = 15
DW_TAG_reference_type = 16
DW_TAG_typedef     = 22
DW_TAG_inheritance = 28
DW_TAG_ptr_to_member_type = 31
DW_TAG_const_type  = 38
DW_TAG_friend     = 42
DW_TAG_volatile_type = 53
DW_TAG_restrict_type = 55
DW_TAG_atomic_type = 71
```

DW_TAG_member is used to define a member of a *composite type*. The type of the member is the `baseType:`. The `offset:` is the member's bit offset. If the composite type has an ODR `identifier:` and does not set `flags: DIFwdDecl`, then the member is uniqued based only on its `name:` and `scope:`.

DW_TAG_inheritance and DW_TAG_friend are used in the `elements:` field of *composite types* to describe parents and friends.

DW_TAG_typedef is used to provide a name for the `baseType:`.

DW_TAG_pointer_type, DW_TAG_reference_type, DW_TAG_const_type, DW_TAG_volatile_type, DW_TAG_restrict_type and DW_TAG_atomic_type are used to qualify the `baseType:`.

Note that the `void *` type is expressed as a type derived from NULL.

DICompositeType

DICompositeType nodes represent types composed of other types, like structures and unions. `elements:` points to a tuple of the composed types.

If the source language supports ODR, the `identifier:` field gives the unique identifier used for type merging between modules. When specified, *subprogram declarations* and *member derived types* that reference the ODR-type in their `scope:` change uniquing rules.

For a given `identifier:`, there should only be a single composite type that does not have `flags: DIFlagFwdDecl` set. LLVM tools that link modules together will unique such definitions at parse time via the `identifier:` field, even if the nodes are distinct.

```
!0 = !DIEnumerator(name: "SixKind", value: 7)
!1 = !DIEnumerator(name: "SevenKind", value: 7)
!2 = !DIEnumerator(name: "NegEightKind", value: -8)
!3 = !DICompositeType(tag: DW_TAG_enumeration_type, name: "Enum", file: !12,
                      line: 2, size: 32, align: 32, identifier: "_M4Enum",
                      elements: !(!0, !1, !2))
```

The following tag: values are valid:

```
DW_TAG_array_type      = 1
DW_TAG_class_type      = 2
DW_TAG_enumeration_type = 4
DW_TAG_structure_type  = 19
DW_TAG_union_type      = 23
```

For DW_TAG_array_type, the `elements:` should be *subrange descriptors*, each representing the range of subscripts at that level of indexing. The `DIFlagVector` flag to `flags:` indicates that an array type is a native packed vector.

For DW_TAG_enumeration_type, the `elements:` should be *enumerator descriptors*, each representing the definition of an enumeration value for the set. All enumeration type descriptors are collected in the `enums:` field of the *compile unit*.

For DW_TAG_structure_type, DW_TAG_class_type, and DW_TAG_union_type, the `elements:` should be *derived types* with `tag: DW_TAG_member`, `tag: DW_TAG_inheritance`, or `tag: DW_TAG_friend`; or *subprograms* with `isDefinition:` false.

DISubrange

DISubrange nodes are the elements for DW_TAG_array_type variants of *DICompositeType*.

- count: -1 indicates an empty array.
- count: !9 describes the count with a *DILocalVariable*.
- count: !11 describes the count with a *DIGlobalVariable*.

```
!0 = !DISubrange(count: 5, lowerBound: 0) ; array counting from 0
!1 = !DISubrange(count: 5, lowerBound: 1) ; array counting from 1
!2 = !DISubrange(count: -1) ; empty array.

; Scopes used in rest of example
!6 = !DIFile(filename: "vla.c", directory: "/path/to/file")
!7 = distinct !DICompileUnit(language: DW_LANG_C99, file: !6)
!8 = distinct !DISubprogram(name: "foo", scope: !7, file: !6, line: 5)

; Use of local variable as count value
!9 = !DIBasicType(name: "int", size: 32, encoding: DW_ATE_signed)
!10 = !DILocalVariable(name: "count", scope: !8, file: !6, line: 42, type: !9)
!11 = !DISubrange(count: !10, lowerBound: 0)

; Use of global variable as count value
!12 = !DIGlobalVariable(name: "count", scope: !8, file: !6, line: 22, type: !9)
!13 = !DISubrange(count: !12, lowerBound: 0)
```

DIEnumerator

DIEnumerator nodes are the elements for DW_TAG_enumeration_type variants of *DICompositeType*.

```
!0 = !DIEnumerator(name: "SixKind", value: 7)
!1 = !DIEnumerator(name: "SevenKind", value: 7)
!2 = !DIEnumerator(name: "NegEightKind", value: -8)
```

DITemplateTypeParameter

DITemplateTypeParameter nodes represent type parameters to generic source language constructs. They are used (optionally) in *DICompositeType* and *DISubprogram* templateParams: fields.

```
!0 = !DITemplateTypeParameter(name: "Ty", type: !1)
```

DITemplateValueParameter

DITemplateValueParameter nodes represent value parameters to generic source language constructs. tag: defaults to DW_TAG_template_value_parameter, but if specified can also be set to DW_TAG_GNU_template_template_param or DW_TAG_GNU_template_param_pack. They are used (optionally) in *DICompositeType* and *DISubprogram* templateParams: fields.

```
!0 = !DITemplateValueParameter(name: "Ty", type: !1, value: i32 7)
```

DINamespace

DINamespace nodes represent namespaces in the source language.

```
!0 = !DINamespace(name: "myawesomeproject", scope: !1, file: !2, line: 7)
```

DIGlobalVariable

DIGlobalVariable nodes represent global variables in the source language.

```
@foo = global i32, !dbg !0
!0 = !DIGlobalVariableExpression(var: !1, expr: !DIExpression())
!1 = !DIGlobalVariable(name: "foo", linkageName: "foo", scope: !2,
                        file: !3, line: 7, type: !4, isLocal: true,
                        isDefinition: false, declaration: !5)
```

DIGlobalVariableExpression

DIGlobalVariableExpression nodes tie a *DIGlobalVariable* together with a *DIExpression*.

```
@lower = global i32, !dbg !0
@upper = global i32, !dbg !1
!0 = !DIGlobalVariableExpression(
    var: !2,
    expr: !DIExpression(DW_OP_LLVM_fragment, 0, 32)
)
!1 = !DIGlobalVariableExpression(
    var: !2,
    expr: !DIExpression(DW_OP_LLVM_fragment, 32, 32)
)
!2 = !DIGlobalVariable(name: "split64", linkageName: "split64", scope: !3,
                        file: !4, line: 8, type: !5, declaration: !6)
```

All global variable expressions should be referenced by the *globals:* field of a *compile unit*.

DISubprogram

DISubprogram nodes represent functions from the source language. A distinct DISubprogram may be attached to a function definition using !dbg metadata. A unique DISubprogram may be attached to a function declaration used for call site debug info. The *variables:* field points at *variables* that must be retained, even if their IR counterparts are optimized out of the IR. The *type:* field must point at an *DISubroutineType*.

When *isDefinition:* `false`, subprograms describe a declaration in the type tree as opposed to a definition of a function. If the scope is a composite type with an ODR identifier: and that does not set flags: `DIFwdDecl`, then the subprogram declaration is uniqued based only on its *linkageName:* and *scope:*.

```
define void @_Z3foov() !dbg !0 {
    ...
}

!0 = distinct !DISubprogram(name: "foo", linkageName: "_Zfoov", scope: !1,
                             file: !2, line: 7, type: !3, isLocal: true,
```

(continues on next page)

(continued from previous page)

```
isDefinition: true, scopeLine: 8,
containingType: !4,
virtuality: DW_VIRTUALITY_pure_virtual,
virtualIndex: 10, flags: DIFlagPrototyped,
isOptimized: true, unit: !5, templateParams: !6,
declaration: !7, variables: !8, thrownTypes: !9)
```

DILexicalBlock

DILexicalBlock nodes describe nested blocks within a *subprogram*. The line number and column numbers are used to distinguish two lexical blocks at same depth. They are valid targets for `scope:` fields.

```
!0 = distinct !DILexicalBlock(scope: !1, file: !2, line: 7, column: 35)
```

Usually lexical blocks are distinct to prevent node merging based on operands.

DILexicalBlockFile

DILexicalBlockFile nodes are used to discriminate between sections of a *lexical block*. The `file:` field can be changed to indicate textual inclusion, or the `discriminator:` field can be used to discriminate between control flow within a single block in the source language.

```
!0 = !DILexicalBlock(scope: !3, file: !4, line: 7, column: 35)
!1 = !DILexicalBlockFile(scope: !0, file: !4, discriminator: 0)
!2 = !DILexicalBlockFile(scope: !0, file: !4, discriminator: 1)
```

DILocation

DILocation nodes represent source debug locations. The `scope:` field is mandatory, and points at an *DILexicalBlockFile*, an *DILexicalBlock*, or an *DISubprogram*.

```
!0 = !DILocation(line: 2900, column: 42, scope: !1, inlinedAt: !2)
```

DILocalVariable

DILocalVariable nodes represent local variables in the source language. If the `arg:` field is set to non-zero, then this variable is a subprogram parameter, and it will be included in the `variables:` field of its *DISubprogram*.

```
!0 = !DILocalVariable(name: "this", arg: 1, scope: !3, file: !2, line: 7,
                      type: !3, flags: DIFlagArtificial)
!1 = !DILocalVariable(name: "x", arg: 2, scope: !4, file: !2, line: 7,
                      type: !3)
!2 = !DILocalVariable(name: "y", scope: !5, file: !2, line: 7, type: !3)
```

DIExpression

DIExpression nodes represent expressions that are inspired by the DWARF expression language. They are used in *debug intrinsics* (such as `llvm.dbg.declare` and `llvm.dbg.value`) to describe how the referenced LLVM variable relates to the source language variable. Debug intrinsics are interpreted left-to-right: start by pushing the value/address operand of the intrinsic onto a stack, then repeatedly push and evaluate opcodes from the DIExpression until the final variable description is produced.

The current supported opcode vocabulary is limited:

- `DW_OP_deref` dereferences the top of the expression stack.
- `DW_OP_plus` pops the last two entries from the expression stack, adds them together and appends the result to the expression stack.
- `DW_OP_minus` pops the last two entries from the expression stack, subtracts the last entry from the second last entry and appends the result to the expression stack.
- `DW_OP_plus_uconst, 93` adds 93 to the working expression.
- `DW_OP_LLVM_fragment, 16, 8` specifies the offset and size (16 and 8 here, respectively) of the variable fragment from the working expression. Note that contrary to `DW_OP_bit_piece`, the offset is describing the location within the described source variable.
- `DW_OP_LLVM_convert, 16, DW_ATE_signed` specifies a bit size and encoding (16 and `DW_ATE_signed` here, respectively) to which the top of the expression stack is to be converted. Maps into a `DW_OP_convert` operation that references a base type constructed from the supplied values.
- `DW_OP_LLVM_tag_offset, tag_offset` specifies that a memory tag should be optionally applied to the pointer. The memory tag is derived from the given tag offset in an implementation-defined manner.
- `DW_OP_swap` swaps top two stack entries.
- `DW_OP_xderef` provides extended dereference mechanism. The entry at the top of the stack is treated as an address. The second stack entry is treated as an address space identifier.
- `DW_OP_stack_value` marks a constant value.
- If an expression is marked with `DW_OP_entry_value` all register and memory read operations refer to the respective value at the function entry. The first operand of `DW_OP_entry_value` is the size of following DWARF expression. `DW_OP_entry_value` may appear after the `LiveDebugValues` pass. LLVM only supports entry values for function parameters that are unmodified throughout a function and that are described as simple register location descriptions. `DW_OP_entry_value` may also appear after the `AsmPrinter` pass when a call site parameter value (`DW_AT_call_site_parameter_value`) is represented as entry value of the parameter.

DWARF specifies three kinds of simple location descriptions: Register, memory, and implicit location descriptions. Note that a location description is defined over certain ranges of a program, i.e the location of a variable may change over the course of the program. Register and memory location descriptions describe the *concrete location* of a source variable (in the sense that a debugger might modify its value), whereas *implicit locations* describe merely the actual *value* of a source variable which might not exist in registers or in memory (see `DW_OP_stack_value`).

A `llvm.dbg.addr` or `llvm.dbg.declare` intrinsic describes an indirect value (the address) of a source variable. The first operand of the intrinsic must be an address of some kind. A DIExpression attached to the intrinsic refines this address to produce a concrete location for the source variable.

A `llvm.dbg.value` intrinsic describes the direct value of a source variable. The first operand of the intrinsic may be a direct or indirect value. A DIExpression attached to the intrinsic refines the first operand to produce a direct value. For example, if the first operand is an indirect value, it may be necessary to insert `DW_OP_deref` into the DIExpression in order to produce a valid debug intrinsic.

Note: A `DIExpression` is interpreted in the same way regardless of which kind of debug intrinsic it's attached to.

```
!0 = !DIExpression(DW_OP_deref)
!1 = !DIExpression(DW_OP_plus_uconst, 3)
!1 = !DIExpression(DW_OP_constu, 3, DW_OP_plus)
!2 = !DIExpression(DW_OP_bit_piece, 3, 7)
!3 = !DIExpression(DW_OP_deref, DW_OP_constu, 3, DW_OP_plus, DW_OP_LLVM_fragment, 3, 7)
!4 = !DIExpression(DW_OP_constu, 2, DW_OP_swap, DW_OP_xderef)
!5 = !DIExpression(DW_OP_constu, 42, DW_OP_stack_value)
```

DIFlags

These flags encode various properties of `DINodes`.

The *ArgumentNotModified* flag marks a function argument whose value is not modified throughout of a function. This flag is used to decide whether a `DW_OP_entry_value` can be used in a location description after the function prologue. The language frontend is expected to compute this property for each `DILocalVariable`. The flag should be used only in optimized code.

DIObjCProperty

`DIObjCProperty` nodes represent Objective-C property nodes.

```
!3 = !DIObjCProperty(name: "foo", file: !1, line: 7, setter: "setFoo",
                     getter: "getFoo", attributes: 7, type: !2)
```

DIIImportedEntity

`DIIImportedEntity` nodes represent entities (such as modules) imported into a compile unit.

```
!2 = !DIIImportedEntity(tag: DW_TAG_imported_module, name: "foo", scope: !0,
                       entity: !1, line: 7)
```

DIMacro

`DIMacro` nodes represent definition or undefinition of a macro identifiers. The `name:` field is the macro identifier, followed by macro parameters when defining a function-like macro, and the `value` field is the token-string used to expand the macro identifier.

```
!2 = !DIMacro(macinfo: DW_MACINFO_define, line: 7, name: "foo(x)",
              value: "((x) + 1)")
!3 = !DIMacro(macinfo: DW_MACINFO_undef, line: 30, name: "foo")
```

DIMacroFile

DIMacroFile nodes represent inclusion of source files. The `nodes:` field is a list of DIMacro and DIMacroFile nodes that appear in the included source file.

```
!2 = !DIMacroFile(macinfo: DW_MACINFO_start_file, line: 7, file: !2,
                  nodes: !3)
```

'tbaa' Metadata

In LLVM IR, memory does not have types, so LLVM's own type system is not suitable for doing type based alias analysis (TBAA). Instead, metadata is added to the IR to describe a type system of a higher level language. This can be used to implement C/C++ strict type aliasing rules, but it can also be used to implement custom alias analysis behavior for other languages.

This description of LLVM's TBAA system is broken into two parts: *Semantics* talks about high level issues, and *Representation* talks about the metadata encoding of various entities.

It is always possible to trace any TBAA node to a "root" TBAA node (details in the *Representation* section). TBAA nodes with different roots have an unknown aliasing relationship, and LLVM conservatively infers MayAlias between them. The rules mentioned in this section only pertain to TBAA nodes living under the same root.

Semantics

The TBAA metadata system, referred to as "struct path TBAA" (not to be confused with `tbaa.struct`), consists of the following high level concepts: *Type Descriptors*, further subdivided into scalar type descriptors and struct type descriptors; and *Access Tags*.

Type descriptors describe the type system of the higher level language being compiled. **Scalar type descriptors** describe types that do not contain other types. Each scalar type has a parent type, which must also be a scalar type or the TBAA root. Via this parent relation, scalar types within a TBAA root form a tree. **Struct type descriptors** denote types that contain a sequence of other type descriptors, at known offsets. These contained type descriptors can either be struct type descriptors themselves or scalar type descriptors.

Access tags are metadata nodes attached to load and store instructions. Access tags use type descriptors to describe the *location* being accessed in terms of the type system of the higher level language. Access tags are tuples consisting of a base type, an access type and an offset. The base type is a scalar type descriptor or a struct type descriptor, the access type is a scalar type descriptor, and the offset is a constant integer.

The access tag (`BaseTy`, `AccessTy`, `Offset`) can describe one of two things:

- If `BaseTy` is a struct type, the tag describes a memory access (load or store) of a value of type `AccessTy` contained in the struct type `BaseTy` at offset `Offset`.
- If `BaseTy` is a scalar type, `Offset` must be 0 and `BaseTy` and `AccessTy` must be the same; and the access tag describes a scalar access with scalar type `AccessTy`.

We first define an `ImmediateParent` relation on (`BaseTy`, `Offset`) tuples this way:

- If `BaseTy` is a scalar type then `ImmediateParent(BaseTy, 0)` is (`ParentTy`, 0) where `ParentTy` is the parent of the scalar type as described in the TBAA metadata. `ImmediateParent(BaseTy, Offset)` is undefined if `Offset` is non-zero.
- If `BaseTy` is a struct type then `ImmediateParent(BaseTy, Offset)` is (`NewTy`, `NewOffset`) where `NewTy` is the type contained in `BaseTy` at offset `Offset` and `NewOffset` is `Offset` adjusted to be relative within that inner type.

A memory access with an access tag (BaseTy1 , AccessTy1 , Offset1) aliases a memory access with an access tag (BaseTy2 , AccessTy2 , Offset2) if either (BaseTy1 , Offset1) is reachable from (BaseTy2 , Offset2) via the Parent relation or vice versa.

As a concrete example, the type descriptor graph for the following program

```
struct Inner {
    int i;    // offset 0
    float f;  // offset 4
};

struct Outer {
    float f;  // offset 0
    double d; // offset 4
    struct Inner inner_a; // offset 12
};

void f(struct Outer* outer, struct Inner* inner, float* f, int* i, char* c) {
    outer->f = 0;           // tag0: (OuterStructTy, FloatScalarTy, 0)
    outer->inner_a.i = 0;    // tag1: (OuterStructTy, IntScalarTy, 12)
    outer->inner_a.f = 0.0;  // tag2: (OuterStructTy, FloatScalarTy, 16)
    *f = 0.0;               // tag3: (FloatScalarTy, FloatScalarTy, 0)
}
```

is (note that in C and C++, char can be used to access any arbitrary type):

```
Root = "TBAA Root"
CharScalarTy = ("char", Root, 0)
FloatScalarTy = ("float", CharScalarTy, 0)
DoubleScalarTy = ("double", CharScalarTy, 0)
IntScalarTy = ("int", CharScalarTy, 0)
InnerStructTy = {"Inner" (IntScalarTy, 0), (FloatScalarTy, 4)}
OuterStructTy = {"Outer", (FloatScalarTy, 0), (DoubleScalarTy, 4),
                 (InnerStructTy, 12)}
```

with (e.g.) $\text{ImmediateParent}(\text{OuterStructTy}, 12) = (\text{InnerStructTy}, 0)$, $\text{ImmediateParent}(\text{InnerStructTy}, 0) = (\text{IntScalarTy}, 0)$, and $\text{ImmediateParent}(\text{IntScalarTy}, 0) = (\text{CharScalarTy}, 0)$.

Representation

The root node of a TBAA type hierarchy is an MDNode with 0 operands or with exactly one MDString operand.

Scalar type descriptors are represented as an MDNode s with two operands. The first operand is an MDString denoting the name of the struct type. LLVM does not assign meaning to the value of this operand, it only cares about it being an MDString. The second operand is an MDNode which points to the parent for said scalar type descriptor, which is either another scalar type descriptor or the TBAA root. Scalar type descriptors can have an optional third argument, but that must be the constant integer zero.

Struct type descriptors are represented as MDNode s with an odd number of operands greater than 1. The first operand is an MDString denoting the name of the struct type. Like in scalar type descriptors the actual value of this name operand is irrelevant to LLVM. After the name operand, the struct type descriptors have a sequence of alternating MDNode and ConstantInt operands. With N starting from 1, the $2N - 1$ th operand, an MDNode, denotes a contained field, and the $2N$ th operand, a ConstantInt, is the offset of the said contained field. The offsets must be in non-decreasing order.

Access tags are represented as MDNode s with either 3 or 4 operands. The first operand is an MDNode pointing to the node representing the base type. The second operand is an MDNode pointing to the node representing the access

type. The third operand is a `ConstantInt` that states the offset of the access. If a fourth field is present, it must be a `ConstantInt` valued at 0 or 1. If it is 1 then the access tag states that the location being accessed is "constant" (meaning `pointsToConstantMemory` should return true; see [other useful AliasAnalysis methods](#)). The TBAA root of the access type and the base type of an access tag must be the same, and that is the TBAA root of the access tag.

'`tbaa.struct`' Metadata

The `llvm.memcpy` is often used to implement aggregate assignment operations in C and similar languages, however it is defined to copy a contiguous region of memory, which is more than strictly necessary for aggregate types which contain holes due to padding. Also, it doesn't contain any TBAA information about the fields of the aggregate.

`!tbaa.struct` metadata can describe which memory subregions in a `memcpy` are padding and what the TBAA tags of the struct are.

The current metadata format is very simple. `!tbaa.struct` metadata nodes are a list of operands which are in conceptual groups of three. For each group of three, the first operand gives the byte offset of a field in bytes, the second gives its size in bytes, and the third gives its tbaa tag. e.g.:

```
!4 = !{ i64 0, i64 4, !1, i64 8, i64 4, !2 }
```

This describes a struct with two fields. The first is at offset 0 bytes with size 4 bytes, and has tbaa tag !1. The second is at offset 8 bytes and has size 4 bytes and has tbaa tag !2.

Note that the fields need not be contiguous. In this example, there is a 4 byte gap between the two fields. This gap represents padding which does not carry useful data and need not be preserved.

'`noalias`' and '`alias.scope`' Metadata

`noalias` and `alias.scope` metadata provide the ability to specify generic `noalias` memory-access sets. This means that some collection of memory access instructions (loads, stores, memory-accessing calls, etc.) that carry `noalias` metadata can specifically be specified not to alias with some other collection of memory access instructions that carry `alias.scope` metadata. Each type of metadata specifies a list of scopes where each scope has an id and a domain.

When evaluating an aliasing query, if for some domain, the set of scopes with that domain in one instruction's `alias.scope` list is a subset of (or equal to) the set of scopes for that domain in another instruction's `noalias` list, then the two memory accesses are assumed not to alias.

Because scopes in one domain don't affect scopes in other domains, separate domains can be used to compose multiple independent `noalias` sets. This is used for example during inlining. As the `noalias` function parameters are turned into `noalias scope` metadata, a new domain is used every time the function is inlined.

The metadata identifying each domain is itself a list containing one or two entries. The first entry is the name of the domain. Note that if the name is a string then it can be combined across functions and translation units. A self-reference can be used to create globally unique domain names. A descriptive string may optionally be provided as a second list entry.

The metadata identifying each scope is also itself a list containing two or three entries. The first entry is the name of the scope. Note that if the name is a string then it can be combined across functions and translation units. A self-reference can be used to create globally unique scope names. A metadata reference to the scope's domain is the second entry. A descriptive string may optionally be provided as a third list entry.

For example,

```

; Two scope domains:
!0 = !{!0}
!1 = !{!1}

; Some scopes in these domains:
!2 = !{!2, !0}
!3 = !{!3, !0}
!4 = !{!4, !1}

; Some scope lists:
!5 = !{!4} ; A list containing only scope !4
!6 = !{!4, !3, !2}
!7 = !{!3}

; These two instructions don't alias:
%0 = load float, float* %c, align 4, !alias.scope !5
store float %0, float* %arrayidx.i, align 4, !noalias !5

; These two instructions also don't alias (for domain !1, the set of scopes
; in the !alias.scope equals that in the !noalias list):
%2 = load float, float* %c, align 4, !alias.scope !5
store float %2, float* %arrayidx.i2, align 4, !noalias !6

; These two instructions may alias (for domain !0, the set of scopes in
; the !noalias list is not a superset of, or equal to, the scopes in the
; !alias.scope list):
%2 = load float, float* %c, align 4, !alias.scope !6
store float %0, float* %arrayidx.i, align 4, !noalias !7

```

'fpmath' Metadata

fpmath metadata may be attached to any instruction of floating-point type. It can be used to express the maximum acceptable error in the result of that instruction, in ULPs, thus potentially allowing the compiler to use a more efficient but less accurate method of computing it. ULP is defined as follows:

If x is a real number that lies between two finite consecutive floating-point numbers a and b , without being equal to one of them, then $\text{ulp}(x) = |b - a|$, otherwise $\text{ulp}(x)$ is the distance between the two non-equal finite floating-point numbers nearest x . Moreover, $\text{ulp}(\text{NaN})$ is NaN.

The metadata node shall consist of a single positive float type number representing the maximum relative error, for example:

```
!0 = !{ float 2.5 } ; maximum acceptable inaccuracy is 2.5 ULPs
```

'range' Metadata

range metadata may be attached only to load, call and invoke of integer types. It expresses the possible ranges the loaded value or the value returned by the called function at this call site is in. If the loaded or returned value is not in the specified range, the behavior is undefined. The ranges are represented with a flattened list of integers. The loaded value or the value returned is known to be in the union of the ranges defined by each consecutive pair. Each pair has the following properties:

- The type must match the type loaded by the instruction.
- The pair a, b represents the range $[a, b)$.

- Both `a` and `b` are constants.
- The range is allowed to wrap.
- The range should not represent the full or empty set. That is, `a != b`.

In addition, the pairs must be in signed order of the lower bound and they must be non-contiguous.

Examples:

```
%a = load i8, i8* %x, align 1, !range !0 ; Can only be 0 or 1
%b = load i8, i8* %y, align 1, !range !1 ; Can only be 255 (-1), 0 or 1
%c = call i8 @foo(), !range !2 ; Can only be 0, 1, 3, 4 or 5
%d = invoke i8 @bar() to label %cont
      unwind label %lpad, !range !3 ; Can only be -2, -1, 3, 4 or 5
...
!0 = !{ i8 0, i8 2 }
!1 = !{ i8 255, i8 2 }
!2 = !{ i8 0, i8 2, i8 3, i8 6 }
!3 = !{ i8 -2, i8 0, i8 3, i8 6 }
```

'absolute_symbol' Metadata

`absolute_symbol` metadata may be attached to a global variable declaration. It marks the declaration as a reference to an absolute symbol, which causes the backend to use absolute relocations for the symbol even in position independent code, and expresses the possible ranges that the global variable's *address* (not its value) is in, in the same format as `range` metadata, with the extension that the pair all-ones, all-ones may be used to represent the full set.

Example (assuming 64-bit pointers):

```
@a = external global i8, !absolute_symbol !0 ; Absolute symbol in range [0,256)
@b = external global i8, !absolute_symbol !1 ; Absolute symbol in range [0,2^64)
...
!0 = !{ i64 0, i64 256 }
!1 = !{ i64 -1, i64 -1 }
```

'callees' Metadata

`callees` metadata may be attached to indirect call sites. If `callees` metadata is attached to a call site, and any callee is not among the set of functions provided by the metadata, the behavior is undefined. The intent of this metadata is to facilitate optimizations such as indirect-call promotion. For example, in the code below, the call instruction may only target the `add` or `sub` functions:

```
%result = call i64 @binop(i64 %x, i64 %y), !callees !0
...
!0 = !{i64 (i64, i64)* @add, i64 (i64, i64)* @sub}
```

'callback' Metadata

`callback` metadata may be attached to a function declaration, or definition. (Call sites are excluded only due to the lack of a use case.) For ease of exposition, we'll refer to the function annotated w/ metadata as a broker function. The metadata describes how the arguments of a call to the broker are in turn passed to the callback function specified by the metadata. Thus, the `callback` metadata provides a partial description of a call site inside the broker function with regards to the arguments of a call to the broker. The only semantic restriction on the broker function itself is that it is not allowed to inspect or modify arguments referenced in the `callback` metadata as pass-through to the callback function.

The broker is not required to actually invoke the callback function at runtime. However, the assumptions about not inspecting or modifying arguments that would be passed to the specified callback function still hold, even if the callback function is not dynamically invoked. The broker is allowed to invoke the callback function more than once per invocation of the broker. The broker is also allowed to invoke (directly or indirectly) the function passed as a callback through another use. Finally, the broker is also allowed to relay the callback callee invocation to a different thread.

The metadata is structured as follows: At the outer level, `callback` metadata is a list of `callback` encodings. Each encoding starts with a constant `i64` which describes the argument position of the callback function in the call to the broker. The following elements, except the last, describe what arguments are passed to the callback function. Each element is again an `i64` constant identifying the argument of the broker that is passed through, or `i64 -1` to indicate an unknown or inspected argument. The order in which they are listed has to be the same in which they are passed to the callback callee. The last element of the encoding is a boolean which specifies how variadic arguments of the broker are handled. If it is true, all variadic arguments of the broker are passed through to the callback function *after* the arguments encoded explicitly before.

In the code below, the `pthread_create` function is marked as a broker through the `!callback !1` metadata. In the example, there is only one callback encoding, namely `!2`, associated with the broker. This encoding identifies the callback function as the second argument of the broker (`i64 2`) and the sole argument of the callback function as the third one of the broker function (`i64 3`).

```
declare !callback !1 dso_local i32 @pthread_create(i64*, %union.pthread_attr_t*, i8*  
  ↪ (i8*)*, i8*)  
  
...  
!2 = !{i64 2, i64 3, i1 false}  
!1 = !{!2}
```

Another example is shown below. The callback callee is the second argument of the `__kmpc_fork_call` function (`i64 2`). The callee is given two unknown values (each identified by a `i64 -1`) and afterwards all variadic arguments that are passed to the `__kmpc_fork_call` call (due to the final `i1 true`).

```
declare !callback !0 dso_local void @__kmpc_fork_call(%struct.ident_t*, i32, void_  
  ↪ (i32*, i32*, ...)*, ...)  
  
...  
!1 = !{i64 2, i64 -1, i64 -1, i1 true}  
!0 = !{!1}
```

'unpredictable' Metadata

`unpredictable` metadata may be attached to any branch or switch instruction. It can be used to express the unpredictability of control flow. Similar to the `llvm.expect` intrinsic, it may be used to alter optimizations related to compare and branch instructions. The metadata is treated as a boolean value; if it exists, it signals that the branch or switch that it is attached to is completely unpredictable.

'llvm.loop'

It is sometimes useful to attach information to loop constructs. Currently, loop metadata is implemented as metadata attached to the branch instruction in the loop latch block. This type of metadata refers to a metadata node that is guaranteed to be separate for each loop. The loop identifier metadata is specified with the name `llvm.loop`.

The loop identifier metadata is implemented using a metadata that refers to itself to avoid merging it with any other identifier metadata, e.g., during module linkage or function inlining. That is, each loop should refer to their own identification metadata even if they reside in separate functions. The following example contains loop identifier metadata for two separate loop constructs:

```
!0 = !{!0}
!1 = !{!1}
```

The loop identifier metadata can be used to specify additional per-loop metadata. Any operands after the first operand can be treated as user-defined metadata. For example the `llvm.loop.unroll.count` suggests an unroll factor to the loop unroller:

```
br i1 %exitcond, label %._crit_edge, label %lr.ph, !llvm.loop !0
...
!0 = !{!0, !1}
!1 = !{"llvm.loop.unroll.count", i32 4}
```

'llvm.loop.disable_nonforced'

This metadata disables all optional loop transformations unless explicitly instructed using other transformation metadata such as `llvm.loop.unroll.enable`. That is, no heuristic will try to determine whether a transformation is profitable. The purpose is to avoid that the loop is transformed to a different loop before an explicitly requested (forced) transformation is applied. For instance, loop fusion can make other transformations impossible. Mandatory loop canonicalizations such as loop rotation are still applied.

It is recommended to use this metadata in addition to any `llvm.loop.*` transformation directive. Also, any loop should have at most one directive applied to it (and a sequence of transformations built using `followup-attributes`). Otherwise, which transformation will be applied depends on implementation details such as the pass pipeline order.

See [Code Transformation Metadata](#) for details.

'llvm.loop.vectorize' and 'llvm.loop.interleave'

Metadata prefixed with `llvm.loop.vectorize` or `llvm.loop.interleave` are used to control per-loop vectorization and interleaving parameters such as vectorization width and interleave count. These metadata should be used in conjunction with `llvm.loop` loop identification metadata. The `llvm.loop.vectorize` and `llvm.loop.interleave` metadata are only optimization hints and the optimizer will only interleave and vectorize loops if it believes it is safe to do so. The `llvm.loop.parallel_accesses` metadata which contains information about loop-carried memory dependencies can be helpful in determining the safety of these transformations.

'llvm.loop.interleave.count' Metadata

This metadata suggests an interleave count to the loop interleaver. The first operand is the string `llvm.loop.interleave.count` and the second operand is an integer specifying the interleave count. For example:

```
!0 = !{"llvm.loop.interleave.count", i32 4}
```

Note that setting `llvm.loop.interleave.count` to 1 disables interleaving multiple iterations of the loop. If `llvm.loop.interleave.count` is set to 0 then the interleave count will be determined automatically.

'llvm.loop.vectorize.enable' Metadata

This metadata selectively enables or disables vectorization for the loop. The first operand is the string `llvm.loop.vectorize.enable` and the second operand is a bit. If the bit operand value is 1 vectorization is enabled. A value of 0 disables vectorization:

```
!0 = !{"llvm.loop.vectorize.enable", i1 0}
!1 = !{"llvm.loop.vectorize.enable", i1 1}
```

'llvm.loop.vectorize.width' Metadata

This metadata sets the target width of the vectorizer. The first operand is the string `llvm.loop.vectorize.width` and the second operand is an integer specifying the width. For example:

```
!0 = !{"llvm.loop.vectorize.width", i32 4}
```

Note that setting `llvm.loop.vectorize.width` to 1 disables vectorization of the loop. If `llvm.loop.vectorize.width` is set to 0 or if the loop does not have this metadata the width will be determined automatically.

'llvm.loop.vectorize.followup_vectorized' Metadata

This metadata defines which loop attributes the vectorized loop will have. See *Code Transformation Metadata* for details.

'llvm.loop.vectorize.followup_epilogue' Metadata

This metadata defines which loop attributes the epilogue will have. The epilogue is not vectorized and is executed when either the vectorized loop is not known to preserve semantics (because e.g., it processes two arrays that are found to alias by a runtime check) or for the last iterations that do not fill a complete set of vector lanes. See [Transformation Metadata](#) for details.

'llvm.loop.vectorize.followup_all' Metadata

Attributes in the metadata will be added to both the vectorized and epilogue loop. See [Transformation Metadata](#) for details.

'llvm.loop.unroll'

Metadata prefixed with `llvm.loop.unroll` are loop unrolling optimization hints such as the unroll factor. `llvm.loop.unroll` metadata should be used in conjunction with `llvm.loop` loop identification metadata. The `llvm.loop.unroll` metadata are only optimization hints and the unrolling will only be performed if the optimizer believes it is safe to do so.

'llvm.loop.unroll.count' Metadata

This metadata suggests an unroll factor to the loop unroller. The first operand is the string `llvm.loop.unroll.count` and the second operand is a positive integer specifying the unroll factor. For example:

```
!0 = !{"llvm.loop.unroll.count", i32 4}
```

If the trip count of the loop is less than the unroll count the loop will be partially unrolled.

'llvm.loop.unroll.disable' Metadata

This metadata disables loop unrolling. The metadata has a single operand which is the string `llvm.loop.unroll.disable`. For example:

```
!0 = !{"llvm.loop.unroll.disable"}
```

'llvm.loop.unroll.runtime.disable' Metadata

This metadata disables runtime loop unrolling. The metadata has a single operand which is the string `llvm.loop.unroll.runtime.disable`. For example:

```
!0 = !{"llvm.loop.unroll.runtime.disable"}
```

'llvm.loop.unroll.enable' Metadata

This metadata suggests that the loop should be fully unrolled if the trip count is known at compile time and partially unrolled if the trip count is not known at compile time. The metadata has a single operand which is the string `llvm.loop.unroll.enable`. For example:

```
!0 = !{"llvm.loop.unroll.enable"}
```

'llvm.loop.unroll.full' Metadata

This metadata suggests that the loop should be unrolled fully. The metadata has a single operand which is the string `llvm.loop.unroll.full`. For example:

```
!0 = !{"llvm.loop.unroll.full"}
```

'llvm.loop.unroll.followup' Metadata

This metadata defines which loop attributes the unrolled loop will have. See *Transformation Metadata* for details.

'llvm.loop.unroll.followup_remainder' Metadata

This metadata defines which loop attributes the remainder loop after partial/runtime unrolling will have. See *Transformation Metadata* for details.

'llvm.loop.unroll_and_jam'

This metadata is treated very similarly to the `llvm.loop.unroll` metadata above, but affect the unroll and jam pass. In addition any loop with `llvm.loop.unroll` metadata but no `llvm.loop.unroll_and_jam` metadata will disable unroll and jam (so `llvm.loop.unroll` metadata will be left to the unroller, plus `llvm.loop.unroll.disable` metadata will disable unroll and jam too.)

The metadata for unroll and jam otherwise is the same as for `unroll.llvm.loop.unroll_and_jam.enable`, `llvm.loop.unroll_and_jam.disable` and `llvm.loop.unroll_and_jam.count` do the same as for unroll. `llvm.loop.unroll_and_jam.full` is not supported. Again these are only hints and the normal safety checks will still be performed.

'llvm.loop.unroll_and_jam.count' Metadata

This metadata suggests an unroll and jam factor to use, similarly to `llvm.loop.unroll.count`. The first operand is the string `llvm.loop.unroll_and_jam.count` and the second operand is a positive integer specifying the unroll factor. For example:

```
!0 = !{"llvm.loop.unroll_and_jam.count", i32 4}
```

If the trip count of the loop is less than the unroll count the loop will be partially unroll and jammed.

'llvm.loop.unroll_and_jam.disable' Metadata

This metadata disables loop unroll and jamming. The metadata has a single operand which is the string `llvm.loop.unroll_and_jam.disable`. For example:

```
!0 = !{"llvm.loop.unroll_and_jam.disable"}
```

'llvm.loop.unroll_and_jam.enable' Metadata

This metadata suggests that the loop should be fully unroll and jammed if the trip count is known at compile time and partially unrolled if the trip count is not known at compile time. The metadata has a single operand which is the string `llvm.loop.unroll_and_jam.enable`. For example:

```
!0 = !{"llvm.loop.unroll_and_jam.enable"}
```

'llvm.loop.unroll_and_jam.followup_outer' Metadata

This metadata defines which loop attributes the outer unrolled loop will have. See *Transformation Metadata* for details.

'llvm.loop.unroll_and_jam.followup_inner' Metadata

This metadata defines which loop attributes the inner jammed loop will have. See *Transformation Metadata* for details.

'llvm.loop.unroll_and_jam.followup_remainder_outer' Metadata

This metadata defines which attributes the epilogue of the outer loop will have. This loop is usually unrolled, meaning there is no such loop. This attribute will be ignored in this case. See *Transformation Metadata* for details.

'llvm.loop.unroll_and_jam.followup_remainder_inner' Metadata

This metadata defines which attributes the inner loop of the epilogue will have. The outer epilogue will usually be unrolled, meaning there can be multiple inner remainder loops. See *Transformation Metadata* for details.

'llvm.loop.unroll_and_jam.followup_all' Metadata

Attributes specified in the metadata is added to all `llvm.loop.unroll_and_jam.*` loops. See *Transformation Metadata* for details.

'llvm.loop.licm_versioning.disable' Metadata

This metadata indicates that the loop should not be versioned for the purpose of enabling loop-invariant code motion (LICM). The metadata has a single operand which is the string `llvm.loop.licm_versioning.disable`. For example:

```
!0 = !{"llvm.loop.licm_versioning.disable"}
```

'llvm.loop.distribute.enable' Metadata

Loop distribution allows splitting a loop into multiple loops. Currently, this is only performed if the entire loop cannot be vectorized due to unsafe memory dependencies. The transformation will attempt to isolate the unsafe dependencies into their own loop.

This metadata can be used to selectively enable or disable distribution of the loop. The first operand is the string `llvm.loop.distribute.enable` and the second operand is a bit. If the bit operand value is 1 distribution is enabled. A value of 0 disables distribution:

```
!0 = !{"llvm.loop.distribute.enable", i1 0}
!1 = !{"llvm.loop.distribute.enable", i1 1}
```

This metadata should be used in conjunction with `llvm.loop` loop identification metadata.

'llvm.loop.distribute.followup_coincident' Metadata

This metadata defines which attributes extracted loops with no cyclic dependencies will have (i.e. can be vectorized). See *Transformation Metadata* for details.

'llvm.loop.distribute.followup_sequential' Metadata

This metadata defines which attributes the isolated loops with unsafe memory dependencies will have. See *Transformation Metadata* for details.

'llvm.loop.distribute.followup_fallback' Metadata

If loop versioning is necessary, this metadata defined the attributes the non-distributed fallback version will have. See *Transformation Metadata* for details.

'llvm.loop.distribute.followup_all' Metadata

These attributes in this metadata is added to all followup loops of the loop distribution pass. See *Transformation Metadata* for details.

'llvm.access.group' Metadata

llvm.access.group metadata can be attached to any instruction that potentially accesses memory. It can point to a single distinct metadata node, which we call access group. This node represents all memory access instructions referring to it via llvm.access.group. When an instruction belongs to multiple access groups, it can also point to a list of accesses groups, illustrated by the following example.

```
%val = load i32, i32* %arrayidx, !llvm.access.group !0
...
!0 = !{!1, !2}
!1 = distinct !{}
!2 = distinct !{}
```

It is illegal for the list node to be empty since it might be confused with an access group.

The access group metadata node must be 'distinct' to avoid collapsing multiple access groups by content. A access group metadata node must always be empty which can be used to distinguish an access group metadata node from a list of access groups. Being empty avoids the situation that the content must be updated which, because metadata is immutable by design, would required finding and updating all references to the access group node.

The access group can be used to refer to a memory access instruction without pointing to it directly (which is not possible in global metadata). Currently, the only metadata making use of it is llvm.loop.parallel_accesses.

'llvm.loop.parallel_accesses' Metadata

The llvm.loop.parallel_accesses metadata refers to one or more access group metadata nodes (see llvm.access.group). It denotes that no loop-carried memory dependence exist between it and other instructions in the loop with this metadata.

Let m1 and m2 be two instructions that both have the llvm.access.group metadata to the access group g1, respectively g2 (which might be identical). If a loop contains both access groups in its llvm.loop.parallel_accesses metadata, then the compiler can assume that there is no dependency between m1 and m2 carried by this loop. Instructions that belong to multiple access groups are considered having this property if at least one of the access groups matches the llvm.loop.parallel_accesses list.

If all memory-accessing instructions in a loop have llvm.loop.parallel_accesses metadata that refers to that loop, then the loop has no loop carried memory dependences and is considered to be a parallel loop.

Note that if not all memory access instructions belong to an access group referred to by llvm.loop.parallel_accesses, then the loop must not be considered trivially parallel. Additional memory dependence analysis is required to make that determination. As a fail safe mechanism, this causes loops that were originally parallel to be considered sequential (if optimization passes that are unaware of the parallel semantics insert new memory instructions into the loop body).

Example of a loop that is considered parallel due to its correct use of both llvm.access.group and llvm.loop.parallel_accesses metadata types.

```
for.body:
...
%val0 = load i32, i32* %arrayidx, !llvm.access.group !1
...
store i32 %val0, i32* %arrayidx1, !llvm.access.group !1
...
br i1 %exitcond, label %for.end, label %for.body, !llvm.loop !0

for.end:
```

(continues on next page)

(continued from previous page)

```
...
!0 = distinct !{!0, !{"llvm.loop.parallel_accesses", !1}}
!1 = distinct !{}
```

It is also possible to have nested parallel loops:

```
outer.for.body:
    ...
    %val1 = load i32, i32* %arrayidx3, !llvm.access.group !4
    ...
    br label %inner.for.body

inner.for.body:
    ...
    %val0 = load i32, i32* %arrayidx1, !llvm.access.group !3
    ...
    store i32 %val0, i32* %arrayidx2, !llvm.access.group !3
    ...
    br i1 %exitcond, label %inner.for.end, label %inner.for.body, !llvm.loop !1

inner.for.end:
    ...
    store i32 %val1, i32* %arrayidx4, !llvm.access.group !4
    ...
    br i1 %exitcond, label %outer.for.end, label %outer.for.body, !llvm.loop !2

outer.for.end:                                ; preds = %for.body
...
!1 = distinct !{!1, !{"llvm.loop.parallel_accesses", !3}}      ; metadata for the_
↳inner loop
!2 = distinct !{!2, !{"llvm.loop.parallel_accesses", !3, !4}} ; metadata for the_
↳outer loop
!3 = distinct !{} ; access group for instructions in the inner loop (which are_
↳implicitly contained in outer loop as well)
!4 = distinct !{} ; access group for instructions in the outer, but not the inner loop
```

'irr_loop' Metadata

`irr_loop` metadata may be attached to the terminator instruction of a basic block that's an irreducible loop header (note that an irreducible loop has more than once header basic blocks.) If `irr_loop` metadata is attached to the terminator instruction of a basic block that is not really an irreducible loop header, the behavior is undefined. The intent of this metadata is to improve the accuracy of the block frequency propagation. For example, in the code below, the block `header0` may have a loop header weight (relative to the other headers of the irreducible loop) of 100:

```
header0:
    ...
    br i1 %cmp, label %t1, label %t2, !irr_loop !0

    ...
    !0 = !{"loop_header_weight", i64 100}
```

Irreducible loop header weights are typically based on profile data.

'invariant.group' Metadata

The experimental `invariant.group` metadata may be attached to `load/store` instructions referencing a single metadata with no entries. The existence of the `invariant.group` metadata on the instruction tells the optimizer that every `load` and `store` to the same pointer operand can be assumed to load or store the same value (but see the `llvm.laundry.invariant.group` intrinsic which affects when two pointers are considered the same). Pointers returned by `bitcast` or `getelementptr` with only zero indices are considered the same.

Examples:

```
@unknownPtr = external global i8
...
%ptr = alloca i8
store i8 42, i8* %ptr, !invariant.group !0
call void @foo(i8* %ptr)

%a = load i8, i8* %ptr, !invariant.group !0 ; Can assume that value under %ptr didn't
↳ change
call void @foo(i8* %ptr)

%newPtr = call i8* @getPointer(i8* %ptr)
%c = load i8, i8* %newPtr, !invariant.group !0 ; Can't assume anything, because we
↳ only have information about %ptr

%unknownValue = load i8, i8* @unknownPtr
store i8 %unknownValue, i8* %ptr, !invariant.group !0 ; Can assume that %unknownValue
↳ == 42

call void @foo(i8* %ptr)
%newPtr2 = call i8* @llvm.laundry.invariant.group(i8* %ptr)
%d = load i8, i8* %newPtr2, !invariant.group !0 ; Can't step through laundry.
↳ invariant.group to get value of %ptr

...
declare void @foo(i8*)
declare i8* @getPointer(i8*)
declare i8* @llvm.laundry.invariant.group(i8*)

!0 = !{}
```

The `invariant.group` metadata must be dropped when replacing one pointer by another based on aliasing information. This is because `invariant.group` is tied to the SSA value of the pointer operand.

```
%v = load i8, i8* %x, !invariant.group !0
; if %x must alias %y then we can replace the above instruction with
%v = load i8, i8* %y
```

Note that this is an experimental feature, which means that its semantics might change in the future.

'type' Metadata

See *Type Metadata*.

'associated' Metadata

The `associated` metadata may be attached to a global object declaration with a single argument that references another global object.

This metadata prevents discarding of the global object in linker GC unless the referenced object is also discarded. The linker support for this feature is spotty. For best compatibility, globals carrying this metadata may also:

- Be in a comdat with the referenced global.
- Be in `@llvm.compiler.used`.
- Have an explicit section with a name which is a valid C identifier.

It does not have any effect on non-ELF targets.

Example:

```
$a = comdat any
@a = global i32 1, comdat $a
@b = internal global i32 2, comdat $a, section "abc", !associated !0
!0 = !{i32* @a}
```

'prof' Metadata

The `prof` metadata is used to record profile data in the IR. The first operand of the metadata node indicates the profile metadata type. There are currently 3 types: *branch_weights*, *function_entry_count*, and *VP*.

branch_weights

Branch weight metadata attached to a branch, select, switch or call instruction represents the likeliness of the associated branch being taken. For more information, see *LLVM Branch Weight Metadata*.

function_entry_count

Function entry count metadata can be attached to function definitions to record the number of times the function is called. Used with BFI information, it is also used to derive the basic block profile count. For more information, see *LLVM Branch Weight Metadata*.

VP

VP (value profile) metadata can be attached to instructions that have value profile information. Currently this is indirect calls (where it records the hottest callees) and calls to memory intrinsics such as `memcpy`, `memmove`, and `memset` (where it records the hottest byte lengths).

Each VP metadata node contains "VP" string, then a `uint32_t` value for the value profiling kind, a `uint64_t` value for the total number of times the instruction is executed, followed by `uint64_t` value and execution count pairs. The value profiling kind is 0 for indirect call targets and 1 for memory operations. For indirect call targets, each profile value is a hash of the callee function name, and for memory operations each value is the byte length.

Note that the value counts do not need to add up to the total count listed in the third operand (in practice only the top hottest values are tracked and reported).

Indirect call example:

```
call void %f(), !prof !1
!1 = !{"VP", i32 0, i64 1600, i64 7651369219802541373, i64 1030, i64 -
  ↪4377547752858689819, i64 410}
```

Note that the VP type is 0 (the second operand), which indicates this is an indirect call value profile data. The third operand indicates that the indirect call executed 1600 times. The 4th and 6th operands give the hashes of the 2 hottest target functions' names (this is the same hash used to represent function names in the profile database), and the 5th and 7th operands give the execution count that each of the respective prior target functions was called.

1.1.9 Module Flags Metadata

Information about the module as a whole is difficult to convey to LLVM's subsystems. The LLVM IR isn't sufficient to transmit this information. The `llvm.module.flags` named metadata exists in order to facilitate this. These flags are in the form of key / value pairs --- much like a dictionary --- making it easy for any subsystem who cares about a flag to look it up.

The `llvm.module.flags` metadata contains a list of metadata triplets. Each triplet has the following form:

- The first element is a *behavior* flag, which specifies the behavior when two (or more) modules are merged together, and it encounters two (or more) metadata with the same ID. The supported behaviors are described below.
- The second element is a metadata string that is a unique ID for the metadata. Each module may only have one flag entry for each unique ID (not including entries with the **Require** behavior).
- The third element is the value of the flag.

When two (or more) modules are merged together, the resulting `llvm.module.flags` metadata is the union of the modules' flags. That is, for each unique metadata ID string, there will be exactly one entry in the merged modules `llvm.module.flags` metadata table, and the value for that entry will be determined by the merge behavior flag, as described below. The only exception is that entries with the *Require* behavior are always preserved.

The following behaviors are supported:

Value	Behavior
1	Error Emits an error if two values disagree, otherwise the resulting value is that of the operands.
2	Warning Emits a warning if two values disagree. The result value will be the operand for the flag from the first module being linked.
3	Require Adds a requirement that another module flag be present and have a specified value after linking is performed. The value must be a metadata pair, where the first element of the pair is the ID of the module flag to be restricted, and the second element of the pair is the value the module flag should be restricted to. This behavior can be used to restrict the allowable results (via triggering of an error) of linking IDs with the Override behavior.
4	Override Uses the specified value, regardless of the behavior or value of the other module. If both modules specify Override , but the values differ, an error will be emitted.
5	Append Appends the two values, which are required to be metadata nodes.
6	AppendUnique Appends the two values, which are required to be metadata nodes. However, duplicate entries in the second list are dropped during the append operation.
7	Max Takes the max of the two values, which are required to be integers.

It is an error for a particular unique flag ID to have multiple behaviors, except in the case of **Require** (which adds restrictions on another metadata value) or **Override**.

An example of module flags:

```
!0 = !{ i32 1, !"foo", i32 1 }
!1 = !{ i32 4, !"bar", i32 37 }
!2 = !{ i32 2, !"qux", i32 42 }
!3 = !{ i32 3, !"qux",
  !{
    !"foo", i32 1
  }
}
!llvm.module.flags = !{ !0, !1, !2, !3 }
```

- Metadata !0 has the ID !"foo" and the value '1'. The behavior if two or more !"foo" flags are seen is to emit an error if their values are not equal.
- Metadata !1 has the ID !"bar" and the value '37'. The behavior if two or more !"bar" flags are seen is to use the value '37'.
- Metadata !2 has the ID !"qux" and the value '42'. The behavior if two or more !"qux" flags are seen is to emit a warning if their values are not equal.
- Metadata !3 has the ID !"qux" and the value:

```
!{ !"foo", i32 1 }
```

The behavior is to emit an error if the `llvm.module.flags` does not contain a flag with the ID `!"foo"` that has the value '1' after linking is performed.

Objective-C Garbage Collection Module Flags Metadata

On the Mach-O platform, Objective-C stores metadata about garbage collection in a special section called "image info". The metadata consists of a version number and a bitmask specifying what types of garbage collection are supported (if any) by the file. If two or more modules are linked together their garbage collection metadata needs to be merged rather than appended together.

The Objective-C garbage collection module flags metadata consists of the following key-value pairs:

Key	Value
Objective-C Version	[Required] --- The Objective-C ABI version. Valid values are 1 and 2.
Objective-C Image Info Version	[Required] --- The version of the image info section. Currently always 0.
Objective-C Image Info Section	[Required] --- The section to place the metadata. Valid values are <code>"__OBJC, __image_info, regular"</code> for Objective-C ABI version 1, and <code>"__DATA, __objc_imageinfo, regular, no_dead_strip"</code> for Objective-C ABI version 2.
Objective-C Garbage Collection	[Required] --- Specifies whether garbage collection is supported or not. Valid values are 0, for no garbage collection, and 2, for garbage collection supported.
Objective-C GC Only	[Optional] --- Specifies that only garbage collection is supported. If present, its value must be 6. This flag requires that the Objective-C Garbage Collection flag have the value 2.

Some important flag interactions:

- If a module with Objective-C Garbage Collection set to 0 is merged with a module with Objective-C Garbage Collection set to 2, then the resulting module has the Objective-C Garbage Collection flag set to 0.
- A module with Objective-C Garbage Collection set to 0 cannot be merged with a module with Objective-C GC Only set to 6.

C type width Module Flags Metadata

The ARM backend emits a section into each generated object file describing the options that it was compiled with (in a compiler-independent way) to prevent linking incompatible objects, and to allow automatic library selection. Some of these options are not visible at the IR level, namely `wchar_t` width and enum width.

To pass this information to the backend, these options are encoded in module flags metadata, using the following key-value pairs:

Key	Value
short_wchar	<ul style="list-style-type: none"> • 0 --- <code>sizeof(wchar_t) == 4</code> • 1 --- <code>sizeof(wchar_t) == 2</code>
short_enum	<ul style="list-style-type: none"> • 0 --- Enums are at least as large as an <code>int</code>. • 1 --- Enums are stored in the smallest integer type which can represent all of its values.

For example, the following metadata section specifies that the module was compiled with a `wchar_t` width of 4 bytes, and the underlying type of an enum is the smallest type which can represent all of its values:

```
!llvm.module.flags = !{!0, !1}
!0 = !{i32 1, !"short_wchar", i32 1}
!1 = !{i32 1, !"short_enum", i32 0}
```

1.1.10 Automatic Linker Flags Named Metadata

Some targets support embedding of flags to the linker inside individual object files. Typically this is used in conjunction with language extensions which allow source files to contain linker command line options, and have these automatically be transmitted to the linker via object files.

These flags are encoded in the IR using named metadata with the name `!llvm.linker.options`. Each operand is expected to be a metadata node which should be a list of other metadata nodes, each of which should be a list of metadata strings defining linker options.

For example, the following metadata section specifies two separate sets of linker options, presumably to link against `libz` and the `Cocoa` framework:

```
!0 = !{ !" -lz" }
!1 = !{ !" -framework", !"Cocoa" }
!llvm.linker.options = !{ !0, !1 }
```

The metadata encoding as lists of lists of options, as opposed to a collapsed list of options, is chosen so that the IR encoding can use multiple option strings to specify e.g., a single library, while still having that specifier be preserved as an atomic element that can be recognized by a target specific assembly writer or object file emitter.

Each individual option is required to be either a valid option for the target's linker, or an option that is reserved by the target specific assembly writer or object file emitter. No other aspect of these options is defined by the IR.

1.1.11 Dependent Libs Named Metadata

Some targets support embedding of strings into object files to indicate a set of libraries to add to the link. Typically this is used in conjunction with language extensions which allow source files to explicitly declare the libraries they depend on, and have these automatically be transmitted to the linker via object files.

The list is encoded in the IR using named metadata with the name `!llvm.dependent-libraries`. Each operand is expected to be a metadata node which should contain a single string operand.

For example, the following metadata section contains two library specifiers:

```
!0 = !{!"a library specifier"}
!1 = !{!"another library specifier"}
!llvm.dependent-libraries = !{ !0, !1 }
```

Each library specifier will be handled independently by the consuming linker. The effect of the library specifiers are defined by the consuming linker.

1.1.12 ThinLTO Summary

Compiling with [ThinLTO](#) causes the building of a compact summary of the module that is emitted into the bitcode. The summary is emitted into the LLVM assembly and identified in syntax by a caret (^).

The summary is parsed into a bitcode output, along with the Module IR, via the "llvm-as" tool. Tools that parse the Module IR for the purposes of optimization (e.g. "clang -x ir" and "opt"), will ignore the summary entries (just as they currently ignore summary entries in a bitcode input file).

Eventually, the summary will be parsed into a ModuleSummaryIndex object under the same conditions where summary index is currently built from bitcode. Specifically, tools that test the Thin Link portion of a ThinLTO compile (i.e. llvm-lto and llvm-lto2), or when parsing a combined index for a distributed ThinLTO backend via clang's "-fthinlto-index=<>" flag (this part is not yet implemented, use llvm-as to create a bitcode object before feeding into thin link tools for now).

There are currently 3 types of summary entries in the LLVM assembly: *module paths*, *global values*, and *type identifiers*.

Module Path Summary Entry

Each module path summary entry lists a module containing global values included in the summary. For a single IR module there will be one such entry, but in a combined summary index produced during the thin link, there will be one module path entry per linked module with summary.

Example:

```
^0 = module: (path: "/path/to/file.o", hash: (2468601609, 1329373163, 1565878005, ↵
↪638838075, 3148790418))
```

The `path` field is a string path to the bitcode file, and the `hash` field is the 160-bit SHA-1 hash of the IR bitcode contents, used for incremental builds and caching.

Global Value Summary Entry

Each global value summary entry corresponds to a global value defined or referenced by a summarized module.

Example:

```
^4 = gv: (name: "f"[, summaries: (Summary)[, (Summary)]*]?) ; guid = ↵
↪14740650423002898831
```

For declarations, there will not be a summary list. For definitions, a global value will contain a list of summaries, one per module containing a definition. There can be multiple entries in a combined summary index for symbols with weak linkage.

Each `Summary` format will depend on whether the global value is a *function*, *variable*, or *alias*.

Function Summary

If the global value is a function, the `Summary` entry will look like:

```
function: (module: ^0, flags: (linkage: external, notEligibleToImport: 0, live: 0, ↵
↵dsoLocal: 0), insts: 2[, FuncFlags]?[, Calls]?[, TypeIdInfo]?[, Refs]?)
```

The `module` field includes the summary entry id for the module containing this definition, and the `flags` field contains information such as the linkage type, a flag indicating whether it is legal to import the definition, whether it is globally live and whether the linker resolved it to a local definition (the latter two are populated during the thin link). The `insts` field contains the number of IR instructions in the function. Finally, there are several optional fields: *FuncFlags*, *Calls*, *TypeIdInfo*, *Refs*.

Global Variable Summary

If the global value is a variable, the `Summary` entry will look like:

```
variable: (module: ^0, flags: (linkage: external, notEligibleToImport: 0, live: 0, ↵
↵dsoLocal: 0)[, Refs]?)
```

The variable entry contains a subset of the fields in a *function summary*, see the descriptions there.

Alias Summary

If the global value is an alias, the `Summary` entry will look like:

```
alias: (module: ^0, flags: (linkage: external, notEligibleToImport: 0, live: 0, ↵
↵dsoLocal: 0), aliasee: ^2)
```

The `module` and `flags` fields are as described for a *function summary*. The `aliasee` field contains a reference to the global value summary entry of the aliasee.

Function Flags

The optional `FuncFlags` field looks like:

```
funcFlags: (readNone: 0, readOnly: 0, noRecurse: 0, returnDoesNotAlias: 0)
```

If unspecified, flags are assumed to hold the conservative `false` value of 0.

Calls

The optional `Calls` field looks like:

```
calls: ((Callee)[, (Callee)]*)
```

where each `Callee` looks like:

```
callee: ^1[, hotness: None]?[, relbf: 0]?
```

The `callee` refers to the summary entry id of the callee. At most one of `hotness` (which can take the values `Unknown`, `Cold`, `None`, `Hot`, and `Critical`), and `relbf` (which holds the integer branch frequency relative to the entry frequency, scaled down by 2^8) may be specified. The defaults are `Unknown` and 0, respectively.

Refs

The optional `Refs` field looks like:

```
refs: ((Ref) [, (Ref)]*)
```

where each `Ref` contains a reference to the summary id of the referenced value (e.g. `^1`).

TypeIdInfo

The optional `TypeIdInfo` field, used for [Control Flow Integrity](#), looks like:

```
typeIdInfo: [(TypeTests)]?[, (TypeTestAssumeVCalls)]?[, (TypeCheckedLoadVCalls)]?[, ↪  
↪ (TypeTestAssumeConstVCalls)]?[, (TypeCheckedLoadConstVCalls)]?
```

These optional fields have the following forms:

TypeTests

```
typeTests: (TypeIdRef [, TypeIdRef]*)
```

Where each `TypeIdRef` refers to a *type id* by summary id or GUID.

TypeTestAssumeVCalls

```
typeTestAssumeVCalls: (VFuncId [, VFuncId]*)
```

Where each `VFuncId` has the format:

```
vFuncId: (TypeIdRef, offset: 16)
```

Where each `TypeIdRef` refers to a *type id* by summary id or GUID preceeded by a `guid: tag`.

TypeCheckedLoadVCalls

```
typeCheckedLoadVCalls: (VFuncId [, VFuncId]*)
```

Where each `VFuncId` has the format described for `TypeTestAssumeVCalls`.

TypeTestAssumeConstVCalls

```
typeTestAssumeConstVCalls: (ConstVCall[, ConstVCall]*)
```

Where each ConstVCall has the format:

```
(VFuncId, args: (Arg[, Arg]*))
```

and where each VFuncId has the format described for TypeTestAssumeVCalls, and each Arg is an integer argument number.

TypeCheckedLoadConstVCalls

```
typeCheckedLoadConstVCalls: (ConstVCall[, ConstVCall]*)
```

Where each ConstVCall has the format described for TypeTestAssumeConstVCalls.

Type ID Summary Entry

Each type id summary entry corresponds to a type identifier resolution which is generated during the LTO link portion of the compile when building with [Control Flow Integrity](#), so these are only present in a combined summary index.

Example:

```
^4 = typeid: (name: "_ZTS1A", summary: (typeTestRes: (kind: allOnes, sizeM1BitWidth: 7, alignLog2: 0)?[, sizeM1: 0]?[, bitMask: 0]?[, inlineBits: 0]?)[, WpdResolutions]?)) ; guid = 7004155349499253778
```

The typeTestRes gives the type test resolution kind (which may be unsat, byteArray, inline, single, or allOnes), and the size-1 bit width. It is followed by optional flags, which default to 0, and an optional WpdResolutions (whole program devirtualization resolution) field that looks like:

```
wpdResolutions: ((offset: 0, WpdRes)[, (offset: 1, WpdRes)]*)
```

where each entry is a mapping from the given byte offset to the whole-program devirtualization resolution WpdRes, that has one of the following formats:

```
wpdRes: (kind: branchFunnel)
wpdRes: (kind: singleImpl, singleImplName: "_ZN1A1nEi")
wpdRes: (kind: indir)
```

Additionally, each wpdRes has an optional resByArg field, which describes the resolutions for calls with all constant integer arguments:

```
resByArg: (ResByArg[, ResByArg]*)
```

where ResByArg is:

```
args: (Arg[, Arg]*), byArg: (kind: UniformRetVal[, info: 0][, byte: 0][, bit: 0])
```

Where the kind can be Indir, UniformRetVal, UniqueRetVal or VirtualConstProp. The info field is only used if the kind is UniformRetVal (indicates the uniform return value), or UniqueRetVal (holds the return value associated with the unique vtable (0 or 1)). The byte and bit fields are only used if the target does not support the use of absolute symbols to store constants.

1.1.13 Intrinsic Global Variables

LLVM has a number of "magic" global variables that contain data that affect code generation or other IR semantics. These are documented here. All globals of this sort should have a section specified as "llvm.metadata". This section and all globals that start with "llvm." are reserved for use by LLVM.

The 'llvm.used' Global Variable

The @llvm.used global is an array which has *appending linkage*. This array contains a list of pointers to named global variables, functions and aliases which may optionally have a pointer cast formed of bitcast or getelementptr. For example, a legal use of it is:

```
@X = global i8 4
@Y = global i32 123

@llvm.used = appending global [2 x i8*] [
    i8* @X,
    i8* bitcast (i32* @Y to i8*)
], section "llvm.metadata"
```

If a symbol appears in the @llvm.used list, then the compiler, assembler, and linker are required to treat the symbol as if there is a reference to the symbol that it cannot see (which is why they have to be named). For example, if a variable has internal linkage and no references other than that from the @llvm.used list, it cannot be deleted. This is commonly used to represent references from inline asms and other things the compiler cannot "see", and corresponds to "attribute((used))" in GNU C.

On some targets, the code generator must emit a directive to the assembler or object file to prevent the assembler and linker from molesting the symbol.

The 'llvm.compiler.used' Global Variable

The @llvm.compiler.used directive is the same as the @llvm.used directive, except that it only prevents the compiler from touching the symbol. On targets that support it, this allows an intelligent linker to optimize references to the symbol without being impeded as it would be by @llvm.used.

This is a rare construct that should only be used in rare circumstances, and should not be exposed to source languages.

The 'llvm.global_ctors' Global Variable

```
%0 = type { i32, void ()*, i8* }
@llvm.global_ctors = appending global [1 x %0] [%0 { i32 65535, void ()* @ctor, i8*_
  ↳@data }]
```

The @llvm.global_ctors array contains a list of constructor functions, priorities, and an associated global or function. The functions referenced by this array will be called in ascending order of priority (i.e. lowest first) when the module is loaded. The order of functions with the same priority is not defined.

If the third field is non-null, and points to a global variable or function, the initializer function will only run if the associated data from the current module is not discarded.

The '@llvm.global_dtors' Global Variable

```
%0 = type { i32, void ()*, i8* }
@llvm.global_dtors = appending global [1 x %0] [%0 { i32 65535, void ()* @dctor, i8*
↳@data }]
```

The @llvm.global_dtors array contains a list of destructor functions, priorities, and an associated global or function. The functions referenced by this array will be called in descending order of priority (i.e. highest first) when the module is unloaded. The order of functions with the same priority is not defined.

If the third field is non-null, and points to a global variable or function, the destructor function will only run if the associated data from the current module is not discarded.

1.1.14 Instruction Reference

The LLVM instruction set consists of several different classifications of instructions: *terminator instructions*, *binary instructions*, *bitwise binary instructions*, *memory instructions*, and *other instructions*.

Terminator Instructions

As mentioned *previously*, every basic block in a program ends with a "Terminator" instruction, which indicates which block should be executed after the current block is finished. These terminator instructions typically yield a 'void' value: they produce control flow, not values (the one exception being the 'invoke' instruction).

The terminator instructions are: 'ret', 'br', 'switch', 'indirectbr', 'invoke', 'callbr', 'resume', 'catchswitch', 'catchret', 'cleanupret', and 'unreachable'.

'ret' Instruction

Syntax:

```
ret <type> <value>      ; Return a value from a non-void function
ret void                ; Return from void function
```

Overview:

The 'ret' instruction is used to return control flow (and optionally a value) from a function back to the caller.

There are two forms of the 'ret' instruction: one that returns a value and then causes control flow, and one that just causes control flow to occur.

Arguments:

The 'ret' instruction optionally accepts a single argument, the return value. The type of the return value must be a *'first class'* type.

A function is not *well formed* if it has a non-void return type and contains a 'ret' instruction with no return value or a return value with a type that does not match its type, or if it has a void return type and contains a 'ret' instruction with a return value.

Semantics:

When the 'ret' instruction is executed, control flow returns back to the calling function's context. If the caller is a "call" instruction, execution continues at the instruction after the call. If the caller was an "invoke" instruction, execution continues at the beginning of the "normal" destination block. If the instruction returns a value, that value shall set the call or invoke instruction's return value.

Example:

```
ret i32 5           ; Return an integer value of 5
ret void           ; Return from a void function
ret { i32, i8 } { i32 4, i8 2 } ; Return a struct of values 4 and 2
```

'br' Instruction

Syntax:

```
br il <cond>, label <iftrue>, label <iffalse>
br label <dest>           ; Unconditional branch
```

Overview:

The 'br' instruction is used to cause control flow to transfer to a different basic block in the current function. There are two forms of this instruction, corresponding to a conditional branch and an unconditional branch.

Arguments:

The conditional branch form of the 'br' instruction takes a single 'il' value and two 'label' values. The unconditional form of the 'br' instruction takes a single 'label' value as a target.

Semantics:

Upon execution of a conditional 'br' instruction, the 'i1' argument is evaluated. If the value is true, control flows to the 'iftrue' label argument. If "cond" is false, control flows to the 'iffalse' label argument.

Example:

```
Test:
  %cond = icmp eq i32 %a, %b
  br i1 %cond, label %IfEqual, label %IfUnequal
IfEqual:
  ret i32 1
IfUnequal:
  ret i32 0
```

'switch' Instruction**Syntax:**

```
switch <intty> <value>, label <defaultdest> [ <intty> <val>, label <dest> ... ]
```

Overview:

The 'switch' instruction is used to transfer control flow to one of several different places. It is a generalization of the 'br' instruction, allowing a branch to occur to one of many possible destinations.

Arguments:

The 'switch' instruction uses three parameters: an integer comparison value 'value', a default 'label' destination, and an array of pairs of comparison value constants and 'label's. The table is not allowed to contain duplicate constant entries.

Semantics:

The switch instruction specifies a table of values and destinations. When the 'switch' instruction is executed, this table is searched for the given value. If the value is found, control flow is transferred to the corresponding destination; otherwise, control flow is transferred to the default destination.

Implementation:

Depending on properties of the target machine and the particular `switch` instruction, this instruction may be code generated in different ways. For example, it could be generated as a series of chained conditional branches or with a lookup table.

Example:

```
; Emulate a conditional br instruction
%Val = zext i1 %value to i32
switch i32 %Val, label %truedest [ i32 0, label %falsedest ]

; Emulate an unconditional br instruction
switch i32 0, label %dest [ ]

; Implement a jump table:
switch i32 %val, label %otherwise [ i32 0, label %onzero
                                   i32 1, label %onone
                                   i32 2, label %ontwo ]
```

'indirectbr' Instruction

Syntax:

```
indirectbr <someTy>* <address>, [ label <dest1>, label <dest2>, ... ]
```

Overview:

The 'indirectbr' instruction implements an indirect branch to a label within the current function, whose address is specified by "address". Address must be derived from a *blockaddress* constant.

Arguments:

The 'address' argument is the address of the label to jump to. The rest of the arguments indicate the full set of possible destinations that the address may point to. Blocks are allowed to occur multiple times in the destination list, though this isn't particularly useful.

This destination list is required so that dataflow analysis has an accurate understanding of the CFG.

Semantics:

Control transfers to the block specified in the address argument. All possible destination blocks must be listed in the label list, otherwise this instruction has undefined behavior. This implies that jumps to labels defined in other functions have undefined behavior as well.

Implementation:

This is typically implemented with a jump through a register.

Example:

```
indirectbr i8* %Addr, [ label %bb1, label %bb2, label %bb3 ]
```

'invoke' Instruction

Syntax:

```
<result> = invoke [cconv] [ret attrs] [addrspace(<num>)] [<ty>|<fnty> <fnptrval>(  
→<function args>)] [fn attrs]  
                [operand bundles] to label <normal label> unwind label <exception label>
```

Overview:

The 'invoke' instruction causes control to transfer to a specified function, with the possibility of control flow transfer to either the 'normal' label or the 'exception' label. If the callee function returns with the "ret" instruction, control flow will return to the "normal" label. If the callee (or any indirect callees) returns via the "*resume*" instruction or other exception handling mechanism, control is interrupted and continued at the dynamically nearest "exception" label.

The 'exception' label is a *landing pad* for the exception. As such, 'exception' label is required to have the "*landingpad*" instruction, which contains the information about the behavior of the program after unwinding happens, as its first non-PHI instruction. The restrictions on the "landingpad" instruction's tightly couples it to the "invoke" instruction, so that the important information contained within the "landingpad" instruction can't be lost through normal code motion.

Arguments:

This instruction requires several arguments:

1. The optional "cconv" marker indicates which *calling convention* the call should use. If none is specified, the call defaults to using C calling conventions.
2. The optional *Parameter Attributes* list for return values. Only 'zeroext', 'signext', and 'inreg' attributes are valid here.
3. The optional addrspace attribute can be used to indicate the address space of the called function. If it is not specified, the program address space from the *datalayout string* will be used.

4. 'ty': the type of the call instruction itself which is also the type of the return value. Functions that return no value are marked `void`.
5. 'fnty': shall be the signature of the function being invoked. The argument types must match the types implied by this signature. This type can be omitted if the function is not varargs.
6. 'fnptrval': An LLVM value containing a pointer to a function to be invoked. In most cases, this is a direct function invocation, but indirect `invoke`'s are just as possible, calling an arbitrary pointer to function value.
7. 'function args': argument list whose types match the function signature argument types and parameter attributes. All arguments must be of *first class* type. If the function signature indicates the function accepts a variable number of arguments, the extra arguments can be specified.
8. 'normal label': the label reached when the called function executes a 'ret' instruction.
9. 'exception label': the label reached when a callee returns via the *resume* instruction or other exception handling mechanism.
10. The optional *function attributes* list.
11. The optional *operand bundles* list.

Semantics:

This instruction is designed to operate as a standard 'call' instruction in most regards. The primary difference is that it establishes an association with a label, which is used by the runtime library to unwind the stack.

This instruction is used in languages with destructors to ensure that proper cleanup is performed in the case of either a `longjmp` or a thrown exception. Additionally, this is important for implementation of 'catch' clauses in high-level languages that support them.

For the purposes of the SSA form, the definition of the value returned by the 'invoke' instruction is deemed to occur on the edge from the current block to the "normal" label. If the callee unwinds then no return value is available.

Example:

```
%retval = invoke i32 @Test(i32 15) to label %Continue
           unwind label %TestCleanup           ; i32:retval set
%retval = invoke coldcc i32 @Testfnptr(i32 15) to label %Continue
           unwind label %TestCleanup           ; i32:retval set
```

'callbr' Instruction

Syntax:

```
<result> = callbr [cconv] [ret attrs] [addrspace(<num>)] [<ty>|<fnty> <fnptrval>(  
  ↪<function args>) [fn attrs]  
  [operand bundles] to label <normal label> or jump [other labels]
```

Overview:

The 'callbr' instruction causes control to transfer to a specified function, with the possibility of control flow transfer to either the 'normal' label or one of the 'other' labels.

This instruction should only be used to implement the "goto" feature of gcc style inline assembly. Any other usage is an error in the IR verifier.

Arguments:

This instruction requires several arguments:

1. The optional "cconv" marker indicates which *calling convention* the call should use. If none is specified, the call defaults to using C calling conventions.
2. The optional *Parameter Attributes* list for return values. Only 'zeroext', 'signext', and 'inreg' attributes are valid here.
3. The optional addrspace attribute can be used to indicate the address space of the called function. If it is not specified, the program address space from the *datalayout string* will be used.
4. 'ty': the type of the call instruction itself which is also the type of the return value. Functions that return no value are marked void.
5. 'fnty': shall be the signature of the function being called. The argument types must match the types implied by this signature. This type can be omitted if the function is not varargs.
6. 'fnptrval': An LLVM value containing a pointer to a function to be called. In most cases, this is a direct function call, but indirect callbr's are just as possible, calling an arbitrary pointer to function value.
7. 'function args': argument list whose types match the function signature argument types and parameter attributes. All arguments must be of *first class* type. If the function signature indicates the function accepts a variable number of arguments, the extra arguments can be specified.
8. 'normal label': the label reached when the called function executes a 'ret' instruction.
9. 'other labels': the labels reached when a callee transfers control to a location other than the normal 'normal label'
10. The optional *function attributes* list.
11. The optional *operand bundles* list.

Semantics:

This instruction is designed to operate as a standard 'call' instruction in most regards. The primary difference is that it establishes an association with additional labels to define where control flow goes after the call.

The only use of this today is to implement the "goto" feature of gcc inline assembly where additional labels can be provided as locations for the inline assembly to jump to.

Example:

```
callbr void asm "", "r,x"(i32 %x, i8 *blockaddress(@foo, %fail))
    to label %normal or jump [label %fail]
```

'resume' Instruction**Syntax:**

```
resume <type> <value>
```

Overview:

The 'resume' instruction is a terminator instruction that has no successors.

Arguments:

The 'resume' instruction requires one argument, which must have the same type as the result of any 'landingpad' instruction in the same function.

Semantics:

The 'resume' instruction resumes propagation of an existing (in-flight) exception whose unwinding was interrupted with a *landingpad* instruction.

Example:

```
resume { i8*, i32 } %exn
```

'catchswitch' Instruction**Syntax:**

```
<resultval> = catchswitch within <parent> [ label <handler1>, label <handler2>, ... ]  
↳unwind to caller  
<resultval> = catchswitch within <parent> [ label <handler1>, label <handler2>, ... ]  
↳unwind label <default>
```

Overview:

The 'catchswitch' instruction is used by LLVM's [exception handling system](#) to describe the set of possible catch handlers that may be executed by the *EH personality routine*.

Arguments:

The `parent` argument is the token of the funclet that contains the `catchswitch` instruction. If the `catchswitch` is not inside a funclet, this operand may be the token `none`.

The `default` argument is the label of another basic block beginning with either a `cleanuppad` or `catchswitch` instruction. This unwind destination must be a legal target with respect to the parent links, as described in the [exception handling documentation](#).

The `handlers` are a nonempty list of successor blocks that each begin with a *catchpad* instruction.

Semantics:

Executing this instruction transfers control to one of the successors in `handlers`, if appropriate, or continues to unwind via the unwind label if present.

The `catchswitch` is both a terminator and a "pad" instruction, meaning that it must be both the first non-phi instruction and last instruction in the basic block. Therefore, it must be the only non-phi instruction in the block.

Example:

```
dispatch1:
  %cs1 = catchswitch within none [label %handler0, label %handler1] unwind to caller
dispatch2:
  %cs2 = catchswitch within %parenthandler [label %handler0] unwind label %cleanup
```

'catchret' Instruction

Syntax:

```
catchret from <token> to label <normal>
```

Overview:

The 'catchret' instruction is a terminator instruction that has a single successor.

Arguments:

The first argument to a 'catchret' indicates which `catchpad` it exits. It must be a *catchpad*. The second argument to a 'catchret' specifies where control will transfer to next.

Semantics:

The 'catchret' instruction ends an existing (in-flight) exception whose unwinding was interrupted with a *catchpad* instruction. The *personality function* gets a chance to execute arbitrary code to, for example, destroy the active exception. Control then transfers to normal.

The token argument must be a token produced by a `catchpad` instruction. If the specified `catchpad` is not the most-recently-entered not-yet-exited funclet pad (as described in the [EH documentation](#)), the `catchret`'s behavior is undefined.

Example:

```
catchret from %catch label %continue
```

'cleanupret' Instruction

Syntax:

```
cleanupret from <value> unwind label <continue>  
cleanupret from <value> unwind to caller
```

Overview:

The 'cleanupret' instruction is a terminator instruction that has an optional successor.

Arguments:

The 'cleanupret' instruction requires one argument, which indicates which `cleanuppad` it exits, and must be a *cleanuppad*. If the specified `cleanuppad` is not the most-recently-entered not-yet-exited funclet pad (as described in the [EH documentation](#)), the `cleanupret`'s behavior is undefined.

The 'cleanupret' instruction also has an optional successor, `continue`, which must be the label of another basic block beginning with either a `cleanuppad` or `catchswitch` instruction. This unwind destination must be a legal target with respect to the parent links, as described in the [exception handling documentation](#).

Semantics:

The 'cleanupret' instruction indicates to the *personality function* that one *cleanuppad* it transferred control to has ended. It transfers control to `continue` or unwinds out of the function.

Example:

```
cleanupret from %cleanup unwind to caller
cleanupret from %cleanup unwind label %continue
```

'unreachable' Instruction**Syntax:**

```
unreachable
```

Overview:

The 'unreachable' instruction has no defined semantics. This instruction is used to inform the optimizer that a particular portion of the code is not reachable. This can be used to indicate that the code after a no-return function cannot be reached, and other facts.

Semantics:

The 'unreachable' instruction has no defined semantics.

Unary Operations

Unary operators require a single operand, execute an operation on it, and produce a single value. The operand might represent multiple data, as is the case with the *vector* data type. The result value has the same type as its operand.

'fneg' Instruction**Syntax:**

```
<result> = fneg [fast-math flags]* <ty> <op1> ; yields ty:result
```

Overview:

The 'fneg' instruction returns the negation of its operand.

Arguments:

The argument to the 'fneg' instruction must be a *floating-point* or *vector* of floating-point values.

Semantics:

The value produced is a copy of the operand with its sign bit flipped. This instruction can also take any number of *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations:

Example:

```
<result> = fneg float %val           ; yields float:result = -%var
```

Binary Operations

Binary operators are used to do most of the computation in a program. They require two operands of the same type, execute an operation on them, and produce a single value. The operands might represent multiple data, as is the case with the *vector* data type. The result value has the same type as its operands.

There are several different binary operators:

'add' Instruction**Syntax:**

```
<result> = add <ty> <op1>, <op2>      ; yields ty:result  
<result> = add nuw <ty> <op1>, <op2>   ; yields ty:result  
<result> = add nsw <ty> <op1>, <op2>   ; yields ty:result  
<result> = add nuw nsw <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'add' instruction returns the sum of its two operands.

Arguments:

The two arguments to the 'add' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The value produced is the integer sum of the two operands.

If the sum has unsigned overflow, the result returned is the mathematical result modulo 2^n , where n is the bit width of the result.

Because LLVM integers use a two's complement representation, this instruction is appropriate for both signed and unsigned integers.

`nuw` and `nsw` stand for "No Unsigned Wrap" and "No Signed Wrap", respectively. If the `nuw` and/or `nsw` keywords are present, the result value of the `add` is a *poison value* if unsigned and/or signed overflow, respectively, occurs.

Example:

```
<result> = add i32 4, %var           ; yields i32:result = 4 + %var
```

'fadd' Instruction**Syntax:**

```
<result> = fadd [fast-math flags]* <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'fadd' instruction returns the sum of its two operands.

Arguments:

The two arguments to the 'fadd' instruction must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

Semantics:

The value produced is the floating-point sum of the two operands. This instruction is assumed to execute in the default *floating-point environment*. This instruction can also take any number of *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations:

Example:

```
<result> = fadd float 4.0, %var          ; yields float:result = 4.0 + %var
```

'sub' Instruction**Syntax:**

```
<result> = sub <ty> <op1>, <op2>      ; yields ty:result
<result> = sub nuw <ty> <op1>, <op2>    ; yields ty:result
<result> = sub nsw <ty> <op1>, <op2>    ; yields ty:result
<result> = sub nuw nsw <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'sub' instruction returns the difference of its two operands.

Note that the 'sub' instruction is used to represent the 'neg' instruction present in most other intermediate representations.

Arguments:

The two arguments to the 'sub' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The value produced is the integer difference of the two operands.

If the difference has unsigned overflow, the result returned is the mathematical result modulo 2^n , where n is the bit width of the result.

Because LLVM integers use a two's complement representation, this instruction is appropriate for both signed and unsigned integers.

nuw and nsw stand for "No Unsigned Wrap" and "No Signed Wrap", respectively. If the nuw and/or nsw keywords are present, the result value of the sub is a *poison value* if unsigned and/or signed overflow, respectively, occurs.

Example:

```
<result> = sub i32 4, %var              ; yields i32:result = 4 - %var
<result> = sub i32 0, %val              ; yields i32:result = -%var
```

'fsub' Instruction

Syntax:

```
<result> = fsub [fast-math flags]* <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'fsub' instruction returns the difference of its two operands.

Arguments:

The two arguments to the 'fsub' instruction must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

Semantics:

The value produced is the floating-point difference of the two operands. This instruction is assumed to execute in the default *floating-point environment*. This instruction can also take any number of *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations:

Example:

```
<result> = fsub float 4.0, %var ; yields float:result = 4.0 - %var
<result> = fsub float -0.0, %val ; yields float:result = -%var
```

'mul' Instruction

Syntax:

```
<result> = mul <ty> <op1>, <op2> ; yields ty:result
<result> = mul nuw <ty> <op1>, <op2> ; yields ty:result
<result> = mul nsw <ty> <op1>, <op2> ; yields ty:result
<result> = mul nuw nsw <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'mul' instruction returns the product of its two operands.

Arguments:

The two arguments to the 'mul' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The value produced is the integer product of the two operands.

If the result of the multiplication has unsigned overflow, the result returned is the mathematical result modulo 2^n , where n is the bit width of the result.

Because LLVM integers use a two's complement representation, and the result is the same width as the operands, this instruction returns the correct result for both signed and unsigned integers. If a full product (e.g. `i32 * i32 -> i64`) is needed, the operands should be sign-extended or zero-extended as appropriate to the width of the full product.

`nuw` and `nsw` stand for "No Unsigned Wrap" and "No Signed Wrap", respectively. If the `nuw` and/or `nsw` keywords are present, the result value of the `mul` is a *poison value* if unsigned and/or signed overflow, respectively, occurs.

Example:

```
<result> = mul i32 4, %var           ; yields i32:result = 4 * %var
```

'fmul' Instruction**Syntax:**

```
<result> = fmul [fast-math flags]* <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'fmul' instruction returns the product of its two operands.

Arguments:

The two arguments to the 'fmul' instruction must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

Semantics:

The value produced is the floating-point product of the two operands. This instruction is assumed to execute in the default *floating-point environment*. This instruction can also take any number of *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations:

Example:

```
<result> = fmul float 4.0, %var          ; yields float:result = 4.0 * %var
```

'udiv' Instruction**Syntax:**

```
<result> = udiv <ty> <op1>, <op2>      ; yields ty:result
<result> = udiv exact <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'udiv' instruction returns the quotient of its two operands.

Arguments:

The two arguments to the 'udiv' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The value produced is the unsigned integer quotient of the two operands.

Note that unsigned integer division and signed integer division are distinct operations; for signed integer division, use 'sdiv'.

Division by zero is undefined behavior. For vectors, if any element of the divisor is zero, the operation has undefined behavior.

If the `exact` keyword is present, the result value of the `udiv` is a *poison value* if `%op1` is not a multiple of `%op2` (as such, "`((a udiv exact b) mul b) == a`").

Example:

```
<result> = udiv i32 4, %var          ; yields i32:result = 4 / %var
```

'sdiv' Instruction**Syntax:**

```
<result> = sdiv <ty> <op1>, <op2>      ; yields ty:result
<result> = sdiv exact <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'sdiv' instruction returns the quotient of its two operands.

Arguments:

The two arguments to the 'sdiv' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The value produced is the signed integer quotient of the two operands rounded towards zero.

Note that signed integer division and unsigned integer division are distinct operations; for unsigned integer division, use 'udiv'.

Division by zero is undefined behavior. For vectors, if any element of the divisor is zero, the operation has undefined behavior. Overflow also leads to undefined behavior; this is a rare case, but can occur, for example, by doing a 32-bit division of -2147483648 by -1.

If the `exact` keyword is present, the result value of the `sdiv` is a *poison value* if the result would be rounded.

Example:

```
<result> = sdiv i32 4, %var          ; yields i32:result = 4 / %var
```

'fdiv' Instruction**Syntax:**

```
<result> = fdiv [fast-math flags]* <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'fdiv' instruction returns the quotient of its two operands.

Arguments:

The two arguments to the 'fdiv' instruction must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

Semantics:

The value produced is the floating-point quotient of the two operands. This instruction is assumed to execute in the default *floating-point environment*. This instruction can also take any number of *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations:

Example:

```
<result> = fdiv float 4.0, %var          ; yields float:result = 4.0 / %var
```

'urem' Instruction**Syntax:**

```
<result> = urem <ty> <op1>, <op2>      ; yields ty:result
```

Overview:

The 'urem' instruction returns the remainder from the unsigned division of its two arguments.

Arguments:

The two arguments to the 'urem' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

This instruction returns the unsigned integer *remainder* of a division. This instruction always performs an unsigned division to get the remainder.

Note that unsigned integer remainder and signed integer remainder are distinct operations; for signed integer remainder, use 'srem'.

Taking the remainder of a division by zero is undefined behavior. For vectors, if any element of the divisor is zero, the operation has undefined behavior.

Example:

```
<result> = urem i32 4, %var              ; yields i32:result = 4 % %var
```

'srem' Instruction

Syntax:

```
<result> = srem <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'srem' instruction returns the remainder from the signed division of its two operands. This instruction can also take *vector* versions of the values in which case the elements must be integers.

Arguments:

The two arguments to the 'srem' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

This instruction returns the *remainder* of a division (where the result is either zero or has the same sign as the dividend, op1), not the *modulo* operator (where the result is either zero or has the same sign as the divisor, op2) of a value. For more information about the difference, see [The Math Forum](#). For a table of how this is implemented in various languages, please see [Wikipedia: modulo operation](#).

Note that signed integer remainder and unsigned integer remainder are distinct operations; for unsigned integer remainder, use 'urem'.

Taking the remainder of a division by zero is undefined behavior. For vectors, if any element of the divisor is zero, the operation has undefined behavior. Overflow also leads to undefined behavior; this is a rare case, but can occur, for example, by taking the remainder of a 32-bit division of -2147483648 by -1. (The remainder doesn't actually overflow, but this rule lets srem be implemented using instructions that return both the result of the division and the remainder.)

Example:

```
<result> = srem i32 4, %var ; yields i32:result = 4 % %var
```

'frem' Instruction

Syntax:

```
<result> = frem [fast-math flags]* <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'frem' instruction returns the remainder from the division of its two operands.

Arguments:

The two arguments to the 'frem' instruction must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

Semantics:

The value produced is the floating-point remainder of the two operands. This is the same output as a libm 'fmod' function, but without any possibility of setting `errno`. The remainder has the same sign as the dividend. This instruction is assumed to execute in the default *floating-point environment*. This instruction can also take any number of *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations:

Example:

```
<result> = frem float 4.0, %var          ; yields float:result = 4.0 % %var
```

Bitwise Binary Operations

Bitwise binary operators are used to do various forms of bit-twiddling in a program. They are generally very efficient instructions and can commonly be strength reduced from other instructions. They require two operands of the same type, execute an operation on them, and produce a single value. The resulting value is the same type as its operands.

'shl' Instruction**Syntax:**

```
<result> = shl <ty> <op1>, <op2>      ; yields ty:result
<result> = shl nuw <ty> <op1>, <op2>   ; yields ty:result
<result> = shl nsw <ty> <op1>, <op2>   ; yields ty:result
<result> = shl nuw nsw <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'shl' instruction returns the first operand shifted to the left a specified number of bits.

Arguments:

Both arguments to the 'shl' instruction must be the same *integer* or *vector* of integer type. 'op2' is treated as an unsigned value.

Semantics:

The value produced is $op1 * 2^{op2} \bmod 2^n$, where n is the width of the result. If $op2$ is (statically or dynamically) equal to or larger than the number of bits in $op1$, this instruction returns a *poison value*. If the arguments are vectors, each vector element of $op1$ is shifted by the corresponding shift amount in $op2$.

If the `nsw` keyword is present, then the shift produces a poison value if it shifts out any non-zero bits. If the `nsz` keyword is present, then the shift produces a poison value if it shifts out any bits that disagree with the resultant sign bit.

Example:

```
<result> = shl i32 4, %var    ; yields i32: 4 << %var
<result> = shl i32 4, 2       ; yields i32: 16
<result> = shl i32 1, 10      ; yields i32: 1024
<result> = shl i32 1, 32      ; undefined
<result> = shl <2 x i32> <i32 1, i32 1>, <i32 1, i32 2> ; yields: result=<2 x i32>
↳ <i32 2, i32 4>
```

'lshr' Instruction

Syntax:

```
<result> = lshr <ty> <op1>, <op2>    ; yields ty:result
<result> = lshr exact <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'lshr' instruction (logical shift right) returns the first operand shifted to the right a specified number of bits with zero fill.

Arguments:

Both arguments to the 'lshr' instruction must be the same *integer* or *vector* of integer type. 'op2' is treated as an unsigned value.

Semantics:

This instruction always performs a logical shift right operation. The most significant bits of the result will be filled with zero bits after the shift. If `op2` is (statically or dynamically) equal to or larger than the number of bits in `op1`, this instruction returns a *poison value*. If the arguments are vectors, each vector element of `op1` is shifted by the corresponding shift amount in `op2`.

If the `exact` keyword is present, the result value of the `lshr` is a poison value if any of the bits shifted out are non-zero.

Example:

```
<result> = lshr i32 4, 1    ; yields i32:result = 2
<result> = lshr i32 4, 2    ; yields i32:result = 1
<result> = lshr i8  4, 3    ; yields i8:result = 0
<result> = lshr i8 -2, 1    ; yields i8:result = 0x7F
<result> = lshr i32 1, 32   ; undefined
<result> = lshr <2 x i32> <i32 -2, i32 4>, <i32 1, i32 2> ; yields: result=<2 x_  
↪i32> <i32 0x7FFFFFFF, i32 1>
```

'ashr' Instruction

Syntax:

```
<result> = ashr <ty> <op1>, <op2>      ; yields ty:result
<result> = ashr exact <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'ashr' instruction (arithmetic shift right) returns the first operand shifted to the right a specified number of bits with sign extension.

Arguments:

Both arguments to the 'ashr' instruction must be the same *integer* or *vector* of integer type. 'op2' is treated as an unsigned value.

Semantics:

This instruction always performs an arithmetic shift right operation. The most significant bits of the result will be filled with the sign bit of `op1`. If `op2` is (statically or dynamically) equal to or larger than the number of bits in `op1`, this instruction returns a *poison value*. If the arguments are vectors, each vector element of `op1` is shifted by the corresponding shift amount in `op2`.

If the `exact` keyword is present, the result value of the `ashr` is a poison value if any of the bits shifted out are non-zero.

Example:

```
<result> = ashr i32 4, 1    ; yields i32:result = 2
<result> = ashr i32 4, 2    ; yields i32:result = 1
<result> = ashr i8  4, 3    ; yields i8:result = 0
<result> = ashr i8 -2, 1    ; yields i8:result = -1
<result> = ashr i32 1, 32   ; undefined
<result> = ashr <2 x i32> < i32 -2, i32 4>, < i32 1, i32 3>    ; yields: result=<2 x i32> < i32 -1, i32 0>
```

'and' Instruction**Syntax:**

```
<result> = and <ty> <op1>, <op2>    ; yields ty:result
```

Overview:

The 'and' instruction returns the bitwise logical and of its two operands.

Arguments:

The two arguments to the 'and' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The truth table used for the 'and' instruction is:

In0	In1	Out
0	0	0
0	1	0
1	0	0
1	1	1

Example:

```
<result> = and i32 4, %var    ; yields i32:result = 4 & %var
<result> = and i32 15, 40     ; yields i32:result = 8
<result> = and i32 4, 8       ; yields i32:result = 0
```

'or' Instruction

Syntax:

```
<result> = or <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'or' instruction returns the bitwise logical inclusive or of its two operands.

Arguments:

The two arguments to the 'or' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The truth table used for the 'or' instruction is:

In0	In1	Out
0	0	0
0	1	1
1	0	1
1	1	1

Example:

```
<result> = or i32 4, %var ; yields i32:result = 4 | %var
<result> = or i32 15, 40 ; yields i32:result = 47
<result> = or i32 4, 8 ; yields i32:result = 12
```

'xor' Instruction

Syntax:

```
<result> = xor <ty> <op1>, <op2> ; yields ty:result
```

Overview:

The 'xor' instruction returns the bitwise logical exclusive or of its two operands. The xor is used to implement the "one's complement" operation, which is the "~" operator in C.

Arguments:

The two arguments to the 'xor' instruction must be *integer* or *vector* of integer values. Both arguments must have identical types.

Semantics:

The truth table used for the 'xor' instruction is:

In0	In1	Out
0	0	0
0	1	1
1	0	1
1	1	0

Example:

```
<result> = xor i32 4, %var      ; yields i32:result = 4 ^ %var
<result> = xor i32 15, 40       ; yields i32:result = 39
<result> = xor i32 4, 8         ; yields i32:result = 12
<result> = xor i32 %V, -1       ; yields i32:result = ~%V
```

Vector Operations

LLVM supports several instructions to represent vector operations in a target-independent manner. These instructions cover the element-access and vector-specific operations needed to process vectors effectively. While LLVM does directly support these vector operations, many sophisticated algorithms will want to use target-specific intrinsics to take full advantage of a specific target.

'extractelement' Instruction

Syntax:

```
<result> = extractelement <n x <ty>> <val>, <ty2> <idx> ; yields <ty>
<result> = extractelement <vscale x n x <ty>> <val>, <ty2> <idx> ; yields <ty>
```

Overview:

The 'extractelement' instruction extracts a single scalar element from a vector at a specified index.

Arguments:

The first operand of an 'extractelement' instruction is a value of *vector* type. The second operand is an index indicating the position from which to extract the element. The index may be a variable of any integer type.

Semantics:

The result is a scalar of the same type as the element type of `val`. Its value is the value at position `idx` of `val`. If `idx` exceeds the length of `val` for a fixed-length vector, the result is a *poison value*. For a scalable vector, if the value of `idx` exceeds the runtime length of the vector, the result is a *poison value*.

Example:

```
<result> = extractelement <4 x i32> %vec, i32 0 ; yields i32
```

'insertelement' Instruction**Syntax:**

```
<result> = insertelement <n x <ty>> <val>, <ty> <elt>, <ty2> <idx> ; yields <n x  
→<ty>>  
<result> = insertelement <vscale x n x <ty>> <val>, <ty> <elt>, <ty2> <idx> ; yields  
→<vscale x n x <ty>>
```

Overview:

The 'insertelement' instruction inserts a scalar element into a vector at a specified index.

Arguments:

The first operand of an 'insertelement' instruction is a value of *vector* type. The second operand is a scalar value whose type must equal the element type of the first operand. The third operand is an index indicating the position at which to insert the value. The index may be a variable of any integer type.

Semantics:

The result is a vector of the same type as `val`. Its element values are those of `val` except at position `idx`, where it gets the value `elt`. If `idx` exceeds the length of `val` for a fixed-length vector, the result is a *poison value*. For a scalable vector, if the value of `idx` exceeds the runtime length of the vector, the result is a *poison value*.

Example:

```
<result> = insertelement <4 x i32> %vec, i32 1, i32 0 ; yields <4 x i32>
```

'shufflevector' Instruction**Syntax:**

```
<result> = shufflevector <n x <ty>> <v1>, <n x <ty>> <v2>, <m x i32> <mask> ;  
→yields <m x <ty>>  
<result> = shufflevector <vscale x n x <ty>> <v1>, <vscale x n x <ty>> <v2>, <vscale x  
→m x i32> <mask> ; yields <vscale x m x <ty>>
```

Overview:

The 'shufflevector' instruction constructs a permutation of elements from two input vectors, returning a vector with the same element type as the input and length that is the same as the shuffle mask.

Arguments:

The first two operands of a 'shufflevector' instruction are vectors with the same type. The third argument is a shuffle mask whose element type is always 'i32'. The result of the instruction is a vector whose length is the same as the shuffle mask and whose element type is the same as the element type of the first two operands.

The shuffle mask operand is required to be a constant vector with either constant integer or undef values.

Semantics:

The elements of the two input vectors are numbered from left to right across both of the vectors. The shuffle mask operand specifies, for each element of the result vector, which element of the two input vectors the result element gets. If the shuffle mask is undef, the result vector is undef. If any element of the mask operand is undef, that element of the result is undef. If the shuffle mask selects an undef element from one of the input vectors, the resulting element is undef.

For scalable vectors, the only valid mask values at present are `zeroinitializer` and `undef`, since we cannot write all indices as literals for a vector with a length unknown at compile time.

Example:

```

<result> = shufflevector <4 x i32> %v1, <4 x i32> %v2,
    <4 x i32> <i32 0, i32 4, i32 1, i32 5> ; yields <4 x i32>
<result> = shufflevector <4 x i32> %v1, <4 x i32> undef,
    <4 x i32> <i32 0, i32 1, i32 2, i32 3> ; yields <4 x i32> -
↳ Identity shuffle.
<result> = shufflevector <8 x i32> %v1, <8 x i32> undef,
    <4 x i32> <i32 0, i32 1, i32 2, i32 3> ; yields <4 x i32>
<result> = shufflevector <4 x i32> %v1, <4 x i32> %v2,
    <8 x i32> <i32 0, i32 1, i32 2, i32 3, i32 4, i32 5, i32 6,
↳ i32 7 > ; yields <8 x i32>

```

Aggregate Operations

LLVM supports several instructions for working with *aggregate* values.

'extractvalue' Instruction**Syntax:**

```

<result> = extractvalue <aggregate type> <val>, <idx>{, <idx>}*

```

Overview:

The 'extractvalue' instruction extracts the value of a member field from an *aggregate* value.

Arguments:

The first operand of an 'extractvalue' instruction is a value of *struct* or *array* type. The other operands are constant indices to specify which value to extract in a similar manner as indices in a 'getelementptr' instruction.

The major differences to `getelementptr` indexing are:

- Since the value being indexed is not a pointer, the first index is omitted and assumed to be zero.
- At least one index must be specified.
- Not only struct indices but also array indices must be in bounds.

Semantics:

The result is the value at the position in the aggregate specified by the index operands.

Example:

```
<result> = extractvalue {i32, float} %agg, 0 ; yields i32
```

'insertvalue' Instruction**Syntax:**

```
<result> = insertvalue <aggregate type> <val>, <ty> <elt>, <idx>{, <idx>}* ;  
↳yields <aggregate type>
```

Overview:

The 'insertvalue' instruction inserts a value into a member field in an *aggregate* value.

Arguments:

The first operand of an 'insertvalue' instruction is a value of *struct* or *array* type. The second operand is a first-class value to insert. The following operands are constant indices indicating the position at which to insert the value in a similar manner as indices in a 'extractvalue' instruction. The value to insert must have the same type as the value identified by the indices.

Semantics:

The result is an aggregate of the same type as *val*. Its value is that of *val* except that the value at the position specified by the indices is that of *elt*.

Example:

```
%agg1 = insertvalue {i32, float} undef, i32 1, 0 ; yields {i32 1, float  
↳undef}  
%agg2 = insertvalue {i32, float} %agg1, float %val, 1 ; yields {i32 1, float  
↳%val}  
%agg3 = insertvalue {i32, {float}} undef, float %val, 1, 0 ; yields {i32 undef,  
↳{float %val}}
```

Memory Access and Addressing Operations

A key design point of an SSA-based representation is how it represents memory. In LLVM, no memory locations are in SSA form, which makes things very simple. This section describes how to read, write, and allocate memory in LLVM.

'alloca' Instruction

Syntax:

```
<result> = alloca [inalloca] <type> [, <ty> <NumElements>] [, align <alignment>] [, ↪
↪addrspace(<num>)] ; yields type addrspace(num)*:result
```

Overview:

The 'alloca' instruction allocates memory on the stack frame of the currently executing function, to be automatically released when this function returns to its caller. The object is always allocated in the address space for allocas indicated in the datalayout.

Arguments:

The 'alloca' instruction allocates `sizeof(<type>) * NumElements` bytes of memory on the runtime stack, returning a pointer of the appropriate type to the program. If "NumElements" is specified, it is the number of elements allocated, otherwise "NumElements" is defaulted to be one. If a constant alignment is specified, the value result of the allocation is guaranteed to be aligned to at least that boundary. The alignment may not be greater than `1 << 29`. If not specified, or if zero, the target can choose to align the allocation on any convenient boundary compatible with the type.

'type' may be any sized type.

Semantics:

Memory is allocated; a pointer is returned. The allocated memory is uninitialized, and loading from uninitialized memory produces an undefined value. The operation itself is undefined if there is insufficient stack space for the allocation. 'alloca'd memory is automatically released when the function returns. The 'alloca' instruction is commonly used to represent automatic variables that must have an address available. When the function returns (either with the `ret` or `resume` instructions), the memory is reclaimed. Allocating zero bytes is legal, but the returned pointer may not be unique. The order in which memory is allocated (ie., which way the stack grows) is not specified.

Example:

```
%ptr = alloca i32 ; yields i32*:ptr
%ptr = alloca i32, i32 4 ; yields i32*:ptr
%ptr = alloca i32, i32 4, align 1024 ; yields i32*:ptr
%ptr = alloca i32, align 1024 ; yields i32*:ptr
```

'load' Instruction

Syntax:

```
<result> = load [volatile] <ty>, <ty>* <pointer>[, align <alignment>][, !nontemporal !  
↪<index>][, !invariant.load !<index>][, !invariant.group !<index>][, !nonnull !  
↪<index>][, !dereferenceable !<deref_bytes_node>][, !dereferenceable_or_null !<deref_  
↪bytes_node>][, !align !<align_node>]  
<result> = load atomic [volatile] <ty>, <ty>* <pointer> [syncscope("<target-scope>")]  
↪<ordering>, align <alignment> [, !invariant.group !<index>]  
!<index> = !{ i32 1 }  
!<deref_bytes_node> = !{i64 <dereferenceable_bytes>}  
!<align_node> = !{ i64 <value_alignment> }
```

Overview:

The 'load' instruction is used to read from memory.

Arguments:

The argument to the `load` instruction specifies the memory address from which to load. The type specified must be a *first class* type of known size (i.e. not containing an *opaque structural type*). If the load is marked as *volatile*, then the optimizer is not allowed to modify the number or order of execution of this load with other *volatile operations*.

If the load is marked as *atomic*, it takes an extra *ordering* and optional `syncscope("<target-scope>")` argument. The `release` and `acq_rel` orderings are not valid on load instructions. Atomic loads produce *defined* results when they may see multiple atomic stores. The type of the pointee must be an integer, pointer, or floating-point type whose bit width is a power of two greater than or equal to eight and less than or equal to a target-specific size limit. `align` must be explicitly specified on atomic loads, and the load has undefined behavior if the alignment is not set to a value which is at least the size in bytes of the pointee. `!nontemporal` does not have any defined semantics for atomic loads.

The optional constant `align` argument specifies the alignment of the operation (that is, the alignment of the memory address). A value of 0 or an omitted `align` argument means that the operation has the ABI alignment for the target. It is the responsibility of the code emitter to ensure that the alignment information is correct. Overestimating the alignment results in undefined behavior. Underestimating the alignment may produce less efficient code. An alignment of 1 is always safe. The maximum possible alignment is $1 \ll 29$. An alignment value higher than the size of the loaded type implies memory up to the alignment value bytes can be safely loaded without trapping in the default address space. Access of the high bytes can interfere with debugging tools, so should not be accessed if the function has the `sanitize_thread` or `sanitize_address` attributes.

The optional `!nontemporal` metadata must reference a single metadata name `<index>` corresponding to a metadata node with one `i32` entry of value 1. The existence of the `!nontemporal` metadata on the instruction tells the optimizer and code generator that this load is not expected to be reused in the cache. The code generator may select special instructions to save cache bandwidth, such as the `MOVNT` instruction on x86.

The optional `!invariant.load` metadata must reference a single metadata name `<index>` corresponding to a metadata node with no entries. If a load instruction tagged with the `!invariant.load` metadata is executed, the optimizer may assume the memory location referenced by the load contains the same value at all points in the program where the memory location is known to be dereferenceable; otherwise, the behavior is undefined.

The optional `!invariant.group` metadata must reference a single metadata name `<index>` corresponding to a metadata node with no entries. See `invariant.group` metadata.

The optional `!nonnull` metadata must reference a single metadata name `<index>` corresponding to a metadata node with no entries. The existence of the `!nonnull` metadata on the instruction tells the optimizer that the value loaded is known to never be null. If the value is null at runtime, the behavior is undefined. This is analogous to the `nonnull` attribute on parameters and return values. This metadata can only be applied to loads of a pointer type.

The optional `!dereferenceable` metadata must reference a single metadata name `<deref_bytes_node>` corresponding to a metadata node with one `i64` entry. The existence of the `!dereferenceable` metadata on the instruction tells the optimizer that the value loaded is known to be dereferenceable. The number of bytes known to be dereferenceable is specified by the integer value in the metadata node. This is analogous to the "dereferenceable" attribute on parameters and return values. This metadata can only be applied to loads of a pointer type.

The optional `!dereferenceable_or_null` metadata must reference a single metadata name `<deref_bytes_node>` corresponding to a metadata node with one `i64` entry. The existence of the `!dereferenceable_or_null` metadata on the instruction tells the optimizer that the value loaded is known to be either dereferenceable or null. The number of bytes known to be dereferenceable is specified by the integer value in the metadata node. This is analogous to the "dereferenceable_or_null" attribute on parameters and return values. This metadata can only be applied to loads of a pointer type.

The optional `!align` metadata must reference a single metadata name `<align_node>` corresponding to a metadata node with one `i64` entry. The existence of the `!align` metadata on the instruction tells the optimizer that the value loaded is known to be aligned to a boundary specified by the integer value in the metadata node. The alignment must be a power of 2. This is analogous to the "align" attribute on parameters and return values. This metadata can only be applied to loads of a pointer type. If the returned value is not appropriately aligned at runtime, the behavior is undefined.

Semantics:

The location of memory pointed to is loaded. If the value being loaded is of scalar type then the number of bytes read does not exceed the minimum number of bytes needed to hold all bits of the type. For example, loading an `i24` reads at most three bytes. When loading a value of a type like `i20` with a size that is not an integral number of bytes, the result is undefined if the value was not originally written using a store of the same type.

Examples:

```
%ptr = alloca i32                ; yields i32*:ptr
store i32 3, i32* %ptr          ; yields void
%val = load i32, i32* %ptr      ; yields i32:val = i32 3
```

'store' Instruction

Syntax:

```
store [volatile] <ty> <value>, <ty>* <pointer>[, align <alignment>][, !nontemporal !
↳<index>][, !invariant.group !<index>] ; yields void
store atomic [volatile] <ty> <value>, <ty>* <pointer> [syncscope("<target-scope>")]
↳<ordering>, align <alignment> [, !invariant.group !<index>] ; yields void
```

Overview:

The 'store' instruction is used to write to memory.

Arguments:

There are two arguments to the `store` instruction: a value to store and an address at which to store it. The type of the `<pointer>` operand must be a pointer to the *first class* type of the `<value>` operand. If the `store` is marked as *volatile*, then the optimizer is not allowed to modify the number or order of execution of this `store` with other *volatile operations*. Only values of *first class* types of known size (i.e. not containing an *opaque structural type*) can be stored.

If the `store` is marked as *atomic*, it takes an extra *ordering* and optional `syncscope ("<target-scope>")` argument. The `acquire` and `acq_rel` orderings aren't valid on `store` instructions. Atomic loads produce *defined* results when they may see multiple atomic stores. The type of the pointee must be an integer, pointer, or floating-point type whose bit width is a power of two greater than or equal to eight and less than or equal to a target-specific size limit. `align` must be explicitly specified on atomic stores, and the store has undefined behavior if the alignment is not set to a value which is at least the size in bytes of the pointee. `!nontemporal` does not have any defined semantics for atomic stores.

The optional constant `align` argument specifies the alignment of the operation (that is, the alignment of the memory address). A value of 0 or an omitted `align` argument means that the operation has the ABI alignment for the target. It is the responsibility of the code emitter to ensure that the alignment information is correct. Overestimating the alignment results in undefined behavior. Underestimating the alignment may produce less efficient code. An alignment of 1 is always safe. The maximum possible alignment is `1 << 29`. An alignment value higher than the size of the stored type implies memory up to the alignment value bytes can be stored to without trapping in the default address space. Storing to the higher bytes however may result in data races if another thread can access the same address. Introducing a data race is not allowed. Storing to the extra bytes is not allowed even in situations where a data race is known to not exist if the function has the `sanitize_address` attribute.

The optional `!nontemporal` metadata must reference a single metadata name `<index>` corresponding to a metadata node with one `i32` entry of value 1. The existence of the `!nontemporal` metadata on the instruction tells the optimizer and code generator that this load is not expected to be reused in the cache. The code generator may select special instructions to save cache bandwidth, such as the `MOVNT` instruction on x86.

The optional `!invariant.group` metadata must reference a single metadata name `<index>`. See `invariant.group` metadata.

Semantics:

The contents of memory are updated to contain `<value>` at the location specified by the `<pointer>` operand. If `<value>` is of scalar type then the number of bytes written does not exceed the minimum number of bytes needed to hold all bits of the type. For example, storing an `i24` writes at most three bytes. When writing a value of a type like `i20` with a size that is not an integral number of bytes, it is unspecified what happens to the extra bits that do not belong to the type, but they will typically be overwritten.

Example:

```

%ptr = alloca i32                ; yields i32*:ptr
store i32 3, i32* %ptr          ; yields void
%val = load i32, i32* %ptr       ; yields i32:val = i32 3

```

'fence' Instruction**Syntax:**

```
fence [syncscope("<target-scope>")] <ordering> ; yields void
```

Overview:

The 'fence' instruction is used to introduce happens-before edges between operations.

Arguments:

'fence' instructions take an *ordering* argument which defines what *synchronizes-with* edges they add. They can only be given acquire, release, acq_rel, and seq_cst orderings.

Semantics:

A fence A which has (at least) release ordering semantics *synchronizes with* a fence B with (at least) acquire ordering semantics if and only if there exist atomic operations X and Y, both operating on some atomic object M, such that A is sequenced before X, X modifies M (either directly or through some side effect of a sequence headed by X), Y is sequenced before B, and Y observes M. This provides a *happens-before* dependency between A and B. Rather than an explicit fence, one (but not both) of the atomic operations X or Y might provide a release or acquire (resp.) ordering constraint and still *synchronize-with* the explicit fence and establish the *happens-before* edge.

A fence which has seq_cst ordering, in addition to having both acquire and release semantics specified above, participates in the global program order of other seq_cst operations and/or fences.

A fence instruction can also take an optional "*syncscope*" argument.

Example:

```

fence acquire                ; yields void
fence syncscope("singlethread") seq_cst      ; yields void
fence syncscope("agent") seq_cst             ; yields void

```

'cmpxchg' Instruction

Syntax:

```
cmpxchg [weak] [volatile] <ty>* <pointer>, <ty> <cmp>, <ty> <new> [syncscope("<target-  
→scope>")] <success ordering> <failure ordering> ; yields { ty, i1 }
```

Overview:

The 'cmpxchg' instruction is used to atomically modify memory. It loads a value in memory and compares it to a given value. If they are equal, it tries to store a new value into the memory.

Arguments:

There are three arguments to the 'cmpxchg' instruction: an address to operate on, a value to compare to the value currently be at that address, and a new value to place at that address if the compared values are equal. The type of '<cmp>' must be an integer or pointer type whose bit width is a power of two greater than or equal to eight and less than or equal to a target-specific size limit. '<cmp>' and '<new>' must have the same type, and the type of '<pointer>' must be a pointer to that type. If the cmpxchg is marked as *volatile*, then the optimizer is not allowed to modify the number or order of execution of this cmpxchg with other *volatile operations*.

The success and failure *ordering* arguments specify how this cmpxchg synchronizes with other atomic operations. Both ordering parameters must be at least *monotonic*, the ordering constraint on failure must be no stronger than that on success, and the failure ordering cannot be either *release* or *acq_rel*.

A cmpxchg instruction can also take an optional "*syncscope*" argument.

The pointer passed into cmpxchg must have alignment greater than or equal to the size in memory of the operand.

Semantics:

The contents of memory at the location specified by the '<pointer>' operand is read and compared to '<cmp>'; if the values are equal, '<new>' is written to the location. The original value at the location is returned, together with a flag indicating success (true) or failure (false).

If the cmpxchg operation is marked as *weak* then a spurious failure is permitted: the operation may not write <new> even if the comparison matched.

If the cmpxchg operation is strong (the default), the i1 value is 1 if and only if the value loaded equals cmp.

A successful cmpxchg is a read-modify-write instruction for the purpose of identifying release sequences. A failed cmpxchg is equivalent to an atomic load with an ordering parameter determined the second ordering parameter.

Example:

```

entry:
    %orig = load atomic i32, i32* %ptr unordered, align 4           ; yields_
    ↪ i32
    br label %loop

loop:
    %cmp = phi i32 [ %orig, %entry ], [%value_loaded, %loop]
    %squared = mul i32 %cmp, %cmp
    %val_success = cmpxchg i32* %ptr, i32 %cmp, i32 %squared acq_rel monotonic ; yields_
    ↪ { i32, i1 }
    %value_loaded = extractvalue { i32, i1 } %val_success, 0
    %success = extractvalue { i32, i1 } %val_success, 1
    br i1 %success, label %done, label %loop

done:
    ...

```

'atomicrmw' Instruction**Syntax:**

```

atomicrmw [volatile] <operation> <ty>* <pointer>, <ty> <value> [syncscope("<target-
↪ scope>")] <ordering>                               ; yields ty

```

Overview:

The 'atomicrmw' instruction is used to atomically modify memory.

Arguments:

There are three arguments to the 'atomicrmw' instruction: an operation to apply, an address whose value to modify, an argument to the operation. The operation must be one of the following keywords:

- xchg
- add
- sub
- and
- nand
- or
- xor
- max
- min
- umax
- umin

- fadd
- fsub

For most of these operations, the type of '<value>' must be an integer type whose bit width is a power of two greater than or equal to eight and less than or equal to a target-specific size limit. For xchg, this may also be a floating point type with the same size constraints as integers. For fadd/fsub, this must be a floating point type. The type of the '<pointer>' operand must be a pointer to that type. If the `atomicrmw` is marked as `volatile`, then the optimizer is not allowed to modify the number or order of execution of this `atomicrmw` with other *volatile operations*.

A `atomicrmw` instruction can also take an optional "*syncscope*" argument.

Semantics:

The contents of memory at the location specified by the '<pointer>' operand are atomically read, modified, and written back. The original value at the location is returned. The modification is specified by the operation argument:

- xchg: `*ptr = val`
- add: `*ptr = *ptr + val`
- sub: `*ptr = *ptr - val`
- and: `*ptr = *ptr & val`
- nand: `*ptr = ~(*ptr & val)`
- or: `*ptr = *ptr | val`
- xor: `*ptr = *ptr ^ val`
- max: `*ptr = *ptr > val ? *ptr : val` (using a signed comparison)
- min: `*ptr = *ptr < val ? *ptr : val` (using a signed comparison)
- umax: `*ptr = *ptr > val ? *ptr : val` (using an unsigned comparison)
- umin: `*ptr = *ptr < val ? *ptr : val` (using an unsigned comparison)
- fadd: `*ptr = *ptr + val` (using floating point arithmetic)
- fsub: `*ptr = *ptr - val` (using floating point arithmetic)

Example:

```
%old = atomicrmw add i32* %ptr, i32 1 acquire ; yields i32
```

'getelementptr' Instruction

Syntax:

```
<result> = getelementptr <ty>, <ty>* <ptrval>{, [inrange] <ty> <idx>}*  
<result> = getelementptr inbounds <ty>, <ty>* <ptrval>{, [inrange] <ty> <idx>}*  
<result> = getelementptr <ty>, <ptr vector> <ptrval>, [inrange] <vector index type>  
↪<idx>
```

Overview:

The 'getelementptr' instruction is used to get the address of a subelement of an *aggregate* data structure. It performs address calculation only and does not access memory. The instruction can also be used to calculate a vector of such addresses.

Arguments:

The first argument is always a type used as the basis for the calculations. The second argument is always a pointer or a vector of pointers, and is the base address to start from. The remaining arguments are indices that indicate which of the elements of the aggregate object are indexed. The interpretation of each index is dependent on the type being indexed into. The first index always indexes the pointer value given as the second argument, the second index indexes a value of the type pointed to (not necessarily the value directly pointed to, since the first index can be non-zero), etc. The first type indexed into must be a pointer value, subsequent types can be arrays, vectors, and structs. Note that subsequent types being indexed into can never be pointers, since that would require loading the pointer before continuing calculation.

The type of each index argument depends on the type it is indexing into. When indexing into a (optionally packed) structure, only `i32` integer **constants** are allowed (when using a vector of indices they must all be the **same** `i32` integer constant). When indexing into an array, pointer or vector, integers of any width are allowed, and they are not required to be constant. These integers are treated as signed values where relevant.

For example, let's consider a C code fragment and how it gets compiled to LLVM:

```
struct RT {
    char A;
    int B[10][20];
    char C;
};
struct ST {
    int X;
    double Y;
    struct RT Z;
};

int *foo(struct ST *s) {
    return &s[1].Z.B[5][13];
}
```

The LLVM code generated by Clang is:

```
%struct.RT = type { i8, [10 x [20 x i32]], i8 }
%struct.ST = type { i32, double, %struct.RT }

define i32* @foo(%struct.ST* %s) nounwind uwtable readnone optsize ssp {
entry:
    %arrayidx = getelementptr inbounds %struct.ST, %struct.ST* %s, i64 1, i32 2, i32 1,
    ↪ i64 5, i64 13
    ret i32* %arrayidx
}
```

Semantics:

In the example above, the first index is indexing into the '%struct.ST*' type, which is a pointer, yielding a '%struct.ST'='{ i32, double, %struct.RT }' type, a structure. The second index indexes into the third element of the structure, yielding a '%struct.RT'='{ i8 , [10 x [20 x i32]], i8 }' type, another structure. The third index indexes into the second element of the structure, yielding a '[10 x [20 x i32]]' type, an array. The two dimensions of the array are subscripted into, yielding an 'i32' type. The 'getelementptr' instruction returns a pointer to this element, thus computing a value of 'i32*' type.

Note that it is perfectly legal to index partially through a structure, returning a pointer to an inner element. Because of this, the LLVM code for the given testcase is equivalent to:

```
define i32* @foo(%struct.ST* %s) {
    %t1 = getelementptr %struct.ST, %struct.ST* %s, i32 1           ;_
    ↪ yields %struct.ST*:%t1
    %t2 = getelementptr %struct.ST, %struct.ST* %t1, i32 0, i32 2   ;_
    ↪ yields %struct.RT*:%t2
    %t3 = getelementptr %struct.RT, %struct.RT* %t2, i32 0, i32 1  ;_
    ↪ yields [10 x [20 x i32]]*:%t3
    %t4 = getelementptr [10 x [20 x i32]], [10 x [20 x i32]]* %t3, i32 0, i32 5 ;_
    ↪ yields [20 x i32]*:%t4
    %t5 = getelementptr [20 x i32], [20 x i32]* %t4, i32 0, i32 13 ;_
    ↪ yields i32*:%t5
    ret i32* %t5
}
```

If the `inbounds` keyword is present, the result value of the `getelementptr` is a *poison value* if the base pointer is not an *in bounds* address of an allocated object, or if any of the addresses that would be formed by successive addition of the offsets implied by the indices to the base address with infinitely precise signed arithmetic are not an *in bounds* address of that allocated object. The *in bounds* addresses for an allocated object are all the addresses that point into the object, plus the address one byte past the end. The only *in bounds* address for a null pointer in the default address-space is the null pointer itself. In cases where the base is a vector of pointers the `inbounds` keyword applies to each of the computations element-wise.

If the `inbounds` keyword is not present, the offsets are added to the base address with silently-wrapping two's complement arithmetic. If the offsets have a different width from the pointer, they are sign-extended or truncated to the width of the pointer. The result value of the `getelementptr` may be outside the object pointed to by the base pointer. The result value may not necessarily be used to access memory though, even if it happens to point into allocated storage. See the [Pointer Aliasing Rules](#) section for more information.

If the `inrange` keyword is present before any index, loading from or storing to any pointer derived from the `getelementptr` has undefined behavior if the load or store would access memory outside of the bounds of the element selected by the index marked as `inrange`. The result of a pointer comparison or `ptrtoint` (including `ptrtoint`-like operations involving memory) involving a pointer derived from a `getelementptr` with the `inrange` keyword is undefined, with the exception of comparisons in the case where both operands are in the range of the element selected by the `inrange` keyword, inclusive of the address one past the end of that element. Note that the `inrange` keyword is currently only allowed in constant `getelementptr` expressions.

The `getelementptr` instruction is often confusing. For some more insight into how it works, see [the `getelementptr` FAQ](#).

Example:

```

; yields [12 x i8]*:aptr
%aptr = getelementptr {i32, [12 x i8]}, {i32, [12 x i8]}* %saptr, i64 0, i32 1
; yields i8*:vptr
%vptr = getelementptr {i32, <2 x i8>}, {i32, <2 x i8>}* %svptr, i64 0, i32 1, i32 1
; yields i8*:eptr
%eptr = getelementptr [12 x i8], [12 x i8]* %aptr, i64 0, i32 1
; yields i32*:iptr
%iptr = getelementptr [10 x i32], [10 x i32]* @arr, i16 0, i16 0

```

Vector of pointers:

The `getelementptr` returns a vector of pointers, instead of a single address, when one or more of its arguments is a vector. In such cases, all vector arguments should have the same number of elements, and every scalar argument will be effectively broadcast into a vector during address calculation.

```

; All arguments are vectors:
;   A[i] = ptrs[i] + offsets[i]*sizeof(i8)
%A = getelementptr i8, <4 x i8*> %ptrs, <4 x i64> %offsets

; Add the same scalar offset to each pointer of a vector:
;   A[i] = ptrs[i] + offset*sizeof(i8)
%A = getelementptr i8, <4 x i8*> %ptrs, i64 %offset

; Add distinct offsets to the same pointer:
;   A[i] = ptr + offsets[i]*sizeof(i8)
%A = getelementptr i8, i8* %ptr, <4 x i64> %offsets

; In all cases described above the type of the result is <4 x i8*>

```

The two following instructions are equivalent:

```

getelementptr %struct.ST, <4 x %struct.ST*> %s, <4 x i64> %ind1,
  <4 x i32> <i32 2, i32 2, i32 2, i32 2>,
  <4 x i32> <i32 1, i32 1, i32 1, i32 1>,
  <4 x i32> %ind4,
  <4 x i64> <i64 13, i64 13, i64 13, i64 13>

getelementptr %struct.ST, <4 x %struct.ST*> %s, <4 x i64> %ind1,
  i32 2, i32 1, <4 x i32> %ind4, i64 13

```

Let's look at the C code, where the vector version of `getelementptr` makes sense:

```

// Let's assume that we vectorize the following loop:
double *A, *B; int *C;
for (int i = 0; i < size; ++i) {
    A[i] = B[C[i]];
}

```

```

; get pointers for 8 elements from array B
%ptrs = getelementptr double, double* %B, <8 x i32> %C
; load 8 elements from array B into A
%A = call <8 x double> @llvm.masked.gather.v8f64.v8p0f64(<8 x double*> %ptrs,
  i32 8, <8 x i1> %mask, <8 x double> %passthru)

```

Conversion Operations

The instructions in this category are the conversion instructions (casting) which all take a single operand and a type. They perform various bit conversions on the operand.

'trunc .. to' Instruction

Syntax:

```
<result> = trunc <ty> <value> to <ty2>           ; yields ty2
```

Overview:

The 'trunc' instruction truncates its operand to the type `ty2`.

Arguments:

The 'trunc' instruction takes a value to trunc, and a type to trunc it to. Both types must be of *integer* types, or vectors of the same number of integers. The bit size of the `value` must be larger than the bit size of the destination type, `ty2`. Equal sized types are not allowed.

Semantics:

The 'trunc' instruction truncates the high order bits in `value` and converts the remaining bits to `ty2`. Since the source size must be larger than the destination size, `trunc` cannot be a *no-op cast*. It will always truncate bits.

Example:

```
%X = trunc i32 257 to i8           ; yields i8:1
%Y = trunc i32 123 to i1           ; yields i1:true
%Z = trunc i32 122 to i1           ; yields i1:false
%W = trunc <2 x i16> <i16 8, i16 7> to <2 x i8> ; yields <i8 8, i8 7>
```

'zext .. to' Instruction

Syntax:

```
<result> = zext <ty> <value> to <ty2>           ; yields ty2
```

Overview:

The 'zext' instruction zero extends its operand to type `ty2`.

Arguments:

The 'zext' instruction takes a value to cast, and a type to cast it to. Both types must be of *integer* types, or vectors of the same number of integers. The bit size of the `value` must be smaller than the bit size of the destination type, `ty2`.

Semantics:

The `zext` fills the high order bits of the `value` with zero bits until it reaches the size of the destination type, `ty2`.

When zero extending from `i1`, the result will always be either 0 or 1.

Example:

```
%X = zext i32 257 to i64           ; yields i64:257
%Y = zext i1 true to i32          ; yields i32:1
%Z = zext <2 x i16> <i16 8, i16 7> to <2 x i32> ; yields <i32 8, i32 7>
```

'sext .. to' Instruction**Syntax:**

```
<result> = sext <ty> <value> to <ty2>           ; yields ty2
```

Overview:

The 'sext' sign extends `value` to the type `ty2`.

Arguments:

The 'sext' instruction takes a value to cast, and a type to cast it to. Both types must be of *integer* types, or vectors of the same number of integers. The bit size of the `value` must be smaller than the bit size of the destination type, `ty2`.

Semantics:

The 'sext' instruction performs a sign extension by copying the sign bit (highest order bit) of the `value` until it reaches the bit size of the type `ty2`.

When sign extending from `i1`, the extension always results in -1 or 0.

Example:

```
%X = sext i8 -1 to i16 ; yields i16 :65535
%Y = sext i1 true to i32 ; yields i32:-1
%Z = sext <2 x i16> <i16 8, i16 7> to <2 x i32> ; yields <i32 8, i32 7>
```

'fptrunc .. to' Instruction**Syntax:**

```
<result> = fptrunc <ty> <value> to <ty2> ; yields ty2
```

Overview:

The 'fptrunc' instruction truncates value to type ty2.

Arguments:

The 'fptrunc' instruction takes a *floating-point* value to cast and a *floating-point* type to cast it to. The size of value must be larger than the size of ty2. This implies that fptrunc cannot be used to make a *no-op cast*.

Semantics:

The 'fptrunc' instruction casts a value from a larger *floating-point* type to a smaller *floating-point* type. This instruction is assumed to execute in the default *floating-point environment*.

Example:

```
%X = fptrunc double 16777217.0 to float ; yields float:16777216.0
%Y = fptrunc double 1.0E+300 to half ; yields half:+infinity
```

'fpext .. to' Instruction**Syntax:**

```
<result> = fpext <ty> <value> to <ty2> ; yields ty2
```

Overview:

The 'fpext' extends a floating-point value to a larger floating-point value.

Arguments:

The 'fpext' instruction takes a *floating-point* value to cast, and a *floating-point* type to cast it to. The source type must be smaller than the destination type.

Semantics:

The 'fpext' instruction extends the value from a smaller *floating-point* type to a larger *floating-point* type. The fpext cannot be used to make a *no-op cast* because it always changes bits. Use bitcast to make a *no-op cast* for a floating-point cast.

Example:

```
%X = fpext float 3.125 to double      ; yields double:3.125000e+00
%Y = fpext double %X to fp128         ; yields
↳ fp128:0xL00000000000000000400090000000000
```

'fptoui .. to' Instruction**Syntax:**

```
<result> = fptoui <ty> <value> to <ty2>      ; yields ty2
```

Overview:

The 'fptoui' converts a floating-point value to its unsigned integer equivalent of type ty2.

Arguments:

The 'fptoui' instruction takes a value to cast, which must be a scalar or vector *floating-point* value, and a type to cast it to ty2, which must be an *integer* type. If ty is a vector floating-point type, ty2 must be a vector integer type with the same number of elements as ty

Semantics:

The 'fptoui' instruction converts its *floating-point* operand into the nearest (rounding towards zero) unsigned integer value. If the value cannot fit in `ty2`, the result is a *poison value*.

Example:

```
%X = fptoui double 123.0 to i32      ; yields i32:123
%Y = fptoui float 1.0E+300 to i1     ; yields undefined:1
%Z = fptoui float 1.04E+17 to i8     ; yields undefined:1
```

'fptosi .. to' Instruction**Syntax:**

```
<result> = fptosi <ty> <value> to <ty2>          ; yields ty2
```

Overview:

The 'fptosi' instruction converts *floating-point* value to type `ty2`.

Arguments:

The 'fptosi' instruction takes a value to cast, which must be a scalar or vector *floating-point* value, and a type to cast it to `ty2`, which must be an *integer* type. If `ty` is a vector floating-point type, `ty2` must be a vector integer type with the same number of elements as `ty`.

Semantics:

The 'fptosi' instruction converts its *floating-point* operand into the nearest (rounding towards zero) signed integer value. If the value cannot fit in `ty2`, the result is a *poison value*.

Example:

```
%X = fptosi double -123.0 to i32     ; yields i32:-123
%Y = fptosi float 1.0E-247 to i1     ; yields undefined:1
%Z = fptosi float 1.04E+17 to i8     ; yields undefined:1
```

'uitofp .. to' Instruction

Syntax:

```
<result> = uitofp <ty> <value> to <ty2> ; yields ty2
```

Overview:

The 'uitofp' instruction regards `value` as an unsigned integer and converts that value to the `ty2` type.

Arguments:

The 'uitofp' instruction takes a value to cast, which must be a scalar or vector *integer* value, and a type to cast it to `ty2`, which must be an *floating-point* type. If `ty` is a vector integer type, `ty2` must be a vector floating-point type with the same number of elements as `ty`.

Semantics:

The 'uitofp' instruction interprets its operand as an unsigned integer quantity and converts it to the corresponding floating-point value. If the value cannot be exactly represented, it is rounded using the default rounding mode.

Example:

```
%X = uitofp i32 257 to float ; yields float:257.0
%Y = uitofp i8 -1 to double ; yields double:255.0
```

'sitofp .. to' Instruction

Syntax:

```
<result> = sitofp <ty> <value> to <ty2> ; yields ty2
```

Overview:

The 'sitofp' instruction regards `value` as a signed integer and converts that value to the `ty2` type.

Arguments:

The 'sitofp' instruction takes a value to cast, which must be a scalar or vector *integer* value, and a type to cast it to `ty2`, which must be an *floating-point* type. If `ty` is a vector integer type, `ty2` must be a vector floating-point type with the same number of elements as `ty`.

Semantics:

The 'sitofp' instruction interprets its operand as a signed integer quantity and converts it to the corresponding floating-point value. If the value cannot be exactly represented, it is rounded using the default rounding mode.

Example:

```
%X = sitofp i32 257 to float      ; yields float:257.0
%Y = sitofp i8 -1 to double      ; yields double:-1.0
```

'ptrtoint .. to' Instruction

Syntax:

```
<result> = ptrtoint <ty> <value> to <ty2>          ; yields ty2
```

Overview:

The 'ptrtoint' instruction converts the pointer or a vector of pointers `value` to the integer (or vector of integers) type `ty2`.

Arguments:

The 'ptrtoint' instruction takes a `value` to cast, which must be a value of type *pointer* or a vector of pointers, and a type to cast it to `ty2`, which must be an *integer* or a vector of integers type.

Semantics:

The 'ptrtoint' instruction converts `value` to integer type `ty2` by interpreting the pointer value as an integer and either truncating or zero extending that value to the size of the integer type. If `value` is smaller than `ty2` then a zero extension is done. If `value` is larger than `ty2` then a truncation is done. If they are the same size, then nothing is done (*no-op cast*) other than a type change.

Example:

```
%X = ptrtoint i32* %P to i8           ; yields truncation on 32-bit_
↳architecture
%Y = ptrtoint i32* %P to i64         ; yields zero extension on 32-bit_
↳architecture
%Z = ptrtoint <4 x i32*> %P to <4 x i64>; yields vector zero extension for a vector_
↳of addresses on 32-bit architecture
```

'inttoptr .. to' Instruction**Syntax:**

```
<result> = inttoptr <ty> <value> to <ty2>           ; yields ty2
```

Overview:

The 'inttoptr' instruction converts an integer value to a pointer type, ty2.

Arguments:

The 'inttoptr' instruction takes an *integer* value to cast, and a type to cast it to, which must be a *pointer* type.

Semantics:

The 'inttoptr' instruction converts value to type ty2 by applying either a zero extension or a truncation depending on the size of the integer value. If value is larger than the size of a pointer then a truncation is done. If value is smaller than the size of a pointer then a zero extension is done. If they are the same size, nothing is done (*no-op cast*).

Example:

```
%X = inttoptr i32 255 to i32*         ; yields zero extension on 64-bit architecture
%Y = inttoptr i32 255 to i32*         ; yields no-op on 32-bit architecture
%Z = inttoptr i64 0 to i32*           ; yields truncation on 32-bit architecture
%Z = inttoptr <4 x i32> %G to <4 x i8*>; yields truncation of vector G to four_
↳pointers
```

'bitcast .. to' Instruction

Syntax:

```
<result> = bitcast <ty> <value> to <ty2> ; yields ty2
```

Overview:

The 'bitcast' instruction converts `value` to type `ty2` without changing any bits.

Arguments:

The 'bitcast' instruction takes a value to cast, which must be a non-aggregate first class value, and a type to cast it to, which must also be a non-aggregate *first class* type. The bit sizes of `value` and the destination type, `ty2`, must be identical. If the source type is a pointer, the destination type must also be a pointer of the same size. This instruction supports bitwise conversion of vectors to integers and to vectors of other types (as long as they have the same size).

Semantics:

The 'bitcast' instruction converts `value` to type `ty2`. It is always a *no-op cast* because no bits change with this conversion. The conversion is done as if the `value` had been stored to memory and read back as type `ty2`. Pointer (or vector of pointers) types may only be converted to other pointer (or vector of pointers) types with the same address space through this instruction. To convert pointers to other types, use the *inttoptr* or *ptrtoint* instructions first.

Example:

```
%X = bitcast i8 255 to i8 ; yields i8 :-1
%Y = bitcast i32* %x to sint* ; yields sint*:%x
%Z = bitcast <2 x int> %V to i64; ; yields i64: %V
%Z = bitcast <2 x i32*> %V to <2 x i64*> ; yields <2 x i64*>
```

'addrspacecast .. to' Instruction

Syntax:

```
<result> = addrspacecast <pty> <ptrval> to <pty2> ; yields pty2
```

Overview:

The 'addrspacecast' instruction converts `ptrval` from `pty` in address space `n` to type `pty2` in address space `m`.

Arguments:

The 'addrspacecast' instruction takes a pointer or vector of pointer value to cast and a pointer type to cast it to, which must have a different address space.

Semantics:

The 'addrspacecast' instruction converts the pointer value `ptrval` to type `pty2`. It can be a *no-op cast* or a complex value modification, depending on the target and the address space pair. Pointer conversions within the same address space must be performed with the `bitcast` instruction. Note that if the address space conversion is legal then both result and operand refer to the same memory location.

Example:

```
%X = addrspacecast i32* %x to i32 addrspace(1)* ; yields i32 addrspace(1)*:%x
%Y = addrspacecast i32 addrspace(1)* %y to i64 addrspace(2)* ; yields i64_
↳addrspace(2)*:%y
%Z = addrspacecast <4 x i32*> %z to <4 x float addrspace(3)*> ; yields <4 x float_
↳addrspace(3)*:%z
```

Other Operations

The instructions in this category are the "miscellaneous" instructions, which defy better classification.

'icmp' Instruction

Syntax:

```
<result> = icmp <cond> <ty> <op1>, <op2> ; yields i1 or <N x i1>:result
```

Overview:

The 'icmp' instruction returns a boolean value or a vector of boolean values based on comparison of its two integer, integer vector, pointer, or pointer vector operands.

Arguments:

The 'icmp' instruction takes three operands. The first operand is the condition code indicating the kind of comparison to perform. It is not a value, just a keyword. The possible condition codes are:

1. `eq`: equal
2. `ne`: not equal
3. `ugt`: unsigned greater than
4. `uge`: unsigned greater or equal
5. `ult`: unsigned less than
6. `ule`: unsigned less or equal
7. `sgt`: signed greater than
8. `sge`: signed greater or equal
9. `slt`: signed less than
10. `sle`: signed less or equal

The remaining two arguments must be *integer* or *pointer* or integer *vector* typed. They must also be identical types.

Semantics:

The 'icmp' compares `op1` and `op2` according to the condition code given as `cond`. The comparison performed always yields either an *i1* or vector of *i1* result, as follows:

1. `eq`: yields `true` if the operands are equal, `false` otherwise. No sign interpretation is necessary or performed.
2. `ne`: yields `true` if the operands are unequal, `false` otherwise. No sign interpretation is necessary or performed.
3. `ugt`: interprets the operands as unsigned values and yields `true` if `op1` is greater than `op2`.
4. `uge`: interprets the operands as unsigned values and yields `true` if `op1` is greater than or equal to `op2`.
5. `ult`: interprets the operands as unsigned values and yields `true` if `op1` is less than `op2`.
6. `ule`: interprets the operands as unsigned values and yields `true` if `op1` is less than or equal to `op2`.
7. `sgt`: interprets the operands as signed values and yields `true` if `op1` is greater than `op2`.
8. `sge`: interprets the operands as signed values and yields `true` if `op1` is greater than or equal to `op2`.
9. `slt`: interprets the operands as signed values and yields `true` if `op1` is less than `op2`.
10. `sle`: interprets the operands as signed values and yields `true` if `op1` is less than or equal to `op2`.

If the operands are *pointer* typed, the pointer values are compared as if they were integers.

If the operands are integer vectors, then they are compared element by element. The result is an *i1* vector with the same number of elements as the values being compared. Otherwise, the result is an *i1*.

Example:

```

<result> = icmp eq i32 4, 5           ; yields: result=false
<result> = icmp ne float* %X, %X      ; yields: result=false
<result> = icmp ult i16 4, 5          ; yields: result=true
<result> = icmp sgt i16 4, 5          ; yields: result=false
<result> = icmp ule i16 -4, 5         ; yields: result=false
<result> = icmp sge i16 4, 5          ; yields: result=false

```

'fcmp' Instruction**Syntax:**

```

<result> = fcmp [fast-math flags]* <cond> <ty> <op1>, <op2>      ; yields i1 or <N x_
↳i1>:result

```

Overview:

The 'fcmp' instruction returns a boolean value or vector of boolean values based on comparison of its operands.

If the operands are floating-point scalars, then the result type is a boolean (*i1*).

If the operands are floating-point vectors, then the result type is a vector of boolean with the same number of elements as the operands being compared.

Arguments:

The 'fcmp' instruction takes three operands. The first operand is the condition code indicating the kind of comparison to perform. It is not a value, just a keyword. The possible condition codes are:

1. false: no comparison, always returns false
2. oeq: ordered and equal
3. ogt: ordered and greater than
4. oge: ordered and greater than or equal
5. olt: ordered and less than
6. ole: ordered and less than or equal
7. one: ordered and not equal
8. ord: ordered (no nans)
9. ueq: unordered or equal
10. ugt: unordered or greater than
11. uge: unordered or greater than or equal
12. ult: unordered or less than
13. ule: unordered or less than or equal
14. une: unordered or not equal

- 15. `uno`: unordered (either nans)
- 16. `true`: no comparison, always returns true

Ordered means that neither operand is a QNAN while *unordered* means that either operand may be a QNAN.

Each of `val1` and `val2` arguments must be either a *floating-point* type or a *vector* of floating-point type. They must have identical types.

Semantics:

The `fcmp` instruction compares `op1` and `op2` according to the condition code given as `cond`. If the operands are vectors, then the vectors are compared element by element. Each comparison performed always yields an *!i* result, as follows:

- 1. `false`: always yields `false`, regardless of operands.
- 2. `oeq`: yields `true` if both operands are not a QNAN and `op1` is equal to `op2`.
- 3. `ogt`: yields `true` if both operands are not a QNAN and `op1` is greater than `op2`.
- 4. `oge`: yields `true` if both operands are not a QNAN and `op1` is greater than or equal to `op2`.
- 5. `olt`: yields `true` if both operands are not a QNAN and `op1` is less than `op2`.
- 6. `ole`: yields `true` if both operands are not a QNAN and `op1` is less than or equal to `op2`.
- 7. `one`: yields `true` if both operands are not a QNAN and `op1` is not equal to `op2`.
- 8. `ord`: yields `true` if both operands are not a QNAN.
- 9. `ueq`: yields `true` if either operand is a QNAN or `op1` is equal to `op2`.
- 10. `ugt`: yields `true` if either operand is a QNAN or `op1` is greater than `op2`.
- 11. `uge`: yields `true` if either operand is a QNAN or `op1` is greater than or equal to `op2`.
- 12. `ult`: yields `true` if either operand is a QNAN or `op1` is less than `op2`.
- 13. `ule`: yields `true` if either operand is a QNAN or `op1` is less than or equal to `op2`.
- 14. `une`: yields `true` if either operand is a QNAN or `op1` is not equal to `op2`.
- 15. `uno`: yields `true` if either operand is a QNAN.
- 16. `true`: always yields `true`, regardless of operands.

The `fcmp` instruction can also optionally take any number of *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations.

Any set of fast-math flags are legal on an `fcmp` instruction, but the only flags that have any effect on its semantics are those that allow assumptions to be made about the values of input arguments; namely `nnan`, `ninf`, and `reassoc`. See *Fast-Math Flags* for more information.

Example:

```

<result> = fcmp oeq float 4.0, 5.0    ; yields: result=false
<result> = fcmp one float 4.0, 5.0    ; yields: result=true
<result> = fcmp olt float 4.0, 5.0    ; yields: result=true
<result> = fcmp ueq double 1.0, 2.0   ; yields: result=false

```

'phi' Instruction**Syntax:**

```

<result> = phi <ty> [ <val0>, <label0>], ...

```

Overview:

The 'phi' instruction is used to implement the `phi` node in the SSA graph representing the function.

Arguments:

The type of the incoming values is specified with the first type field. After this, the 'phi' instruction takes a list of pairs as arguments, with one pair for each predecessor basic block of the current block. Only values of *first class* type may be used as the value arguments to the PHI node. Only labels may be used as the label arguments.

There must be no non-phi instructions between the start of a basic block and the PHI instructions: i.e. PHI instructions must be first in a basic block.

For the purposes of the SSA form, the use of each incoming value is deemed to occur on the edge from the corresponding predecessor block to the current block (but after any definition of an 'invoke' instruction's return value on the same edge).

Semantics:

At runtime, the 'phi' instruction logically takes on the value specified by the pair corresponding to the predecessor basic block that executed just prior to the current block.

Example:

```

Loop:      ; Infinite loop that counts from 0 on up...
  %indvar = phi i32 [ 0, %LoopHeader ], [ %nextindvar, %Loop ]
  %nextindvar = add i32 %indvar, 1
  br label %Loop

```

'select' Instruction

Syntax:

```
<result> = select [fast-math flags] selty <cond>, <ty> <val1>, <ty> <val2>
↳ ; yields ty

selty is either i1 or {<N x i1>}
```

Overview:

The 'select' instruction is used to choose one value based on a condition, without IR-level branching.

Arguments:

The 'select' instruction requires an 'i1' value or a vector of 'i1' values indicating the condition, and two values of the same *first class* type.

1. The optional `fast-math flags` marker indicates that the select has one or more *fast-math flags*. These are optimization hints to enable otherwise unsafe floating-point optimizations. Fast-math flags are only valid for selects that return a floating-point scalar or vector type.

Semantics:

If the condition is an i1 and it evaluates to 1, the instruction returns the first value argument; otherwise, it returns the second value argument.

If the condition is a vector of i1, then the value arguments must be vectors of the same size, and the selection is done element by element.

If the condition is an i1 and the value arguments are vectors of the same size, then an entire vector is selected.

Example:

```
%X = select i1 true, i8 17, i8 42 ; yields i8:17
```

'call' Instruction

Syntax:

```
<result> = [tail | musttail | notail] call [fast-math flags] [cconv] [ret attrs]
↳ [addrspace(<num>)]
   [<ty>|<fnty> <fnptrval>(<function args>) [fn attrs] [operand bundles ]
```

Overview:

The 'call' instruction represents a simple function call.

Arguments:

This instruction requires several arguments:

1. The optional `tail` and `musttail` markers indicate that the optimizers should perform tail call optimization. The `tail` marker is a hint that *can be ignored*. The `musttail` marker means that the call must be tail call optimized in order for the program to be correct. The `musttail` marker provides these guarantees:
 1. The call will not cause unbounded stack growth if it is part of a recursive cycle in the call graph.
 2. Arguments with the *inalloca* attribute are forwarded in place.
 3. If the `musttail` call appears in a function with the "thunk" attribute and the caller and callee both have varargs, then any unprototyped arguments in register or memory are forwarded to the callee. Similarly, the return value of the callee is returned to the caller's caller, even if a void return type is in use.

Both markers imply that the callee does not access allocas from the caller. The `tail` marker additionally implies that the callee does not access varargs from the caller. Calls marked `musttail` must obey the following additional rules:

- The call must immediately precede a *ret* instruction, or a pointer bitcast followed by a *ret* instruction.
- The *ret* instruction must return the (possibly bitcasted) value produced by the call or void.
- The caller and callee prototypes must match. Pointer types of parameters or return types may differ in pointee type, but not in address space.
- The calling conventions of the caller and callee must match.
- All ABI-impacting function attributes, such as `sret`, `byval`, `inreg`, `returned`, and `inalloca`, must match.
- The callee must be varargs iff the caller is varargs. Bitcasting a non-varargs function to the appropriate varargs type is legal so long as the non-varargs prefixes obey the other rules.

Tail call optimization for calls marked `tail` is guaranteed to occur if the following conditions are met:

- Caller and callee both have the calling convention `fastcc`.
 - The call is in tail position (*ret* immediately follows call and *ret* uses value of call or is void).
 - Option `-tailcallopt` is enabled, or `llvm::GuaranteedTailCallOpt` is true.
 - *Platform-specific constraints are met*.
2. The optional `notail` marker indicates that the optimizers should not add `tail` or `musttail` markers to the call. It is used to prevent tail call optimization from being performed on the call.
 3. The optional `fast-math flags` marker indicates that the call has one or more *fast-math flags*, which are optimization hints to enable otherwise unsafe floating-point optimizations. Fast-math flags are only valid for calls that return a floating-point scalar or vector type.
 4. The optional "cconv" marker indicates which *calling convention* the call should use. If none is specified, the call defaults to using C calling conventions. The calling convention of the call must match the calling convention of the target function, or else the behavior is undefined.
 5. The optional *Parameter Attributes* list for return values. Only 'zeroext', 'signext', and 'inreg' attributes are valid here.

6. The optional `addrspace` attribute can be used to indicate the address space of the called function. If it is not specified, the program address space from the *datalayout string* will be used.
7. `'ty'`: the type of the call instruction itself which is also the type of the return value. Functions that return no value are marked `void`.
8. `'fnty'`: shall be the signature of the function being called. The argument types must match the types implied by this signature. This type can be omitted if the function is not varargs.
9. `'fnptrval'`: An LLVM value containing a pointer to a function to be called. In most cases, this is a direct function call, but indirect `call`'s are just as possible, calling an arbitrary pointer to function value.
10. `'function args'`: argument list whose types match the function signature argument types and parameter attributes. All arguments must be of *first class* type. If the function signature indicates the function accepts a variable number of arguments, the extra arguments can be specified.
11. The optional *function attributes* list.
12. The optional *operand bundles* list.

Semantics:

The `'call'` instruction is used to cause control flow to transfer to a specified function, with its incoming arguments bound to the specified values. Upon a `'ret'` instruction in the called function, control flow continues with the instruction after the function call, and the return value of the function is bound to the result argument.

Example:

```
%retval = call i32 @test(i32 %argc)
call i32 (i8*, ...) @printf(i8* %msg, i32 12, i8 42)      ; yields i32
%X = tail call i32 @foo()                               ; yields i32
%Y = tail call fastcc i32 @foo() ; yields i32
call void @foo(i8 97 signext)

%struct.A = type { i32, i8 }
%r = call %struct.A @foo()                               ; yields { i32, i8 }
%gr = extractvalue %struct.A %r, 0                       ; yields i32
%gr1 = extractvalue %struct.A %r, 1                      ; yields i8
%Z = call void @foo() noreturn                           ; indicates that %foo never returns
↪normally
%ZZ = call zeroext i32 @bar()                             ; Return value is %zero extended
```

llvm treats calls to some functions with names and arguments that match the standard C99 library as being the C99 library functions, and may perform optimizations or generate code for them under that assumption. This is something we'd like to change in the future to provide better support for freestanding environments and non-C-based languages.

'va_arg' Instruction

Syntax:

```
<resultval> = va_arg <va_list*> <arglist>, <argty>
```

Overview:

The 'va_arg' instruction is used to access arguments passed through the "variable argument" area of a function call. It is used to implement the `va_arg` macro in C.

Arguments:

This instruction takes a `va_list*` value and the type of the argument. It returns a value of the specified argument type and increments the `va_list` to point to the next argument. The actual type of `va_list` is target specific.

Semantics:

The 'va_arg' instruction loads an argument of the specified type from the specified `va_list` and causes the `va_list` to point to the next argument. For more information, see the variable argument handling *Intrinsic Functions*.

It is legal for this instruction to be called in a function which does not take a variable number of arguments, for example, the `vfprintf` function.

`va_arg` is an LLVM instruction instead of an *intrinsic function* because it takes a type as an argument.

Example:

See the *variable argument processing* section.

Note that the code generator does not yet fully support `va_arg` on many targets. Also, it does not currently support `va_arg` with aggregate types on any target.

'landingpad' Instruction

Syntax:

```
<resultval> = landingpad <resultty> <clause>+
<resultval> = landingpad <resultty> cleanup <clause>*

<clause> := catch <type> <value>
<clause> := filter <array constant type> <array constant>
```

Overview:

The 'landingpad' instruction is used by LLVM's [exception handling system](#) to specify that a basic block is a landing pad --- one where the exception lands, and corresponds to the code found in the `catch` portion of a `try/catch` sequence. It defines values supplied by the [personality function](#) upon re-entry to the function. The `resultval` has the type `resultty`.

Arguments:

The optional `cleanup` flag indicates that the landing pad block is a cleanup.

A clause begins with the clause type --- `catch` or `filter` --- and contains the global variable representing the "type" that may be caught or filtered respectively. Unlike the `catch` clause, the `filter` clause takes an array constant as its argument. Use "[0 x i8**] undef" for a filter which cannot throw. The 'landingpad' instruction must contain *at least* one clause or the `cleanup` flag.

Semantics:

The 'landingpad' instruction defines the values which are set by the [personality function](#) upon re-entry to the function, and therefore the "result type" of the landingpad instruction. As with calling conventions, how the personality function results are represented in LLVM IR is target specific.

The clauses are applied in order from top to bottom. If two landingpad instructions are merged together through inlining, the clauses from the calling function are appended to the list of clauses. When the call stack is being unwound due to an exception being thrown, the exception is compared against each clause in turn. If it doesn't match any of the clauses, and the `cleanup` flag is not set, then unwinding continues further up the call stack.

The landingpad instruction has several restrictions:

- A landing pad block is a basic block which is the unwind destination of an 'invoke' instruction.
- A landing pad block must have a 'landingpad' instruction as its first non-PHI instruction.
- There can be only one 'landingpad' instruction within the landing pad block.
- A basic block that is not a landing pad block may not include a 'landingpad' instruction.

Example:

```
;; A landing pad which can catch an integer.
%res = landingpad { i8*, i32 }
      catch i8** @_ZTIi
;; A landing pad that is a cleanup.
%res = landingpad { i8*, i32 }
      cleanup
;; A landing pad which can catch an integer and can only throw a double.
%res = landingpad { i8*, i32 }
      catch i8** @_ZTIi
      filter [1 x i8**] [@_ZTId]
```

'catchpad' Instruction

Syntax:

```
<resultval> = catchpad within <catchswitch> [<args>*]
```

Overview:

The 'catchpad' instruction is used by [LLVM's exception handling system](#) to specify that a basic block begins a catch handler --- one where a personality routine attempts to transfer control to catch an exception.

Arguments:

The `catchswitch` operand must always be a token produced by a [catchswitch](#) instruction in a predecessor block. This ensures that each `catchpad` has exactly one predecessor block, and it always terminates in a `catchswitch`.

The `args` correspond to whatever information the personality routine requires to know if this is an appropriate handler for the exception. Control will transfer to the `catchpad` if this is the first appropriate handler for the exception.

The `resultval` has the type [token](#) and is used to match the `catchpad` to corresponding [catchrets](#) and other nested EH pads.

Semantics:

When the call stack is being unwound due to an exception being thrown, the exception is compared against the `args`. If it doesn't match, control will not reach the `catchpad` instruction. The representation of `args` is entirely target and personality function-specific.

Like the [landingpad](#) instruction, the `catchpad` instruction must be the first non-phi of its parent basic block.

The meaning of the tokens produced and consumed by `catchpad` and other "pad" instructions is described in the [Windows exception handling documentation](#).

When a `catchpad` has been "entered" but not yet "exited" (as described in the [EH documentation](#)), it is undefined behavior to execute a [call](#) or [invoke](#) that does not carry an appropriate ["funcler" bundle](#).

Example:

```
dispatch:
  %cs = catchswitch within none [label %handler0] unwind to caller
  ;; A catch block which can catch an integer.
handler0:
  %tok = catchpad within %cs [i8** @_ZTIi]
```

'cleanuppad' Instruction

Syntax:

```
<resultval> = cleanuppad within <parent> [<args>*]
```

Overview:

The 'cleanuppad' instruction is used by [LLVM's exception handling system](#) to specify that a basic block is a cleanup block --- one where a personality routine attempts to transfer control to run cleanup actions. The `args` correspond to whatever additional information the *personality function* requires to execute the cleanup. The `resultval` has the type *token* and is used to match the cleanuppad to corresponding *cleanuprets*. The `parent` argument is the token of the funclet that contains the cleanuppad instruction. If the cleanuppad is not inside a funclet, this operand may be the token `none`.

Arguments:

The instruction takes a list of arbitrary values which are interpreted by the *personality function*.

Semantics:

When the call stack is being unwound due to an exception being thrown, the *personality function* transfers control to the cleanuppad with the aid of the personality-specific arguments. As with calling conventions, how the personality function results are represented in LLVM IR is target specific.

The cleanuppad instruction has several restrictions:

- A cleanup block is a basic block which is the unwind destination of an exceptional instruction.
- A cleanup block must have a 'cleanuppad' instruction as its first non-PHI instruction.
- There can be only one 'cleanuppad' instruction within the cleanup block.
- A basic block that is not a cleanup block may not include a 'cleanuppad' instruction.

When a cleanuppad has been "entered" but not yet "exited" (as described in the [EH documentation](#)), it is undefined behavior to execute a *call* or *invoke* that does not carry an appropriate *"funclet" bundle*.

Example:

```
%tok = cleanuppad within %cs []
```

1.1.15 Intrinsic Functions

LLVM supports the notion of an "intrinsic function". These functions have well known names and semantics and are required to follow certain restrictions. Overall, these intrinsics represent an extension mechanism for the LLVM language that does not require changing all of the transformations in LLVM when adding to the language (or the bitcode reader/writer, the parser, etc...).

Intrinsic function names must all start with an "llvm." prefix. This prefix is reserved in LLVM for intrinsic names; thus, function names may not begin with this prefix. Intrinsic functions must always be external functions: you cannot define the body of intrinsic functions. Intrinsic functions may only be used in call or invoke instructions: it is illegal to take the address of an intrinsic function. Additionally, because intrinsic functions are part of the LLVM language, it is required if any are added that they be documented here.

Some intrinsic functions can be overloaded, i.e., the intrinsic represents a family of functions that perform the same operation but on different data types. Because LLVM can represent over 8 million different integer types, overloading is used commonly to allow an intrinsic function to operate on any integer type. One or more of the argument types or the result type can be overloaded to accept any integer type. Argument types may also be defined as exactly matching a previous argument's type or the result type. This allows an intrinsic function which accepts multiple arguments, but needs all of them to be of the same type, to only be overloaded with respect to a single argument or the result.

Overloaded intrinsics will have the names of its overloaded argument types encoded into its function name, each preceded by a period. Only those types which are overloaded result in a name suffix. Arguments whose type is matched against another type do not. For example, the `llvm.ctpop` function can take an integer of any width and returns an integer of exactly the same integer width. This leads to a family of functions such as `i8 @llvm.ctpop.i8(i8 %val)` and `i29 @llvm.ctpop.i29(i29 %val)`. Only one type, the return type, is overloaded, and only one type suffix is required. Because the argument's type is matched against the return type, it does not require its own name suffix.

For target developers who are defining intrinsics for back-end code generation, any intrinsic overloads based solely the distinction between integer or floating point types should not be relied upon for correct code generation. In such cases, the recommended approach for target maintainers when defining intrinsics is to create separate integer and FP intrinsics rather than rely on overloading. For example, if different codegen is required for `llvm.target.foo(<4 x i32>)` and `llvm.target.foo(<4 x float>)` then these should be split into different intrinsics.

To learn how to add an intrinsic function, please see the [Extending LLVM Guide](#).

Variable Argument Handling Intrinsics

Variable argument support is defined in LLVM with the `va_arg` instruction and these three intrinsic functions. These functions are related to the similarly named macros defined in the `<stdarg.h>` header file.

All of these functions operate on arguments that use a target-specific value type "va_list". The LLVM assembly language reference manual does not define what this type is, so all transformations should be prepared to handle these functions regardless of the type used.

This example shows how the `va_arg` instruction and the variable argument handling intrinsic functions are used.

```
; This struct is different for every platform. For most platforms,
; it is merely an i8*.
%struct.va_list = type { i8* }

; For Unix x86_64 platforms, va_list is the following struct:
; %struct.va_list = type { i32, i32, i8*, i8* }

define i32 @test(i32 %X, ...) {
  ; Initialize variable argument processing
  %ap = alloca %struct.va_list
```

(continues on next page)

(continued from previous page)

```
%ap2 = bitcast %struct.va_list* %ap to i8*
call void @llvm.va_start(i8* %ap2)

; Read a single integer argument
%tmp = va_arg i8* %ap2, i32

; Demonstrate usage of llvm.va_copy and llvm.va_end
%aq = alloca i8*
%aq2 = bitcast i8** %aq to i8*
call void @llvm.va_copy(i8* %aq2, i8* %ap2)
call void @llvm.va_end(i8* %aq2)

; Stop processing of arguments.
call void @llvm.va_end(i8* %ap2)
ret i32 %tmp
}

declare void @llvm.va_start(i8*)
declare void @llvm.va_copy(i8*, i8*)
declare void @llvm.va_end(i8*)
```

'llvm.va_start' Intrinsic

Syntax:

```
declare void @llvm.va_start(i8* <arglist>)
```

Overview:

The 'llvm.va_start' intrinsic initializes *<arglist> for subsequent use by va_arg.

Arguments:

The argument is a pointer to a va_list element to initialize.

Semantics:

The 'llvm.va_start' intrinsic works just like the va_start macro available in C. In a target-dependent way, it initializes the va_list element to which the argument points, so that the next call to va_arg will produce the first variable argument passed to the function. Unlike the C va_start macro, this intrinsic does not need to know the last argument of the function as the compiler can figure that out.

'llvm.va_end' Intrinsic

Syntax:

```
declare void @llvm.va_end(i8* <arglist>)
```

Overview:

The 'llvm.va_end' intrinsic destroys **<arglist>*, which has been initialized previously with `llvm.va_start` or `llvm.va_copy`.

Arguments:

The argument is a pointer to a `va_list` to destroy.

Semantics:

The 'llvm.va_end' intrinsic works just like the `va_end` macro available in C. In a target-dependent way, it destroys the `va_list` element to which the argument points. Calls to *llvm.va_start* and *llvm.va_copy* must be matched exactly with calls to `llvm.va_end`.

'llvm.va_copy' Intrinsic

Syntax:

```
declare void @llvm.va_copy(i8* <destarglist>, i8* <srcarglist>)
```

Overview:

The 'llvm.va_copy' intrinsic copies the current argument position from the source argument list to the destination argument list.

Arguments:

The first argument is a pointer to a `va_list` element to initialize. The second argument is a pointer to a `va_list` element to copy from.

Semantics:

The `'llvm.va_copy'` intrinsic works just like the `va_copy` macro available in C. In a target-dependent way, it copies the source `va_list` element into the destination `va_list` element. This intrinsic is necessary because the `'llvm.va_start'` intrinsic may be arbitrarily complex and require, for example, memory allocation.

Accurate Garbage Collection Intrinsics

LLVM's support for [Accurate Garbage Collection](#) (GC) requires the frontend to generate code containing appropriate intrinsic calls and select an appropriate GC strategy which knows how to lower these intrinsics in a manner which is appropriate for the target collector.

These intrinsics allow identification of *GC roots on the stack*, as well as garbage collector implementations that require *read* and *write* barriers. Frontends for type-safe garbage collected languages should generate these intrinsics to make use of the LLVM garbage collectors. For more details, see [Garbage Collection with LLVM](#).

Experimental Statepoint Intrinsics

LLVM provides an second experimental set of intrinsics for describing garbage collection safepoints in compiled code. These intrinsics are an alternative to the `llvm.gcroot` intrinsics, but are compatible with the ones for *read* and *write* barriers. The differences in approach are covered in the [Garbage Collection with LLVM](#) documentation. The intrinsics themselves are described in *Garbage Collection Safepoints in LLVM*.

'llvm.gcroot' Intrinsic

Syntax:

```
declare void @llvm.gcroot(i8** %ptrloc, i8* %metadata)
```

Overview:

The `'llvm.gcroot'` intrinsic declares the existence of a GC root to the code generator, and allows some metadata to be associated with it.

Arguments:

The first argument specifies the address of a stack object that contains the root pointer. The second pointer (which must be either a constant or a global value address) contains the meta-data to be associated with the root.

Semantics:

At runtime, a call to this intrinsic stores a null pointer into the "ptrloc" location. At compile-time, the code generator generates information to allow the runtime to find the pointer at GC safe points. The 'llvm.gcroot' intrinsic may only be used in a function which *specifies a GC algorithm*.

'llvm.gcread' Intrinsic**Syntax:**

```
declare i8* @llvm.gcread(i8* %ObjPtr, i8** %Ptr)
```

Overview:

The 'llvm.gcread' intrinsic identifies reads of references from heap locations, allowing garbage collector implementations that require read barriers.

Arguments:

The second argument is the address to read from, which should be an address allocated from the garbage collector. The first object is a pointer to the start of the referenced object, if needed by the language runtime (otherwise null).

Semantics:

The 'llvm.gcread' intrinsic has the same semantics as a load instruction, but may be replaced with substantially more complex code by the garbage collector runtime, as needed. The 'llvm.gcread' intrinsic may only be used in a function which *specifies a GC algorithm*.

'llvm.gcwrite' Intrinsic**Syntax:**

```
declare void @llvm.gcwrite(i8* %P1, i8* %Obj, i8** %P2)
```

Overview:

The 'llvm.gcwrite' intrinsic identifies writes of references to heap locations, allowing garbage collector implementations that require write barriers (such as generational or reference counting collectors).

Arguments:

The first argument is the reference to store, the second is the start of the object to store it to, and the third is the address of the field of Obj to store to. If the runtime does not require a pointer to the object, Obj may be null.

Semantics:

The 'llvm.gcwrite' intrinsic has the same semantics as a store instruction, but may be replaced with substantially more complex code by the garbage collector runtime, as needed. The 'llvm.gcwrite' intrinsic may only be used in a function which *specifies a GC algorithm*.

Code Generator Intrinsics

These intrinsics are provided by LLVM to expose special features that may only be implemented with code generator support.

'llvm.returnaddress' Intrinsic

Syntax:

```
declare i8* @llvm.returnaddress(i32 <level>)
```

Overview:

The 'llvm.returnaddress' intrinsic attempts to compute a target-specific value indicating the return address of the current function or one of its callers.

Arguments:

The argument to this intrinsic indicates which function to return the address for. Zero indicates the calling function, one indicates its caller, etc. The argument is **required** to be a constant integer value.

Semantics:

The 'llvm.returnaddress' intrinsic either returns a pointer indicating the return address of the specified call frame, or zero if it cannot be identified. The value returned by this intrinsic is likely to be incorrect or 0 for arguments other than zero, so it should only be used for debugging purposes.

Note that calling this intrinsic does not prevent function inlining or other aggressive transformations, so the value returned may not be that of the obvious source-language caller.

'llvm.addressofreturnaddress' Intrinsic

Syntax:

```
declare i8* @llvm.addressofreturnaddress()
```

Overview:

The 'llvm.addressofreturnaddress' intrinsic returns a target-specific pointer to the place in the stack frame where the return address of the current function is stored.

Semantics:

Note that calling this intrinsic does not prevent function inlining or other aggressive transformations, so the value returned may not be that of the obvious source-language caller.

This intrinsic is only implemented for x86 and aarch64.

'llvm.sponentry' Intrinsic

Syntax:

```
declare i8* @llvm.sponentry()
```

Overview:

The 'llvm.sponentry' intrinsic returns the stack pointer value at the entry of the current function calling this intrinsic.

Semantics:

Note this intrinsic is only verified on AArch64.

'llvm.frameaddress' Intrinsic

Syntax:

```
declare i8* @llvm.frameaddress(i32 <level>)
```

Overview:

The `'llvm.frameaddress'` intrinsic attempts to return the target-specific frame pointer value for the specified stack frame.

Arguments:

The argument to this intrinsic indicates which function to return the frame pointer for. Zero indicates the calling function, one indicates its caller, etc. The argument is **required** to be a constant integer value.

Semantics:

The `'llvm.frameaddress'` intrinsic either returns a pointer indicating the frame address of the specified call frame, or zero if it cannot be identified. The value returned by this intrinsic is likely to be incorrect or 0 for arguments other than zero, so it should only be used for debugging purposes.

Note that calling this intrinsic does not prevent function inlining or other aggressive transformations, so the value returned may not be that of the obvious source-language caller.

'llvm.localescape' and 'llvm.localrecover' Ininsics

Syntax:

```
declare void @llvm.localescape(...)
declare i8* @llvm.localrecover(i8* %func, i8* %fp, i32 %idx)
```

Overview:

The `'llvm.localescape'` intrinsic escapes offsets of a collection of static allocas, and the `'llvm.localrecover'` intrinsic applies those offsets to a live frame pointer to recover the address of the allocation. The offset is computed during frame layout of the caller of `llvm.localescape`.

Arguments:

All arguments to `'llvm.localescape'` must be pointers to static allocas or casts of static allocas. Each function can only call `'llvm.localescape'` once, and it can only do so from the entry block.

The `func` argument to `'llvm.localrecover'` must be a constant bitcasted pointer to a function defined in the current module. The code generator cannot determine the frame allocation offset of functions defined in other modules.

The `fp` argument to `'llvm.localrecover'` must be a frame pointer of a call frame that is currently live. The return value of `'llvm.localaddress'` is one way to produce such a value, but various runtimes also expose a suitable pointer in platform-specific ways.

The `idx` argument to `'llvm.localrecover'` indicates which alloca passed to `'llvm.localescape'` to recover. It is zero-indexed.

Semantics:

These intrinsics allow a group of functions to share access to a set of local stack allocations of a one parent function. The parent function may call the 'llvm.localescape' intrinsic once from the function entry block, and the child functions can use 'llvm.localrecover' to access the escaped allocas. The 'llvm.localescape' intrinsic blocks inlining, as inlining changes where the escaped allocas are allocated, which would break attempts to use 'llvm.localrecover'.

'llvm.read_register' and 'llvm.write_register' Intrinsics**Syntax:**

```
declare i32 @llvm.read_register.i32(metadata)
declare i64 @llvm.read_register.i64(metadata)
declare void @llvm.write_register.i32(metadata, i32 @value)
declare void @llvm.write_register.i64(metadata, i64 @value)
!0 = !{"sp\00"}
```

Overview:

The 'llvm.read_register' and 'llvm.write_register' intrinsics provides access to the named register. The register must be valid on the architecture being compiled to. The type needs to be compatible with the register being read.

Semantics:

The 'llvm.read_register' intrinsic returns the current value of the register, where possible. The 'llvm.write_register' intrinsic sets the current value of the register, where possible.

This is useful to implement named register global variables that need to always be mapped to a specific register, as is common practice on bare-metal programs including OS kernels.

The compiler doesn't check for register availability or use of the used register in surrounding code, including inline assembly. Because of that, allocatable registers are not supported.

Warning: So far it only works with the stack pointer on selected architectures (ARM, AArch64, PowerPC and x86_64). Significant amount of work is needed to support other registers and even more so, allocatable registers.

'llvm.stacksave' Intrinsic**Syntax:**

```
declare i8* @llvm.stacksave()
```

Overview:

The `'llvm.stacksave'` intrinsic is used to remember the current state of the function stack, for use with [llvm.stackrestore](#). This is useful for implementing language features like scoped automatic variable sized arrays in C99.

Semantics:

This intrinsic returns an opaque pointer value that can be passed to [llvm.stackrestore](#). When an `llvm.stackrestore` intrinsic is executed with a value saved from `llvm.stacksave`, it effectively restores the state of the stack to the state it was in when the `llvm.stacksave` intrinsic executed. In practice, this pops any [alloca](#) blocks from the stack that were allocated after the `llvm.stacksave` was executed.

'llvm.stackrestore' Intrinsic**Syntax:**

```
declare void @llvm.stackrestore(i8* %ptr)
```

Overview:

The `'llvm.stackrestore'` intrinsic is used to restore the state of the function stack to the state it was in when the corresponding [llvm.stacksave](#) intrinsic executed. This is useful for implementing language features like scoped automatic variable sized arrays in C99.

Semantics:

See the description for [llvm.stacksave](#).

'llvm.get.dynamic.area.offset' Intrinsic**Syntax:**

```
declare i32 @llvm.get.dynamic.area.offset.i32()
declare i64 @llvm.get.dynamic.area.offset.i64()
```

Overview:

The `'llvm.get.dynamic.area.offset.*'` intrinsic family is used to get the offset from native stack pointer to the address of the most recent dynamic alloca on the caller's stack. These intrinsics are intended for use in combination with [llvm.stacksave](#) to get a pointer to the most recent dynamic alloca. This is useful, for example, for AddressSanitizer's stack unpoisoning routines.

Semantics:

These intrinsics return a non-negative integer value that can be used to get the address of the most recent dynamic alloca, allocated by *alloca* on the caller's stack. In particular, for targets where stack grows downwards, adding this offset to the native stack pointer would get the address of the most recent dynamic alloca. For targets where stack grows upwards, the situation is a bit more complicated, because subtracting this value from stack pointer would get the address one past the end of the most recent dynamic alloca.

Although for most targets *llvm.get.dynamic.area.offset* `<int_get_dynamic_area_offset>` returns just a zero, for others, such as PowerPC and PowerPC64, it returns a compile-time-known constant value.

The return value type of *llvm.get.dynamic.area.offset* must match the target's default address space's (address space 0) pointer type.

'llvm.prefetch' Intrinsic**Syntax:**

```
declare void @llvm.prefetch(i8* <address>, i32 <rw>, i32 <locality>, i32 <cache type>)
```

Overview:

The 'llvm.prefetch' intrinsic is a hint to the code generator to insert a prefetch instruction if supported; otherwise, it is a noop. Prefetches have no effect on the behavior of the program but can change its performance characteristics.

Arguments:

address is the address to be prefetched, *rw* is the specifier determining if the fetch should be for a read (0) or write (1), and *locality* is a temporal locality specifier ranging from (0) - no locality, to (3) - extremely local keep in cache. The *cache type* specifies whether the prefetch is performed on the data (1) or instruction (0) cache. The *rw*, *locality* and *cache type* arguments must be constant integers.

Semantics:

This intrinsic does not modify the behavior of the program. In particular, prefetches cannot trap and do not produce a value. On targets that support this intrinsic, the prefetch can provide hints to the processor cache for better performance.

'llvm.pcmarker' Intrinsic**Syntax:**

```
declare void @llvm.pcmarker(i32 <id>)
```

Overview:

The `'llvm.pcmarker'` intrinsic is a method to export a Program Counter (PC) in a region of code to simulators and other tools. The method is target specific, but it is expected that the marker will use exported symbols to transmit the PC of the marker. The marker makes no guarantees that it will remain with any specific instruction after optimizations. It is possible that the presence of a marker will inhibit optimizations. The intended use is to be inserted after optimizations to allow correlations of simulation runs.

Arguments:

`id` is a numerical id identifying the marker.

Semantics:

This intrinsic does not modify the behavior of the program. Backends that do not support this intrinsic may ignore it.

'llvm.readcyclecounter' Intrinsic**Syntax:**

```
declare i64 @llvm.readcyclecounter()
```

Overview:

The `'llvm.readcyclecounter'` intrinsic provides access to the cycle counter register (or similar low latency, high accuracy clocks) on those targets that support it. On X86, it should map to RDTSC. On Alpha, it should map to RPCC. As the backing counters overflow quickly (on the order of 9 seconds on alpha), this should only be used for small timings.

Semantics:

When directly supported, reading the cycle counter should not modify any memory. Implementations are allowed to either return a application specific value or a system wide value. On backends without support, this is lowered to a constant 0.

Note that runtime support may be conditional on the privilege-level code is running at and the host platform.

'llvm.clear_cache' Intrinsic**Syntax:**

```
declare void @llvm.clear_cache(i8*, i8*)
```

Overview:

The 'llvm.clear_cache' intrinsic ensures visibility of modifications in the specified range to the execution unit of the processor. On targets with non-unified instruction and data cache, the implementation flushes the instruction cache.

Semantics:

On platforms with coherent instruction and data caches (e.g. x86), this intrinsic is a nop. On platforms with non-coherent instruction and data cache (e.g. ARM, MIPS), the intrinsic is lowered either to appropriate instructions or a system call, if cache flushing requires special privileges.

The default behavior is to emit a call to `__clear_cache` from the run time library.

This intrinsic does *not* empty the instruction pipeline. Modifications of the current function are outside the scope of the intrinsic.

'llvm.instrprof.increment' Intrinsic**Syntax:**

```
declare void @llvm.instrprof.increment(i8* <name>, i64 <hash>,
                                     i32 <num-counters>, i32 <index>)
```

Overview:

The 'llvm.instrprof.increment' intrinsic can be emitted by a frontend for use with instrumentation based profiling. These will be lowered by the `-instrprof` pass to generate execution counts of a program at runtime.

Arguments:

The first argument is a pointer to a global variable containing the name of the entity being instrumented. This should generally be the (mangled) function name for a set of counters.

The second argument is a hash value that can be used by the consumer of the profile data to detect changes to the instrumented source, and the third is the number of counters associated with `name`. It is an error if `hash` or `num-counters` differ between two instances of `instrprof.increment` that refer to the same name.

The last argument refers to which of the counters for `name` should be incremented. It should be a value between 0 and `num-counters`.

Semantics:

This intrinsic represents an increment of a profiling counter. It will cause the `-instrprof` pass to generate the appropriate data structures and the code to increment the appropriate value, in a format that can be written out by a compiler runtime and consumed via the `llvm-profdata` tool.

'llvm.instrprof.increment.step' Intrinsic

Syntax:

```
declare void @llvm.instrprof.increment.step(i8* <name>, i64 <hash>,  
                                           i32 <num-counters>,  
                                           i32 <index>, i64 <step>)
```

Overview:

The `'llvm.instrprof.increment.step'` intrinsic is an extension to the `'llvm.instrprof.increment'` intrinsic with an additional fifth argument to specify the step of the increment.

Arguments:

The first four arguments are the same as `'llvm.instrprof.increment'` intrinsic.

The last argument specifies the value of the increment of the counter variable.

Semantics:

See description of `'llvm.instrprof.increment'` intrinsic.

'llvm.instrprof.value.profile' Intrinsic

Syntax:

```
declare void @llvm.instrprof.value.profile(i8* <name>, i64 <hash>,  
                                           i64 <value>, i32 <value_kind>,  
                                           i32 <index>)
```

Overview:

The `'llvm.instrprof.value.profile'` intrinsic can be emitted by a frontend for use with instrumentation based profiling. This will be lowered by the `-instrprof` pass to find out the target values, instrumented expressions take in a program at runtime.

Arguments:

The first argument is a pointer to a global variable containing the name of the entity being instrumented. `name` should generally be the (mangled) function name for a set of counters.

The second argument is a hash value that can be used by the consumer of the profile data to detect changes to the instrumented source. It is an error if `hash` differs between two instances of `llvm.instrprof.*` that refer to the same name.

The third argument is the value of the expression being profiled. The profiled expression's value should be representable as an unsigned 64-bit value. The fourth argument represents the kind of value profiling that is being done. The supported value profiling kinds are enumerated through the `InstrProfValueKind` type declared in the `<include/llvm/ProfileData/InstrProf.h>` header file. The last argument is the index of the instrumented expression within `name`. It should be `>= 0`.

Semantics:

This intrinsic represents the point where a call to a runtime routine should be inserted for value profiling of target expressions. `-instrprof` pass will generate the appropriate data structures and replace the `llvm.instrprof.value.profile` intrinsic with the call to the profile runtime library with proper arguments.

'llvm.thread.pointer' Intrinsic**Syntax:**

```
declare i8* @llvm.thread.pointer()
```

Overview:

The `'llvm.thread.pointer'` intrinsic returns the value of the thread pointer.

Semantics:

The `'llvm.thread.pointer'` intrinsic returns a pointer to the TLS area for the current thread. The exact semantics of this value are target specific: it may point to the start of TLS area, to the end, or somewhere in the middle. Depending on the target, this intrinsic may read a register, call a helper function, read from an alternate memory space, or perform other operations necessary to locate the TLS area. Not all targets support this intrinsic.

Standard C Library Intrinsics

LLVM provides intrinsics for a few important standard C library functions. These intrinsics allow source-language front-ends to pass information about the alignment of the pointer arguments to the code generator, providing opportunity for more efficient code generation.

'llvm.memcpy' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.memcpy` on any integer bit width and for different address spaces. Not all targets support all bit widths however.

```
declare void @llvm.memcpy.p0i8.p0i8.i32(i8* <dest>, i8* <src>,  
                                         i32 <len>, i1 <isvolatile>)  
declare void @llvm.memcpy.p0i8.p0i8.i64(i8* <dest>, i8* <src>,  
                                         i64 <len>, i1 <isvolatile>)
```

Overview:

The `'llvm.memcpy.*'` intrinsics copy a block of memory from the source location to the destination location.

Note that, unlike the standard `libc` function, the `llvm.memcpy.*` intrinsics do not return a value, takes extra `isvolatile` arguments and the pointers can be in specified address spaces.

Arguments:

The first argument is a pointer to the destination, the second is a pointer to the source. The third argument is an integer argument specifying the number of bytes to copy, and the fourth is a boolean indicating a volatile access.

The *align* parameter attribute can be provided for the first and second arguments.

If the `isvolatile` parameter is `true`, the `llvm.memcpy` call is a *volatile operation*. The detailed access behavior is not very cleanly specified and it is unwise to depend on it.

Semantics:

The `'llvm.memcpy.*'` intrinsics copy a block of memory from the source location to the destination location, which are not allowed to overlap. It copies "len" bytes of memory over. If the argument is known to be aligned to some boundary, this can be specified as an attribute on the argument.

If "len" is 0, the pointers may be NULL or dangling. However, they must still be appropriately aligned.

'llvm.memmove' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.memmove` on any integer bit width and for different address space. Not all targets support all bit widths however.

```
declare void @llvm.memmove.p0i8.p0i8.i32(i8* <dest>, i8* <src>,  
                                           i32 <len>, i1 <isvolatile>)  
declare void @llvm.memmove.p0i8.p0i8.i64(i8* <dest>, i8* <src>,  
                                           i64 <len>, i1 <isvolatile>)
```

Overview:

The `'llvm.memmove.*'` intrinsics move a block of memory from the source location to the destination location. It is similar to the `'llvm.memcpy'` intrinsic but allows the two memory locations to overlap.

Note that, unlike the standard libc function, the `llvm.memmove.*` intrinsics do not return a value, takes an extra `isvolatile` argument and the pointers can be in specified address spaces.

Arguments:

The first argument is a pointer to the destination, the second is a pointer to the source. The third argument is an integer argument specifying the number of bytes to copy, and the fourth is a boolean indicating a volatile access.

The *align* parameter attribute can be provided for the first and second arguments.

If the `isvolatile` parameter is `true`, the `llvm.memmove` call is a *volatile operation*. The detailed access behavior is not very cleanly specified and it is unwise to depend on it.

Semantics:

The `'llvm.memmove.*'` intrinsics copy a block of memory from the source location to the destination location, which may overlap. It copies "len" bytes of memory over. If the argument is known to be aligned to some boundary, this can be specified as an attribute on the argument.

If "len" is 0, the pointers may be NULL or dangling. However, they must still be appropriately aligned.

'llvm.memset.*' Intrinsics

Syntax:

This is an overloaded intrinsic. You can use `llvm.memset` on any integer bit width and for different address spaces. However, not all targets support all bit widths.

```
declare void @llvm.memset.p0i8.i32(i8* <dest>, i8 <val>,
                                   i32 <len>, i1 <isvolatile>)
declare void @llvm.memset.p0i8.i64(i8* <dest>, i8 <val>,
                                   i64 <len>, i1 <isvolatile>)
```

Overview:

The `'llvm.memset.*'` intrinsics fill a block of memory with a particular byte value.

Note that, unlike the standard libc function, the `llvm.memset` intrinsic does not return a value and takes an extra `volatile` argument. Also, the destination can be in an arbitrary address space.

Arguments:

The first argument is a pointer to the destination to fill, the second is the byte value with which to fill it, the third argument is an integer argument specifying the number of bytes to fill, and the fourth is a boolean indicating a volatile access.

The *align* parameter attribute can be provided for the first arguments.

If the `isvolatile` parameter is `true`, the `llvm.memset` call is a *volatile operation*. The detailed access behavior is not very cleanly specified and it is unwise to depend on it.

Semantics:

The `'llvm.memset.*'` intrinsics fill "len" bytes of memory starting at the destination location. If the argument is known to be aligned to some boundary, this can be specified as an attribute on the argument.

If "len" is 0, the pointers may be NULL or dangling. However, they must still be appropriately aligned.

'llvm.sqrt.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.sqrt` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.sqrt.f32(float %Val)
declare double     @llvm.sqrt.f64(double %Val)
declare x86_fp80   @llvm.sqrt.f80(x86_fp80 %Val)
declare fp128      @llvm.sqrt.f128(fp128 %Val)
declare ppc_fp128  @llvm.sqrt.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.sqrt'` intrinsics return the square root of the specified value.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'sqrt'` function but without trapping or setting `errno`. For types specified by IEEE-754, the result matches a conforming libm implementation.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.powi.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.powi` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.powi.f32(float  %Val, i32 %power)
declare double     @llvm.powi.f64(double %Val, i32 %power)
declare x86_fp80   @llvm.powi.f80(x86_fp80 %Val, i32 %power)
declare fp128      @llvm.powi.f128(fp128 %Val, i32 %power)
declare ppc_fp128  @llvm.powi.ppcf128(ppc_fp128 %Val, i32 %power)
```

Overview:

The `'llvm.powi.*'` intrinsics return the first operand raised to the specified (positive or negative) power. The order of evaluation of multiplications is not defined. When a vector of floating-point type is used, the second argument remains a scalar integer value.

Arguments:

The second argument is an integer power, and the first is a value to raise to that power.

Semantics:

This function returns the first value raised to the second power with an unspecified sequence of rounding operations.

'llvm.sin.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.sin` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.sin.f32(float  %Val)
declare double     @llvm.sin.f64(double %Val)
declare x86_fp80   @llvm.sin.f80(x86_fp80 %Val)
declare fp128      @llvm.sin.f128(fp128 %Val)
declare ppc_fp128  @llvm.sin.ppcf128(ppc_fp128 %Val)
```

Overview:

The `'llvm.sin.*'` intrinsics return the sine of the operand.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'sin'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

`'llvm.cos.*'` Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.cos` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.cos.f32(float  %Val)
declare double     @llvm.cos.f64(double %Val)
declare x86_fp80   @llvm.cos.f80(x86_fp80 %Val)
declare fp128      @llvm.cos.f128(fp128 %Val)
declare ppc_fp128  @llvm.cos.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.cos.*'` intrinsics return the cosine of the operand.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'cos'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.pow.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.pow` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.pow.f32(float  %Val, float %Power)
declare double     @llvm.pow.f64(double %Val, double %Power)
declare x86_fp80   @llvm.pow.f80(x86_fp80 %Val, x86_fp80 %Power)
declare fp128      @llvm.pow.f128(fp128 %Val, fp128 %Power)
declare ppc_fp128  @llvm.pow.ppcf128(ppc_fp128 %Val, ppc_fp128 %Power)
```

Overview:

The `'llvm.pow.*'` intrinsics return the first operand raised to the specified (positive or negative) power.

Arguments:

The arguments and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'pow'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.exp.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.exp` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.exp.f32(float  %Val)
declare double     @llvm.exp.f64(double %Val)
declare x86_fp80   @llvm.exp.f80(x86_fp80 %Val)
declare fp128      @llvm.exp.f128(fp128 %Val)
declare ppc_fp128  @llvm.exp.ppcf128(ppc_fp128 %Val)
```

Overview:

The `'llvm.exp.*'` intrinsics compute the base-e exponential of the specified value.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'exp'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.exp2.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.exp2` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.exp2.f32(float  %Val)
declare double     @llvm.exp2.f64(double %Val)
declare x86_fp80   @llvm.exp2.f80(x86_fp80 %Val)
declare fp128      @llvm.exp2.f128(fp128 %Val)
declare ppc_fp128  @llvm.exp2.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.exp2.*'` intrinsics compute the base-2 exponential of the specified value.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'exp2'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.log.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.log` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.log.f32(float  %Val)
declare double     @llvm.log.f64(double %Val)
declare x86_fp80   @llvm.log.f80(x86_fp80 %Val)
declare fp128      @llvm.log.f128(fp128 %Val)
declare ppc_fp128  @llvm.log.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.log.*'` intrinsics compute the base-e logarithm of the specified value.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'log'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.log10.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.log10` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.log10.f32(float  %Val)
declare double     @llvm.log10.f64(double %Val)
declare x86_fp80   @llvm.log10.f80(x86_fp80 %Val)
declare fp128      @llvm.log10.f128(fp128 %Val)
declare ppc_fp128  @llvm.log10.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.log10.*'` intrinsics compute the base-10 logarithm of the specified value.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'log10'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.log2.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.log2` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.log2.f32(float  %Val)
declare double     @llvm.log2.f64(double %Val)
declare x86_fp80   @llvm.log2.f80(x86_fp80 %Val)
declare fp128      @llvm.log2.f128(fp128 %Val)
declare ppc_fp128  @llvm.log2.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.log2.*'` intrinsics compute the base-2 logarithm of the specified value.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm `'log2'` function but without trapping or setting `errno`.

When specified with the fast-math-flag `'afn'`, the result may be approximated using a less accurate calculation.

'llvm.fma.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.fma` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.fma.f32(float  %a, float  %b, float  %c)
declare double     @llvm.fma.f64(double %a, double %b, double %c)
declare x86_fp80   @llvm.fma.f80(x86_fp80 %a, x86_fp80 %b, x86_fp80 %c)
declare fp128      @llvm.fma.f128(fp128 %a, fp128 %b, fp128 %c)
declare ppc_fp128  @llvm.fma.ppcf128(ppc_fp128 %a, ppc_fp128 %b, ppc_fp128 %c)
```

Overview:

The 'llvm.fma.*' intrinsics perform the fused multiply-add operation.

Arguments:

The arguments and return value are floating-point numbers of the same type.

Semantics:

Return the same value as a corresponding libm 'fma' function but without trapping or setting `errno`.

When specified with the fast-math-flag 'afn', the result may be approximated using a less accurate calculation.

'llvm.fabs.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.fabs` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.fabs.f32(float  %Val)
declare double     @llvm.fabs.f64(double %Val)
declare x86_fp80   @llvm.fabs.f80(x86_fp80 %Val)
declare fp128      @llvm.fabs.f128(fp128 %Val)
declare ppc_fp128  @llvm.fabs.ppcf128(ppc_fp128 %Val)
```

Overview:

The `'llvm.fabs.*'` intrinsics return the absolute value of the operand.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm fabs` functions would, and handles error conditions in the same way.

'llvm.minnum.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.minnum` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.minnum.f32(float %Val0, float %Val1)
declare double     @llvm.minnum.f64(double %Val0, double %Val1)
declare x86_fp80   @llvm.minnum.f80(x86_fp80 %Val0, x86_fp80 %Val1)
declare fp128      @llvm.minnum.f128(fp128 %Val0, fp128 %Val1)
declare ppc_fp128  @llvm.minnum.ppcfp128(ppc_fp128 %Val0, ppc_fp128 %Val1)
```

Overview:

The `'llvm.minnum.*'` intrinsics return the minimum of the two arguments.

Arguments:

The arguments and return value are floating-point numbers of the same type.

Semantics:

Follows the IEEE-754 semantics for `minNum`, except for handling of signaling NaNs. This matches the behavior of `libm's fmin`.

If either operand is a NaN, returns the other non-NaN operand. Returns NaN only if both operands are NaN. The returned NaN is always quiet. If the operands compare equal, returns a value that compares equal to both operands. This means that `fmin(+/-0.0, +/-0.0)` could return either `-0.0` or `0.0`.

Unlike the IEEE-754 2008 behavior, this does not distinguish between signaling and quiet NaN inputs. If a target's implementation follows the standard and returns a quiet NaN if either input is a signaling NaN, the intrinsic lowering is responsible for quieting the inputs to correctly return the non-NaN input (e.g. by using the equivalent of `llvm.canonicalize`).

'llvm.maxnum.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.maxnum` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.maxnum.f32(float %Val0, float %Val1)
declare double     @llvm.maxnum.f64(double %Val0, double %Val1)
declare x86_fp80   @llvm.maxnum.f80(x86_fp80 %Val0, x86_fp80 %Val1)
declare fp128      @llvm.maxnum.f128(fp128 %Val0, fp128 %Val1)
declare ppc_fp128  @llvm.maxnum.ppcfp128(ppcfp128 %Val0, ppcfp128 %Val1)
```

Overview:

The `'llvm.maxnum.*'` intrinsics return the maximum of the two arguments.

Arguments:

The arguments and return value are floating-point numbers of the same type.

Semantics:

Follows the IEEE-754 semantics for `maxNum` except for the handling of signaling NaNs. This matches the behavior of `libm's fmax`.

If either operand is a NaN, returns the other non-NaN operand. Returns NaN only if both operands are NaN. The returned NaN is always quiet. If the operands compare equal, returns a value that compares equal to both operands. This means that `fmax(+/-0.0, +/-0.0)` could return either `-0.0` or `0.0`.

Unlike the IEEE-754 2008 behavior, this does not distinguish between signaling and quiet NaN inputs. If a target's implementation follows the standard and returns a quiet NaN if either input is a signaling NaN, the intrinsic lowering is responsible for quieting the inputs to correctly return the non-NaN input (e.g. by using the equivalent of `llvm.canonicalize`).

'llvm.minimum.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.minimum` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.minimum.f32(float %Val0, float %Val1)
declare double     @llvm.minimum.f64(double %Val0, double %Val1)
declare x86_fp80   @llvm.minimum.f80(x86_fp80 %Val0, x86_fp80 %Val1)
declare fp128      @llvm.minimum.f128(fp128 %Val0, fp128 %Val1)
declare ppc_fp128  @llvm.minimum.ppcfp128(ppcfp128 %Val0, ppcfp128 %Val1)
```

Overview:

The `'llvm.minimum.*'` intrinsics return the minimum of the two arguments, propagating NaNs and treating -0.0 as less than +0.0.

Arguments:

The arguments and return value are floating-point numbers of the same type.

Semantics:

If either operand is a NaN, returns NaN. Otherwise returns the lesser of the two arguments. -0.0 is considered to be less than +0.0 for this intrinsic. Note that these are the semantics specified in the draft of IEEE 754-2018.

`'llvm.maximum.*'` Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.maximum` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.maximum.f32(float %Val0, float %Val1)
declare double     @llvm.maximum.f64(double %Val0, double %Val1)
declare x86_fp80    @llvm.maximum.f80(x86_fp80 %Val0, x86_fp80 %Val1)
declare fp128       @llvm.maximum.f128(fp128 %Val0, fp128 %Val1)
declare ppc_fp128   @llvm.maximum.ppcfp128(ppcfp128 %Val0, ppcfp128 %Val1)
```

Overview:

The `'llvm.maximum.*'` intrinsics return the maximum of the two arguments, propagating NaNs and treating -0.0 as less than +0.0.

Arguments:

The arguments and return value are floating-point numbers of the same type.

Semantics:

If either operand is a NaN, returns NaN. Otherwise returns the greater of the two arguments. -0.0 is considered to be less than +0.0 for this intrinsic. Note that these are the semantics specified in the draft of IEEE 754-2018.

'llvm.copysign.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.copysign` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.copysign.f32(float %Mag, float %Sgn)
declare double     @llvm.copysign.f64(double %Mag, double %Sgn)
declare x86_fp80   @llvm.copysign.f80(x86_fp80 %Mag, x86_fp80 %Sgn)
declare fp128      @llvm.copysign.f128(fp128 %Mag, fp128 %Sgn)
declare ppc_fp128  @llvm.copysign.ppcf128(ppc_fp128 %Mag, ppc_fp128 %Sgn)
```

Overview:

The `'llvm.copysign.*'` intrinsics return a value with the magnitude of the first operand and the sign of the second operand.

Arguments:

The arguments and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm copysign` functions would, and handles error conditions in the same way.

'llvm.floor.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.floor` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.floor.f32(float %Val)
declare double     @llvm.floor.f64(double %Val)
declare x86_fp80   @llvm.floor.f80(x86_fp80 %Val)
declare fp128      @llvm.floor.f128(fp128 %Val)
declare ppc_fp128  @llvm.floor.ppcf128(ppc_fp128 %Val)
```

Overview:

The `'llvm.floor.*'` intrinsics return the floor of the operand.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm floor` functions would, and handles error conditions in the same way.

'llvm.ceil.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.ceil` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.ceil.f32(float  %Val)
declare double     @llvm.ceil.f64(double %Val)
declare x86_fp80   @llvm.ceil.f80(x86_fp80 %Val)
declare fp128      @llvm.ceil.f128(fp128 %Val)
declare ppc_fp128  @llvm.ceil.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.ceil.*'` intrinsics return the ceiling of the operand.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm ceil` functions would, and handles error conditions in the same way.

'llvm.trunc.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.trunc` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.trunc.f32(float  %Val)
declare double     @llvm.trunc.f64(double %Val)
declare x86_fp80   @llvm.trunc.f80(x86_fp80 %Val)
declare fp128      @llvm.trunc.f128(fp128 %Val)
declare ppc_fp128  @llvm.trunc.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.trunc.*'` intrinsics returns the operand rounded to the nearest integer not larger in magnitude than the operand.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm trunc` functions would, and handles error conditions in the same way.

'llvm.rint.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.rint` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.rint.f32(float  %Val)
declare double     @llvm.rint.f64(double %Val)
declare x86_fp80   @llvm.rint.f80(x86_fp80 %Val)
declare fp128      @llvm.rint.f128(fp128 %Val)
declare ppc_fp128  @llvm.rint.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.rint.*'` intrinsics returns the operand rounded to the nearest integer. It may raise an inexact floating-point exception if the operand isn't an integer.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm rint` functions would, and handles error conditions in the same way.

'llvm.nearbyint.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.nearbyint` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float      @llvm.nearbyint.f32(float %Val)
declare double     @llvm.nearbyint.f64(double %Val)
declare x86_fp80    @llvm.nearbyint.f80(x86_fp80 %Val)
declare fp128      @llvm.nearbyint.f128(fp128 %Val)
declare ppc_fp128   @llvm.nearbyint.ppcfp128(ppc_fp128 %Val)
```

Overview:

The `'llvm.nearbyint.*'` intrinsics returns the operand rounded to the nearest integer.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm nearbyint` functions would, and handles error conditions in the same way.

'llvm.round.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.round` on any floating-point or vector of floating-point type. Not all targets support all types however.

```
declare float    @llvm.round.f32(float  %Val)
declare double   @llvm.round.f64(double %Val)
declare x86_fp80 @llvm.round.f80(x86_fp80 %Val)
declare fp128    @llvm.round.f128(fp128 %Val)
declare ppc_fp128 @llvm.round.ppcfp128(ppcfp128 %Val)
```

Overview:

The `'llvm.round.*'` intrinsics returns the operand rounded to the nearest integer.

Arguments:

The argument and return value are floating-point numbers of the same type.

Semantics:

This function returns the same values as the `libm` `round` functions would, and handles error conditions in the same way.

'llvm.lround.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.lround` on any floating-point type. Not all targets support all types however.

```
declare i32 @llvm.lround.i32.f32(float %Val)
declare i32 @llvm.lround.i32.f64(double %Val)
declare i32 @llvm.lround.i32.f80(float %Val)
declare i32 @llvm.lround.i32.f128(double %Val)
declare i32 @llvm.lround.i32.ppcfp128(double %Val)

declare i64 @llvm.lround.i64.f32(float %Val)
declare i64 @llvm.lround.i64.f64(double %Val)
declare i64 @llvm.lround.i64.f80(float %Val)
declare i64 @llvm.lround.i64.f128(double %Val)
declare i64 @llvm.lround.i64.ppcfp128(double %Val)
```

Overview:

The `'llvm.lround.*'` intrinsics returns the operand rounded to the nearest integer.

Arguments:

The argument is a floating-point number and return is an integer type.

Semantics:

This function returns the same values as the `libm lround` functions would, but without setting `errno`.

'llvm.llround.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.llround` on any floating-point type. Not all targets support all types however.

```
declare i64 @llvm.llround.i64.f32(float %Val)
declare i64 @llvm.llround.i64.f64(double %Val)
declare i64 @llvm.llround.i64.f80(float %Val)
declare i64 @llvm.llround.i64.f128(double %Val)
declare i64 @llvm.llround.i64.ppcf128(double %Val)
```

Overview:

The `'llvm.llround.*'` intrinsics returns the operand rounded to the nearest integer.

Arguments:

The argument is a floating-point number and return is an integer type.

Semantics:

This function returns the same values as the `libm llround` functions would, but without setting `errno`.

'llvm.lrint.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.lrint` on any floating-point type. Not all targets support all types however.

```
declare i32 @llvm.lrint.i32.f32(float %Val)
declare i32 @llvm.lrint.i32.f64(double %Val)
declare i32 @llvm.lrint.i32.f80(float %Val)
declare i32 @llvm.lrint.i32.f128(double %Val)
declare i32 @llvm.lrint.i32.ppcf128(double %Val)

declare i64 @llvm.lrint.i64.f32(float %Val)
declare i64 @llvm.lrint.i64.f64(double %Val)
declare i64 @llvm.lrint.i64.f80(float %Val)
declare i64 @llvm.lrint.i64.f128(double %Val)
declare i64 @llvm.lrint.i64.ppcf128(double %Val)
```

Overview:

The `'llvm.lrint.*'` intrinsics returns the operand rounded to the nearest integer.

Arguments:

The argument is a floating-point number and return is an integer type.

Semantics:

This function returns the same values as the `libm lrint` functions would, but without setting `errno`.

'llvm.llrint.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.llrint` on any floating-point type. Not all targets support all types however.

```
declare i64 @llvm.llrint.i64.f32(float %Val)
declare i64 @llvm.llrint.i64.f64(double %Val)
declare i64 @llvm.llrint.i64.f80(float %Val)
declare i64 @llvm.llrint.i64.f128(double %Val)
declare i64 @llvm.llrint.i64.ppcf128(double %Val)
```

Overview:

The `'llvm.llrint.*'` intrinsics returns the operand rounded to the nearest integer.

Arguments:

The argument is a floating-point number and return is an integer type.

Semantics:

This function returns the same values as the `libm llrint` functions would, but without setting `errno`.

Bit Manipulation Intrinsics

LLVM provides intrinsics for a few important bit manipulation operations. These allow efficient code generation for some algorithms.

'llvm.bitreverse.*' Intrinsics**Syntax:**

This is an overloaded intrinsic function. You can use `bitreverse` on any integer type.

```
declare i16 @llvm.bitreverse.i16(i16 <id>)
declare i32 @llvm.bitreverse.i32(i32 <id>)
declare i64 @llvm.bitreverse.i64(i64 <id>)
declare <4 x i32> @llvm.bitreverse.v4i32(<4 x i32> <id>)
```

Overview:

The `'llvm.bitreverse'` family of intrinsics is used to reverse the bitpattern of an integer value or vector of integer values; for example `0b10110110` becomes `0b01101101`.

Semantics:

The `llvm.bitreverse.iN` intrinsic returns an `iN` value that has bit `M` in the input moved to bit `N-M` in the output. The vector intrinsics, such as `llvm.bitreverse.v4i32`, operate on a per-element basis and the element order is not affected.

'llvm.bswap.*' Intrinsics**Syntax:**

This is an overloaded intrinsic function. You can use `bswap` on any integer type that is an even number of bytes (i.e. `BitWidth % 16 == 0`).

```
declare i16 @llvm.bswap.i16(i16 <id>)
declare i32 @llvm.bswap.i32(i32 <id>)
declare i64 @llvm.bswap.i64(i64 <id>)
declare <4 x i32> @llvm.bswap.v4i32(<4 x i32> <id>)
```

Overview:

The `llvm.bswap` family of intrinsics is used to byte swap an integer value or vector of integer values with an even number of bytes (positive multiple of 16 bits).

Semantics:

The `llvm.bswap.i16` intrinsic returns an `i16` value that has the high and low byte of the input `i16` swapped. Similarly, the `llvm.bswap.i32` intrinsic returns an `i32` value that has the four bytes of the input `i32` swapped, so that if the input bytes are numbered 0, 1, 2, 3 then the returned `i32` will have its bytes in 3, 2, 1, 0 order. The `llvm.bswap.i48`, `llvm.bswap.i64` and other intrinsics extend this concept to additional even-byte lengths (6 bytes, 8 bytes and more, respectively). The vector intrinsics, such as `llvm.bswap.v4i32`, operate on a per-element basis and the element order is not affected.

'llvm.ctpop.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.ctpop` on any integer bit width, or on any vector with integer elements. Not all targets support all bit widths or vector types, however.

```
declare i8 @llvm.ctpop.i8(i8 <src>)
declare i16 @llvm.ctpop.i16(i16 <src>)
declare i32 @llvm.ctpop.i32(i32 <src>)
declare i64 @llvm.ctpop.i64(i64 <src>)
declare i256 @llvm.ctpop.i256(i256 <src>)
declare <2 x i32> @llvm.ctpop.v2i32(<2 x i32> <src>)
```

Overview:

The `llvm.ctpop` family of intrinsics counts the number of bits set in a value.

Arguments:

The only argument is the value to be counted. The argument may be of any integer type, or a vector with integer elements. The return type must match the argument type.

Semantics:

The `llvm.ctpop` intrinsic counts the 1's in a variable, or within each element of a vector.

'llvm.ctlz.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.ctlz` on any integer bit width, or any vector whose elements are integers. Not all targets support all bit widths or vector types, however.

```
declare i8  @llvm.ctlz.i8  (i8  <src>, i1 <is_zero_undef>)  
declare i16 @llvm.ctlz.i16 (i16 <src>, i1 <is_zero_undef>)  
declare i32 @llvm.ctlz.i32 (i32 <src>, i1 <is_zero_undef>)  
declare i64 @llvm.ctlz.i64 (i64 <src>, i1 <is_zero_undef>)  
declare i256 @llvm.ctlz.i256(i256 <src>, i1 <is_zero_undef>)  
declare <2 x i32> @llvm.ctlz.v2i32(<2 x i32> <src>, i1 <is_zero_undef>)
```

Overview:

The 'llvm.ctlz' family of intrinsic functions counts the number of leading zeros in a variable.

Arguments:

The first argument is the value to be counted. This argument may be of any integer type, or a vector with integer element type. The return type must match the first argument type.

The second argument must be a constant and is a flag to indicate whether the intrinsic should ensure that a zero as the first argument produces a defined result. Historically some architectures did not provide a defined result for zero values as efficiently, and many algorithms are now predicated on avoiding zero-value inputs.

Semantics:

The 'llvm.ctlz' intrinsic counts the leading (most significant) zeros in a variable, or within each element of the vector. If `src == 0` then the result is the size in bits of the type of `src` if `is_zero_undef == 0` and `undef` otherwise. For example, `llvm.ctlz(i32 2) = 30`.

'llvm.cttz.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.cttz` on any integer bit width, or any vector of integer elements. Not all targets support all bit widths or vector types, however.

```
declare i8  @llvm.cttz.i8  (i8  <src>, i1 <is_zero_undef>)  
declare i16 @llvm.cttz.i16 (i16 <src>, i1 <is_zero_undef>)  
declare i32 @llvm.cttz.i32 (i32 <src>, i1 <is_zero_undef>)  
declare i64 @llvm.cttz.i64 (i64 <src>, i1 <is_zero_undef>)  
declare i256 @llvm.cttz.i256(i256 <src>, i1 <is_zero_undef>)  
declare <2 x i32> @llvm.cttz.v2i32(<2 x i32> <src>, i1 <is_zero_undef>)
```

Overview:

The `'llvm.cttz'` family of intrinsic functions counts the number of trailing zeros.

Arguments:

The first argument is the value to be counted. This argument may be of any integer type, or a vector with integer element type. The return type must match the first argument type.

The second argument must be a constant and is a flag to indicate whether the intrinsic should ensure that a zero as the first argument produces a defined result. Historically some architectures did not provide a defined result for zero values as efficiently, and many algorithms are now predicated on avoiding zero-value inputs.

Semantics:

The `'llvm.cttz'` intrinsic counts the trailing (least significant) zeros in a variable, or within each element of a vector. If `src == 0` then the result is the size in bits of the type of `src` if `is_zero_undef == 0` and `undef` otherwise. For example, `llvm.cttz(2) = 1`.

'llvm.fshl.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.fshl` on any integer bit width or any vector of integer elements. Not all targets support all bit widths or vector types, however.

```
declare i8 @llvm.fshl.i8 (i8 %a, i8 %b, i8 %c)
declare i67 @llvm.fshl.i67 (i67 %a, i67 %b, i67 %c)
declare <2 x i32> @llvm.fshl.v2i32 (<2 x i32> %a, <2 x i32> %b, <2 x i32> %c)
```

Overview:

The `'llvm.fshl'` family of intrinsic functions performs a funnel shift left: the first two values are concatenated as `{ %a : %b }` (`%a` is the most significant bits of the wide value), the combined value is shifted left, and the most significant bits are extracted to produce a result that is the same size as the original arguments. If the first 2 arguments are identical, this is equivalent to a rotate left operation. For vector types, the operation occurs for each element of the vector. The shift argument is treated as an unsigned amount modulo the element size of the arguments.

Arguments:

The first two arguments are the values to be concatenated. The third argument is the shift amount. The arguments may be any integer type or a vector with integer element type. All arguments and the return value must have the same type.

Example:

```
%r = call i8 @llvm.fshl.i8(i8 %x, i8 %y, i8 %z) ; %r = i8: msb_extract((concat(x, y)
↳<< (z % 8)), 8)
%r = call i8 @llvm.fshl.i8(i8 255, i8 0, i8 15) ; %r = i8: 128 (0b10000000)
%r = call i8 @llvm.fshl.i8(i8 15, i8 15, i8 11) ; %r = i8: 120 (0b01111000)
%r = call i8 @llvm.fshl.i8(i8 0, i8 255, i8 8) ; %r = i8: 0 (0b00000000)
```

'llvm.fshr.*' Intrinsic**Syntax:**

This is an overloaded intrinsic. You can use `llvm.fshr` on any integer bit width or any vector of integer elements. Not all targets support all bit widths or vector types, however.

```
declare i8 @llvm.fshr.i8(i8 %a, i8 %b, i8 %c)
declare i67 @llvm.fshr.i67(i67 %a, i67 %b, i67 %c)
declare <2 x i32> @llvm.fshr.v2i32(<2 x i32> %a, <2 x i32> %b, <2 x i32> %c)
```

Overview:

The `'llvm.fshr'` family of intrinsic functions performs a funnel shift right: the first two values are concatenated as `{ %a : %b }` (`%a` is the most significant bits of the wide value), the combined value is shifted right, and the least significant bits are extracted to produce a result that is the same size as the original arguments. If the first 2 arguments are identical, this is equivalent to a rotate right operation. For vector types, the operation occurs for each element of the vector. The shift argument is treated as an unsigned amount modulo the element size of the arguments.

Arguments:

The first two arguments are the values to be concatenated. The third argument is the shift amount. The arguments may be any integer type or a vector with integer element type. All arguments and the return value must have the same type.

Example:

```
%r = call i8 @llvm.fshr.i8(i8 %x, i8 %y, i8 %z) ; %r = i8: lsb_extract((concat(x, y)
↳>> (z % 8)), 8)
%r = call i8 @llvm.fshr.i8(i8 255, i8 0, i8 15) ; %r = i8: 254 (0b11111110)
%r = call i8 @llvm.fshr.i8(i8 15, i8 15, i8 11) ; %r = i8: 225 (0b11100001)
%r = call i8 @llvm.fshr.i8(i8 0, i8 255, i8 8) ; %r = i8: 255 (0b11111111)
```

Arithmetic with Overflow Intrinsics

LLVM provides intrinsics for fast arithmetic overflow checking.

Each of these intrinsics returns a two-element struct. The first element of this struct contains the result of the corresponding arithmetic operation modulo 2^n , where n is the bit width of the result. Therefore, for example, the first element of the struct returned by `llvm.sadd.with.overflow.i32` is always the same as the result of a 32-bit add instruction with the same operands, where the add is *not* modified by an `nsw` or `nuw` flag.

The second element of the result is an `i1` that is 1 if the arithmetic operation overflowed and 0 otherwise. An operation overflows if, for any values of its operands A and B and for any N larger than the operands' width, $\text{ext}(A \text{ op } B) \text{ to } iN$ is not equal to $(\text{ext}(A) \text{ to } iN) \text{ op } (\text{ext}(B) \text{ to } iN)$ where `ext` is `sext` for signed overflow and `zext` for unsigned overflow, and `op` is the underlying arithmetic operation.

The behavior of these intrinsics is well-defined for all argument values.

'llvm.sadd.with.overflow.*' Intrinsics

Syntax:

This is an overloaded intrinsic. You can use `llvm.sadd.with.overflow` on any integer bit width or vectors of integers.

```
declare {i16, i1} @llvm.sadd.with.overflow.i16(i16 %a, i16 %b)
declare {i32, i1} @llvm.sadd.with.overflow.i32(i32 %a, i32 %b)
declare {i64, i1} @llvm.sadd.with.overflow.i64(i64 %a, i64 %b)
declare {<4 x i32>, <4 x i1>} @llvm.sadd.with.overflow.v4i32(<4 x i32> %a, <4 x i32>
→ %b)
```

Overview:

The 'llvm.sadd.with.overflow' family of intrinsic functions perform a signed addition of the two arguments, and indicate whether an overflow occurred during the signed summation.

Arguments:

The arguments (`%a` and `%b`) and the first element of the result structure may be of integer types of any bit width, but they must have the same bit width. The second element of the result structure must be of type `i1`. `%a` and `%b` are the two values that will undergo signed addition.

Semantics:

The 'llvm.sadd.with.overflow' family of intrinsic functions perform a signed addition of the two variables. They return a structure --- the first element of which is the signed summation, and the second element of which is a bit specifying if the signed summation resulted in an overflow.

Examples:

```
%res = call {i32, i1} @llvm.sadd.with.overflow.i32(i32 %a, i32 %b)
%sum = extractvalue {i32, i1} %res, 0
%obit = extractvalue {i32, i1} %res, 1
br i1 %obit, label %overflow, label %normal
```

'llvm.uadd.with.overflow.*' Intrinsics

Syntax:

This is an overloaded intrinsic. You can use `llvm.uadd.with.overflow` on any integer bit width or vectors of integers.

```
declare {i16, i1} @llvm.uadd.with.overflow.i16(i16 %a, i16 %b)
declare {i32, i1} @llvm.uadd.with.overflow.i32(i32 %a, i32 %b)
declare {i64, i1} @llvm.uadd.with.overflow.i64(i64 %a, i64 %b)
declare {<4 x i32>, <4 x i1>} @llvm.uadd.with.overflow.v4i32(<4 x i32> %a, <4 x i32>
→ %b)
```

Overview:

The `'llvm.uadd.with.overflow'` family of intrinsic functions perform an unsigned addition of the two arguments, and indicate whether a carry occurred during the unsigned summation.

Arguments:

The arguments (`%a` and `%b`) and the first element of the result structure may be of integer types of any bit width, but they must have the same bit width. The second element of the result structure must be of type `i1`. `%a` and `%b` are the two values that will undergo unsigned addition.

Semantics:

The `'llvm.uadd.with.overflow'` family of intrinsic functions perform an unsigned addition of the two arguments. They return a structure --- the first element of which is the sum, and the second element of which is a bit specifying if the unsigned summation resulted in a carry.

Examples:

```
%res = call {i32, i1} @llvm.uadd.with.overflow.i32(i32 %a, i32 %b)
%sum = extractvalue {i32, i1} %res, 0
%obit = extractvalue {i32, i1} %res, 1
br i1 %obit, label %carry, label %normal
```

'llvm.ssub.with.overflow.*' Intrinsics

Syntax:

This is an overloaded intrinsic. You can use `llvm.ssub.with.overflow` on any integer bit width or vectors of integers.

```
declare {i16, i1} @llvm.ssub.with.overflow.i16(i16 %a, i16 %b)
declare {i32, i1} @llvm.ssub.with.overflow.i32(i32 %a, i32 %b)
declare {i64, i1} @llvm.ssub.with.overflow.i64(i64 %a, i64 %b)
declare {<4 x i32>, <4 x i1>} @llvm.ssub.with.overflow.v4i32(<4 x i32> %a, <4 x i32>
→ %b)
```

Overview:

The 'llvm.ssub.with.overflow' family of intrinsic functions perform a signed subtraction of the two arguments, and indicate whether an overflow occurred during the signed subtraction.

Arguments:

The arguments (%a and %b) and the first element of the result structure may be of integer types of any bit width, but they must have the same bit width. The second element of the result structure must be of type i1. %a and %b are the two values that will undergo signed subtraction.

Semantics:

The 'llvm.ssub.with.overflow' family of intrinsic functions perform a signed subtraction of the two arguments. They return a structure --- the first element of which is the subtraction, and the second element of which is a bit specifying if the signed subtraction resulted in an overflow.

Examples:

```
%res = call {i32, i1} @llvm.ssub.with.overflow.i32(i32 %a, i32 %b)
%sum = extractvalue {i32, i1} %res, 0
%obit = extractvalue {i32, i1} %res, 1
br i1 %obit, label %overflow, label %normal
```

'llvm.usub.with.overflow.*' Intrinsics

Syntax:

This is an overloaded intrinsic. You can use `llvm.usub.with.overflow` on any integer bit width or vectors of integers.

```
declare {i16, i1} @llvm.usub.with.overflow.i16(i16 %a, i16 %b)
declare {i32, i1} @llvm.usub.with.overflow.i32(i32 %a, i32 %b)
declare {i64, i1} @llvm.usub.with.overflow.i64(i64 %a, i64 %b)
declare {<4 x i32>, <4 x i1>} @llvm.usub.with.overflow.v4i32(<4 x i32> %a, <4 x i32>
→ %b)
```

(continues on next page)

Overview:

The `'llvm.usub.with.overflow'` family of intrinsic functions perform an unsigned subtraction of the two arguments, and indicate whether an overflow occurred during the unsigned subtraction.

Arguments:

The arguments (`%a` and `%b`) and the first element of the result structure may be of integer types of any bit width, but they must have the same bit width. The second element of the result structure must be of type `i1`. `%a` and `%b` are the two values that will undergo unsigned subtraction.

Semantics:

The `'llvm.usub.with.overflow'` family of intrinsic functions perform an unsigned subtraction of the two arguments. They return a structure --- the first element of which is the subtraction, and the second element of which is a bit specifying if the unsigned subtraction resulted in an overflow.

Examples:

```
%res = call {i32, i1} @llvm.usub.with.overflow.i32(i32 %a, i32 %b)
%sum = extractvalue {i32, i1} %res, 0
%obit = extractvalue {i32, i1} %res, 1
br i1 %obit, label %overflow, label %normal
```

'llvm.smul.with.overflow.*' Intrinsics

Syntax:

This is an overloaded intrinsic. You can use `llvm.smul.with.overflow` on any integer bit width or vectors of integers.

```
declare {i16, i1} @llvm.smul.with.overflow.i16(i16 %a, i16 %b)
declare {i32, i1} @llvm.smul.with.overflow.i32(i32 %a, i32 %b)
declare {i64, i1} @llvm.smul.with.overflow.i64(i64 %a, i64 %b)
declare {<4 x i32>, <4 x i1>} @llvm.smul.with.overflow.v4i32(<4 x i32> %a, <4 x i32>
  ↪ %b)
```

Overview:

The 'llvm.smul.with.overflow' family of intrinsic functions perform a signed multiplication of the two arguments, and indicate whether an overflow occurred during the signed multiplication.

Arguments:

The arguments (%a and %b) and the first element of the result structure may be of integer types of any bit width, but they must have the same bit width. The second element of the result structure must be of type i1. %a and %b are the two values that will undergo signed multiplication.

Semantics:

The 'llvm.smul.with.overflow' family of intrinsic functions perform a signed multiplication of the two arguments. They return a structure --- the first element of which is the multiplication, and the second element of which is a bit specifying if the signed multiplication resulted in an overflow.

Examples:

```
%res = call {i32, i1} @llvm.smul.with.overflow.i32(i32 %a, i32 %b)
%sum = extractvalue {i32, i1} %res, 0
%obit = extractvalue {i32, i1} %res, 1
br i1 %obit, label %overflow, label %normal
```

'llvm.umul.with.overflow.*' Intrinsics

Syntax:

This is an overloaded intrinsic. You can use llvm.umul.with.overflow on any integer bit width or vectors of integers.

```
declare {i16, i1} @llvm.umul.with.overflow.i16(i16 %a, i16 %b)
declare {i32, i1} @llvm.umul.with.overflow.i32(i32 %a, i32 %b)
declare {i64, i1} @llvm.umul.with.overflow.i64(i64 %a, i64 %b)
declare {<4 x i32>, <4 x i1>} @llvm.umul.with.overflow.v4i32(<4 x i32> %a, <4 x i32>
↳ %b)
```

Overview:

The 'llvm.umul.with.overflow' family of intrinsic functions perform a unsigned multiplication of the two arguments, and indicate whether an overflow occurred during the unsigned multiplication.

Arguments:

The arguments (%a and %b) and the first element of the result structure may be of integer types of any bit width, but they must have the same bit width. The second element of the result structure must be of type i1. %a and %b are the two values that will undergo unsigned multiplication.

Semantics:

The 'llvm.umul.with.overflow' family of intrinsic functions perform an unsigned multiplication of the two arguments. They return a structure --- the first element of which is the multiplication, and the second element of which is a bit specifying if the unsigned multiplication resulted in an overflow.

Examples:

```
%res = call {i32, i1} @llvm.umul.with.overflow.i32(i32 %a, i32 %b)
%sum = extractvalue {i32, i1} %res, 0
%obit = extractvalue {i32, i1} %res, 1
br i1 %obit, label %overflow, label %normal
```

Saturation Arithmetic Intrinsics

Saturation arithmetic is a version of arithmetic in which operations are limited to a fixed range between a minimum and maximum value. If the result of an operation is greater than the maximum value, the result is set (or "clamped") to this maximum. If it is below the minimum, it is clamped to this minimum.

'llvm.sadd.sat.*' Intrinsics

Syntax

This is an overloaded intrinsic. You can use `llvm.sadd.sat` on any integer bit width or vectors of integers.

```
declare i16 @llvm.sadd.sat.i16(i16 %a, i16 %b)
declare i32 @llvm.sadd.sat.i32(i32 %a, i32 %b)
declare i64 @llvm.sadd.sat.i64(i64 %a, i64 %b)
declare <4 x i32> @llvm.sadd.sat.v4i32(<4 x i32> %a, <4 x i32> %b)
```

Overview

The 'llvm.sadd.sat' family of intrinsic functions perform signed saturation addition on the 2 arguments.

Arguments

The arguments (`%a` and `%b`) and the result may be of integer types of any bit width, but they must have the same bit width. `%a` and `%b` are the two values that will undergo signed addition.

Semantics:

The maximum value this operation can clamp to is the largest signed value representable by the bit width of the arguments. The minimum value is the smallest signed value representable by this bit width.

Examples

```
%res = call i4 @llvm.sadd.sat.i4(i4 1, i4 2) ; %res = 3
%res = call i4 @llvm.sadd.sat.i4(i4 5, i4 6) ; %res = 7
%res = call i4 @llvm.sadd.sat.i4(i4 -4, i4 2) ; %res = -2
%res = call i4 @llvm.sadd.sat.i4(i4 -4, i4 -5) ; %res = -8
```

'llvm.uadd.sat.*' Intrinsics

Syntax

This is an overloaded intrinsic. You can use `llvm.uadd.sat` on any integer bit width or vectors of integers.

```
declare i16 @llvm.uadd.sat.i16(i16 %a, i16 %b)
declare i32 @llvm.uadd.sat.i32(i32 %a, i32 %b)
declare i64 @llvm.uadd.sat.i64(i64 %a, i64 %b)
declare <4 x i32> @llvm.uadd.sat.v4i32(<4 x i32> %a, <4 x i32> %b)
```

Overview

The `'llvm.uadd.sat'` family of intrinsic functions perform unsigned saturation addition on the 2 arguments.

Arguments

The arguments (`%a` and `%b`) and the result may be of integer types of any bit width, but they must have the same bit width. `%a` and `%b` are the two values that will undergo unsigned addition.

Semantics:

The maximum value this operation can clamp to is the largest unsigned value representable by the bit width of the arguments. Because this is an unsigned operation, the result will never saturate towards zero.

Examples

```
%res = call i4 @llvm.uadd.sat.i4(i4 1, i4 2) ; %res = 3
%res = call i4 @llvm.uadd.sat.i4(i4 5, i4 6) ; %res = 11
%res = call i4 @llvm.uadd.sat.i4(i4 8, i4 8) ; %res = 15
```

'llvm.ssub.sat.*' Intrinsics

Syntax

This is an overloaded intrinsic. You can use `llvm.ssub.sat` on any integer bit width or vectors of integers.

```
declare i16 @llvm.ssub.sat.i16(i16 %a, i16 %b)
declare i32 @llvm.ssub.sat.i32(i32 %a, i32 %b)
declare i64 @llvm.ssub.sat.i64(i64 %a, i64 %b)
declare <4 x i32> @llvm.ssub.sat.v4i32(<4 x i32> %a, <4 x i32> %b)
```

Overview

The `'llvm.ssub.sat'` family of intrinsic functions perform signed saturation subtraction on the 2 arguments.

Arguments

The arguments (`%a` and `%b`) and the result may be of integer types of any bit width, but they must have the same bit width. `%a` and `%b` are the two values that will undergo signed subtraction.

Semantics:

The maximum value this operation can clamp to is the largest signed value representable by the bit width of the arguments. The minimum value is the smallest signed value representable by this bit width.

Examples

```
%res = call i4 @llvm.ssub.sat.i4(i4 2, i4 1) ; %res = 1
%res = call i4 @llvm.ssub.sat.i4(i4 2, i4 6) ; %res = -4
%res = call i4 @llvm.ssub.sat.i4(i4 -4, i4 5) ; %res = -8
%res = call i4 @llvm.ssub.sat.i4(i4 4, i4 -5) ; %res = 7
```

'llvm.usub.sat.*' Intrinsics

Syntax

This is an overloaded intrinsic. You can use `llvm.usub.sat` on any integer bit width or vectors of integers.

```
declare i16 @llvm.usub.sat.i16(i16 %a, i16 %b)
declare i32 @llvm.usub.sat.i32(i32 %a, i32 %b)
declare i64 @llvm.usub.sat.i64(i64 %a, i64 %b)
declare <4 x i32> @llvm.usub.sat.v4i32(<4 x i32> %a, <4 x i32> %b)
```

Overview

The 'llvm.usub.sat' family of intrinsic functions perform unsigned saturation subtraction on the 2 arguments.

Arguments

The arguments (`%a` and `%b`) and the result may be of integer types of any bit width, but they must have the same bit width. `%a` and `%b` are the two values that will undergo unsigned subtraction.

Semantics:

The minimum value this operation can clamp to is 0, which is the smallest unsigned value representable by the bit width of the unsigned arguments. Because this is an unsigned operation, the result will never saturate towards the largest possible value representable by this bit width.

Examples

```
%res = call i4 @llvm.usub.sat.i4(i4 2, i4 1) ; %res = 1
%res = call i4 @llvm.usub.sat.i4(i4 2, i4 6) ; %res = 0
```

Fixed Point Arithmetic Intrinsics

A fixed point number represents a real data type for a number that has a fixed number of digits after a radix point (equivalent to the decimal point '.'). The number of digits after the radix point is referred as the `scale`. These are useful for representing fractional values to a specific precision. The following intrinsics perform fixed point arithmetic operations on 2 operands of the same scale, specified as the third argument.

The `llvm.*mul.fix` family of intrinsic functions represents a multiplication of fixed point numbers through scaled integers. Therefore, fixed point multiplication can be represented as

```
:: %result = call i4 @llvm.smul.fix.i4(i4 %a, i4 %b, i32 %scale)
```

```
; Expands to %a2 = sext i4 %a to i8 %b2 = sext i4 %b to i8 %mul = mul nsw nuw i8 %a, %b %scale2 = trunc
i32 %scale to i8 %r = ashr i8 %mul, i8 %scale2 ; this is for a target rounding down towards negative infinity
%result = trunc i8 %r to i4
```

For each of these functions, if the result cannot be represented exactly with the provided scale, the result is rounded. Rounding is unspecified since preferred rounding may vary for different targets. Rounding is specified through a target hook. Different pipelines should legalize or optimize this using the rounding specified by this hook if it is provided.

Operations like constant folding, instruction combining, KnownBits, and ValueTracking should also use this hook, if provided, and not assume the direction of rounding. A rounded result must always be within one unit of precision from the true result. That is, the error between the returned result and the true result must be less than $1/2^{(\text{scale})}$.

'llvm.smul.fix.*' Intrinsics

Syntax

This is an overloaded intrinsic. You can use `llvm.smul.fix` on any integer bit width or vectors of integers.

```
declare i16 @llvm.smul.fix.i16(i16 %a, i16 %b, i32 %scale)
declare i32 @llvm.smul.fix.i32(i32 %a, i32 %b, i32 %scale)
declare i64 @llvm.smul.fix.i64(i64 %a, i64 %b, i32 %scale)
declare <4 x i32> @llvm.smul.fix.v4i32(<4 x i32> %a, <4 x i32> %b, i32 %scale)
```

Overview

The 'llvm.smul.fix' family of intrinsic functions perform signed fixed point multiplication on 2 arguments of the same scale.

Arguments

The arguments (%a and %b) and the result may be of integer types of any bit width, but they must have the same bit width. The arguments may also work with int vectors of the same length and int size. %a and %b are the two values that will undergo signed fixed point multiplication. The argument %scale represents the scale of both operands, and must be a constant integer.

Semantics:

This operation performs fixed point multiplication on the 2 arguments of a specified scale. The result will also be returned in the same scale specified in the third argument.

If the result value cannot be precisely represented in the given scale, the value is rounded up or down to the closest representable value. The rounding direction is unspecified.

It is undefined behavior if the result value does not fit within the range of the fixed point type.

Examples

```
%res = call i4 @llvm.smul.fix.i4(i4 3, i4 2, i32 0) ; %res = 6 (2 x 3 = 6)
%res = call i4 @llvm.smul.fix.i4(i4 3, i4 2, i32 1) ; %res = 3 (1.5 x 1 = 1.5)
%res = call i4 @llvm.smul.fix.i4(i4 3, i4 -2, i32 1) ; %res = -3 (1.5 x -1 = -1.5)

; The result in the following could be rounded up to -2 or down to -2.5
%res = call i4 @llvm.smul.fix.i4(i4 3, i4 -3, i32 1) ; %res = -5 (or -4) (1.5 x -1.5
↳ = -2.25)
```

'llvm.umul.fix.*' Intrinsics

Syntax

This is an overloaded intrinsic. You can use `llvm.umul.fix` on any integer bit width or vectors of integers.

```
declare i16 @llvm.umul.fix.i16(i16 %a, i16 %b, i32 %scale)
declare i32 @llvm.umul.fix.i32(i32 %a, i32 %b, i32 %scale)
declare i64 @llvm.umul.fix.i64(i64 %a, i64 %b, i32 %scale)
declare <4 x i32> @llvm.umul.fix.v4i32(<4 x i32> %a, <4 x i32> %b, i32 %scale)
```

Overview

The 'llvm.umul.fix' family of intrinsic functions perform unsigned fixed point multiplication on 2 arguments of the same scale.

Arguments

The arguments (`%a` and `%b`) and the result may be of integer types of any bit width, but they must have the same bit width. The arguments may also work with int vectors of the same length and int size. `%a` and `%b` are the two values that will undergo unsigned fixed point multiplication. The argument `%scale` represents the scale of both operands, and must be a constant integer.

Semantics:

This operation performs unsigned fixed point multiplication on the 2 arguments of a specified scale. The result will also be returned in the same scale specified in the third argument.

If the result value cannot be precisely represented in the given scale, the value is rounded up or down to the closest representable value. The rounding direction is unspecified.

It is undefined behavior if the result value does not fit within the range of the fixed point type.

Examples

```
%res = call i4 @llvm.umul.fix.i4(i4 3, i4 2, i32 0) ; %res = 6 (2 x 3 = 6)
%res = call i4 @llvm.umul.fix.i4(i4 3, i4 2, i32 1) ; %res = 3 (1.5 x 1 = 1.5)

; The result in the following could be rounded down to 3.5 or up to 4
%res = call i4 @llvm.umul.fix.i4(i4 15, i4 1, i32 1) ; %res = 7 (or 8) (7.5 x 0.5 = 3.75)
↪ 3.75)
```

'llvm.smul.fix.sat.*' Intrinsics

Syntax

This is an overloaded intrinsic. You can use `llvm.smul.fix.sat` on any integer bit width or vectors of integers.

```
declare i16 @llvm.smul.fix.sat.i16(i16 %a, i16 %b, i32 %scale)
declare i32 @llvm.smul.fix.sat.i32(i32 %a, i32 %b, i32 %scale)
declare i64 @llvm.smul.fix.sat.i64(i64 %a, i64 %b, i32 %scale)
declare <4 x i32> @llvm.smul.fix.sat.v4i32(<4 x i32> %a, <4 x i32> %b, i32 %scale)
```

Overview

The `'llvm.smul.fix.sat'` family of intrinsic functions perform signed fixed point saturation multiplication on 2 arguments of the same scale.

Arguments

The arguments (`%a` and `%b`) and the result may be of integer types of any bit width, but they must have the same bit width. `%a` and `%b` are the two values that will undergo signed fixed point multiplication. The argument `%scale` represents the scale of both operands, and must be a constant integer.

Semantics:

This operation performs fixed point multiplication on the 2 arguments of a specified scale. The result will also be returned in the same scale specified in the third argument.

If the result value cannot be precisely represented in the given scale, the value is rounded up or down to the closest representable value. The rounding direction is unspecified.

The maximum value this operation can clamp to is the largest signed value representable by the bit width of the first 2 arguments. The minimum value is the smallest signed value representable by this bit width.

Examples

```
%res = call i4 @llvm.smul.fix.sat.i4(i4 3, i4 2, i32 0) ; %res = 6 (2 x 3 = 6)
%res = call i4 @llvm.smul.fix.sat.i4(i4 3, i4 2, i32 1) ; %res = 3 (1.5 x 1 = 1.5)
%res = call i4 @llvm.smul.fix.sat.i4(i4 3, i4 -2, i32 1) ; %res = -3 (1.5 x -1 = -1.5)
→5)

; The result in the following could be rounded up to -2 or down to -2.5
%res = call i4 @llvm.smul.fix.sat.i4(i4 3, i4 -3, i32 1) ; %res = -5 (or -4) (1.5 x -
→1.5 = -2.25)

; Saturation
%res = call i4 @llvm.smul.fix.sat.i4(i4 7, i4 2, i32 0) ; %res = 7
%res = call i4 @llvm.smul.fix.sat.i4(i4 7, i4 2, i32 2) ; %res = 7
%res = call i4 @llvm.smul.fix.sat.i4(i4 -8, i4 2, i32 2) ; %res = -8
%res = call i4 @llvm.smul.fix.sat.i4(i4 -8, i4 -2, i32 2) ; %res = 7

; Scale can affect the saturation result
```

(continues on next page)

(continued from previous page)

```
%res = call i4 @llvm.smul.fix.sat.i4(i4 2, i4 4, i32 0) ; %res = 7 (2 x 4 -> clamped_
↳to 7)
%res = call i4 @llvm.smul.fix.sat.i4(i4 2, i4 4, i32 1) ; %res = 4 (1 x 2 = 2)
```

Specialised Arithmetic Intrinsics

'llvm.canonicalize.*' Intrinsic

Syntax:

```
declare float @llvm.canonicalize.f32(float %a)
declare double @llvm.canonicalize.f64(double %b)
```

Overview:

The 'llvm.canonicalize.*' intrinsic returns the platform specific canonical encoding of a floating-point number. This canonicalization is useful for implementing certain numeric primitives such as frexp. The canonical encoding is defined by IEEE-754-2008 to be:

2.1.8 canonical encoding: The preferred encoding of a floating-point representation in a format. Applied to declets, significands of finite numbers, infinities, and NaNs, especially in decimal formats.

This operation can also be considered equivalent to the IEEE-754-2008 conversion of a floating-point value to the same format. NaNs are handled according to section 6.2.

Examples of non-canonical encodings:

- x87 pseudo denormals, pseudo NaNs, pseudo Infinity, Unnormals. These are converted to a canonical representation per hardware-specific protocol.
- Many normal decimal floating-point numbers have non-canonical alternative encodings.
- Some machines, like GPUs or ARMv7 NEON, do not support subnormal values. These are treated as non-canonical encodings of zero and will be flushed to a zero of the same sign by this operation.

Note that per IEEE-754-2008 6.2, systems that support signaling NaNs with default exception handling must signal an invalid exception, and produce a quiet NaN result.

This function should always be implementable as multiplication by 1.0, provided that the compiler does not constant fold the operation. Likewise, division by 1.0 and `llvm.minnum(x, x)` are possible implementations. Addition with -0.0 is also sufficient provided that the rounding mode is not -Infinity.

`@llvm.canonicalize` must preserve the equality relation. That is:

- `(@llvm.canonicalize(x) == x)` is equivalent to `(x == x)`
- `(@llvm.canonicalize(x) == @llvm.canonicalize(y))` is equivalent to `(x == y)`

Additionally, the sign of zero must be conserved: `@llvm.canonicalize(-0.0) = -0.0` and `@llvm.canonicalize(+0.0) = +0.0`

The payload bits of a NaN must be conserved, with two exceptions. First, environments which use only a single canonical representation of NaN must perform said canonicalization. Second, SNaNs must be quieted per the usual methods.

The canonicalization operation may be optimized away if:

- The input is known to be canonical. For example, it was produced by a floating-point operation that is required by the standard to be canonical.
- The result is consumed only by (or fused with) other floating-point operations. That is, the bits of the floating-point value are not examined.

'llvm.fmuladd.*' Intrinsic

Syntax:

```
declare float @llvm.fmuladd.f32(float %a, float %b, float %c)
declare double @llvm.fmuladd.f64(double %a, double %b, double %c)
```

Overview:

The 'llvm.fmuladd.*' intrinsic functions represent multiply-add expressions that can be fused if the code generator determines that (a) the target instruction set has support for a fused operation, and (b) that the fused operation is more efficient than the equivalent, separate pair of mul and add instructions.

Arguments:

The 'llvm.fmuladd.*' intrinsics each take three arguments: two multiplicands, a and b, and an addend c.

Semantics:

The expression:

```
%0 = call float @llvm.fmuladd.f32(%a, %b, %c)
```

is equivalent to the expression $a * b + c$, except that rounding will not be performed between the multiplication and addition steps if the code generator fuses the operations. Fusion is not guaranteed, even if the target platform supports it. If a fused multiply-add is required the corresponding `llvm.fma.*` intrinsic function should be used instead. This never sets `errno`, just as 'llvm.fma.*'.

Examples:

```
%r2 = call float @llvm.fmuladd.f32(float %a, float %b, float %c) ; yields float:r2 =
↳ (a * b) + c
```

Experimental Vector Reduction Intrinsics

Horizontal reductions of vectors can be expressed using the following intrinsics. Each one takes a vector operand as an input and applies its respective operation across all elements of the vector, returning a single scalar result of the same element type.

'llvm.experimental.vector.reduce.add.*' Intrinsic

Syntax:

```
declare i32 @llvm.experimental.vector.reduce.add.v4i32(<4 x i32> %a)
declare i64 @llvm.experimental.vector.reduce.add.v2i64(<2 x i64> %a)
```

Overview:

The 'llvm.experimental.vector.reduce.add.*' intrinsics do an integer ADD reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.v2.fadd.*' Intrinsic

Syntax:

```
declare float @llvm.experimental.vector.reduce.v2.fadd.f32.v4f32(float %start_value,
↪ <4 x float> %a)
declare double @llvm.experimental.vector.reduce.v2.fadd.f64.v2f64(double %start_value,
↪ <2 x double> %a)
```

Overview:

The 'llvm.experimental.vector.reduce.v2.fadd.*' intrinsics do a floating-point ADD reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

If the intrinsic call has the 'reassoc' or 'fast' flags set, then the reduction will not preserve the associativity of an equivalent scalarized counterpart. Otherwise the reduction will be *ordered*, thus implying that the operation respects the associativity of a scalarized reduction.

Arguments:

The first argument to this intrinsic is a scalar start value for the reduction. The type of the start value matches the element-type of the vector input. The second argument must be a vector of floating-point values.

Examples:

```
%unord = call reassoc float @llvm.experimental.vector.reduce.v2.fadd.f32.v4f32(float_
↳0.0, <4 x float> %input) ; unordered reduction
%ord = call float @llvm.experimental.vector.reduce.v2.fadd.f32.v4f32(float %start_
↳value, <4 x float> %input) ; ordered reduction
```

'llvm.experimental.vector.reduce.mul.*' Intrinsic

Syntax:

```
declare i32 @llvm.experimental.vector.reduce.mul.v4i32(<4 x i32> %a)
declare i64 @llvm.experimental.vector.reduce.mul.v2i64(<2 x i64> %a)
```

Overview:

The 'llvm.experimental.vector.reduce.mul.*' intrinsics do an integer MUL reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.v2.fmul.*' Intrinsic

Syntax:

```
declare float @llvm.experimental.vector.reduce.v2.fmul.f32.v4f32(float %start_value,
↳<4 x float> %a)
declare double @llvm.experimental.vector.reduce.v2.fmul.f64.v2f64(double %start_value,
↳<2 x double> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.v2.fmul.*'` intrinsics do a floating-point MUL reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

If the intrinsic call has the 'reassoc' or 'fast' flags set, then the reduction will not preserve the associativity of an equivalent scalarized counterpart. Otherwise the reduction will be *ordered*, thus implying that the operation respects the associativity of a scalarized reduction.

Arguments:

The first argument to this intrinsic is a scalar start value for the reduction. The type of the start value matches the element-type of the vector input. The second argument must be a vector of floating-point values.

Examples:

```
%unord = call reassoc float @llvm.experimental.vector.reduce.v2.fmul.f32.v4f32(float_
↪1.0, <4 x float> %input) ; unordered reduction
%ord = call float @llvm.experimental.vector.reduce.v2.fmul.f32.v4f32(float %start_
↪value, <4 x float> %input) ; ordered reduction
```

'llvm.experimental.vector.reduce.and.*' Intrinsic

Syntax:

```
declare i32 @llvm.experimental.vector.reduce.and.v4i32(<4 x i32> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.and.*'` intrinsics do a bitwise AND reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.or.*' Intrinsic

Syntax:

```
declare i32 @llvm.experimental.vector.reduce.or.v4i32(<4 x i32> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.or.*'` intrinsics do a bitwise OR reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.xor.*' Intrinsic**Syntax:**

```
declare i32 @llvm.experimental.vector.reduce.xor.v4i32(<4 x i32> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.xor.*'` intrinsics do a bitwise XOR reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.smax.*' Intrinsic**Syntax:**

```
declare i32 @llvm.experimental.vector.reduce.smax.v4i32(<4 x i32> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.smax.*'` intrinsics do a signed integer MAX reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.smin.*' Intrinsic**Syntax:**

```
declare i32 @llvm.experimental.vector.reduce.smin.v4i32(<4 x i32> %a)
```

Overview:

The 'llvm.experimental.vector.reduce.smin.*' intrinsics do a signed integer MIN reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.umax.*' Intrinsic**Syntax:**

```
declare i32 @llvm.experimental.vector.reduce.umax.v4i32(<4 x i32> %a)
```

Overview:

The 'llvm.experimental.vector.reduce.umax.*' intrinsics do an unsigned integer MAX reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

'llvm.experimental.vector.reduce.umin.*' Intrinsic**Syntax:**

```
declare i32 @llvm.experimental.vector.reduce.umin.v4i32(<4 x i32> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.umin.*'` intrinsics do an unsigned integer MIN reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

Arguments:

The argument to this intrinsic must be a vector of integer values.

`'llvm.experimental.vector.reduce.fmax.*'` Intrinsic**Syntax:**

```
declare float @llvm.experimental.vector.reduce.fmax.v4f32(<4 x float> %a)
declare double @llvm.experimental.vector.reduce.fmax.v2f64(<2 x double> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.fmax.*'` intrinsics do a floating-point MAX reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

If the intrinsic call has the `nnan` fast-math flag then the operation can assume that NaNs are not present in the input vector.

Arguments:

The argument to this intrinsic must be a vector of floating-point values.

`'llvm.experimental.vector.reduce.fmin.*'` Intrinsic**Syntax:**

```
declare float @llvm.experimental.vector.reduce.fmin.v4f32(<4 x float> %a)
declare double @llvm.experimental.vector.reduce.fmin.v2f64(<2 x double> %a)
```

Overview:

The `'llvm.experimental.vector.reduce.fmin.*'` intrinsics do a floating-point MIN reduction of a vector, returning the result as a scalar. The return type matches the element-type of the vector input.

If the intrinsic call has the `nnan` fast-math flag then the operation can assume that NaNs are not present in the input vector.

Arguments:

The argument to this intrinsic must be a vector of floating-point values.

Half Precision Floating-Point Intrinsics

For most target platforms, half precision floating-point is a storage-only format. This means that it is a dense encoding (in memory) but does not support computation in the format.

This means that code must first load the half-precision floating-point value as an `i16`, then convert it to float with *[llvm.convert.from.fp16](#)*. Computation can then be performed on the float value (including extending to double etc). To store the value back to memory, it is first converted to float if needed, then converted to `i16` with *[llvm.convert.to.fp16](#)*, then storing as an `i16` value.

'llvm.convert.to.fp16' Intrinsic**Syntax:**

```
declare i16 @llvm.convert.to.fp16.f32(float %a)
declare i16 @llvm.convert.to.fp16.f64(double %a)
```

Overview:

The `'llvm.convert.to.fp16'` intrinsic function performs a conversion from a conventional floating-point type to half precision floating-point format.

Arguments:

The intrinsic function contains single argument - the value to be converted.

Semantics:

The `'llvm.convert.to.fp16'` intrinsic function performs a conversion from a conventional floating-point format to half precision floating-point format. The return value is an `i16` which contains the converted number.

Examples:

```
%res = call i16 @llvm.convert.to.fp16.f32(float %a)
store i16 %res, i16* @x, align 2
```

'llvm.convert.from.fp16' Intrinsic

Syntax:

```
declare float @llvm.convert.from.fp16.f32(i16 %a)
declare double @llvm.convert.from.fp16.f64(i16 %a)
```

Overview:

The 'llvm.convert.from.fp16' intrinsic function performs a conversion from half precision floating-point format to single precision floating-point format.

Arguments:

The intrinsic function contains single argument - the value to be converted.

Semantics:

The 'llvm.convert.from.fp16' intrinsic function performs a conversion from half single precision floating-point format to single precision floating-point format. The input half-float value is represented by an `i16` value.

Examples:

```
%a = load i16, i16* @x, align 2
%res = call float @llvm.convert.from.fp16(i16 %a)
```

Debugger Intrinsics

The LLVM debugger intrinsics (which all start with `llvm.dbg.` prefix), are described in the [LLVM Source Level Debugging](#) document.

Exception Handling Intrinsics

The LLVM exception handling intrinsics (which all start with `llvm.eh.` prefix), are described in the [LLVM Exception Handling](#) document.

Trampoline Intrinsics

These intrinsics make it possible to excise one parameter, marked with the *nest* attribute, from a function. The result is a callable function pointer lacking the *nest* parameter - the caller does not need to provide a value for it. Instead, the value to use is stored in advance in a "trampoline", a block of memory usually allocated on the stack, which also contains code to splice the *nest* value into the argument list. This is used to implement the GCC nested function address extension.

For example, if the function is `i32 f(i8* nest %c, i32 %x, i32 %y)` then the resulting function pointer has signature `i32 (i32, i32)*`. It can be created as follows:

```
%tramp = alloca [10 x i8], align 4 ; size and alignment only correct for X86
%tramp1 = getelementptr [10 x i8], [10 x i8]* %tramp, i32 0, i32 0
call i8* @llvm.init.trampoline(i8* %tramp1, i8* bitcast (i32 (i8*, i32, i32)* @f to_
↳ i8*), i8* %nval)
%p = call i8* @llvm.adjust.trampoline(i8* %tramp1)
%fp = bitcast i8* %p to i32 (i32, i32)*
```

The call `%val = call i32 %fp(i32 %x, i32 %y)` is then equivalent to `%val = call i32 %f(i8* %nval, i32 %x, i32 %y)`.

'llvm.init.trampoline' Intrinsic

Syntax:

```
declare void @llvm.init.trampoline(i8* <tramp>, i8* <func>, i8* <nval>)
```

Overview:

This fills the memory pointed to by `tramp` with executable code, turning it into a trampoline.

Arguments:

The `llvm.init.trampoline` intrinsic takes three arguments, all pointers. The `tramp` argument must point to a sufficiently large and sufficiently aligned block of memory; this memory is written to by the intrinsic. Note that the size and the alignment are target-specific - LLVM currently provides no portable way of determining them, so a front-end that generates this intrinsic needs to have some target-specific knowledge. The `func` argument must hold a function bitcast to an `i8*`.

Semantics:

The block of memory pointed to by `tramp` is filled with target dependent code, turning it into a function. Then `tramp` needs to be passed to `llvm.adjust.trampoline` to get a pointer which can be *bitcast (to a new function) and called*. The new function's signature is the same as that of `func` with any arguments marked with the `nest` attribute removed. At most one such `nest` argument is allowed, and it must be of pointer type. Calling the new function is equivalent to calling `func` with the same argument list, but with `nval` used for the missing `nest` argument. If, after calling `llvm.init.trampoline`, the memory pointed to by `tramp` is modified, then the effect of any later call to the returned function pointer is undefined.

'llvm.adjust.trampoline' Intrinsic

Syntax:

```
declare i8* @llvm.adjust.trampoline(i8* <tramp>)
```

Overview:

This performs any required machine-specific adjustment to the address of a trampoline (passed as `tramp`).

Arguments:

`tramp` must point to a block of memory which already has trampoline code filled in by a previous call to *llvm.init.trampoline*.

Semantics:

On some architectures the address of the code to be executed needs to be different than the address where the trampoline is actually stored. This intrinsic returns the executable address corresponding to `tramp` after performing the required machine specific adjustments. The pointer returned can then be *bitcast and executed*.

Masked Vector Load and Store Intrinsics

LLVM provides intrinsics for predicated vector load and store operations. The predicate is specified by a mask operand, which holds one bit per vector element, switching the associated vector lane on or off. The memory addresses corresponding to the "off" lanes are not accessed. When all bits of the mask are on, the intrinsic is identical to a regular vector load or store. When all bits are off, no memory is accessed.

'llvm.masked.load.*' Intrinsics**Syntax:**

This is an overloaded intrinsic. The loaded data is a vector of any integer, floating-point or pointer data type.

```
declare <16 x float> @llvm.masked.load.v16f32.p0v16f32 (<16 x float>* <ptr>, i32
↳<alignment>, <16 x i1> <mask>, <16 x float> <passthru>)
declare <2 x double> @llvm.masked.load.v2f64.p0v2f64 (<2 x double>* <ptr>, i32
↳<alignment>, <2 x i1> <mask>, <2 x double> <passthru>)
;; The data is a vector of pointers to double
declare <8 x double*> @llvm.masked.load.v8p0f64.p0v8p0f64 (<8 x double*>* <ptr>,
↳i32 <alignment>, <8 x i1> <mask>, <8 x double*> <passthru>)
;; The data is a vector of function pointers
declare <8 x i32 ()*> @llvm.masked.load.v8p0f_i32f.p0v8p0f_i32f (<8 x i32 ()*>* <ptr>,
↳ i32 <alignment>, <8 x i1> <mask>, <8 x i32 ()*> <passthru>)
```

Overview:

Reads a vector from memory according to the provided mask. The mask holds a bit for each vector lane, and is used to prevent memory accesses to the masked-off lanes. The masked-off lanes in the result vector are taken from the corresponding lanes of the 'passthru' operand.

Arguments:

The first operand is the base pointer for the load. The second operand is the alignment of the source location. It must be a constant integer value. The third operand, mask, is a vector of boolean values with the same number of elements as the return type. The fourth is a pass-through value that is used to fill the masked-off lanes of the result. The return type, underlying type of the base pointer and the type of the 'passthru' operand are the same vector types.

Semantics:

The 'llvm.masked.load' intrinsic is designed for conditional reading of selected vector elements in a single IR operation. It is useful for targets that support vector masked loads and allows vectorizing predicated basic blocks on these targets. Other targets may support this intrinsic differently, for example by lowering it into a sequence of branches that guard scalar load operations. The result of this operation is equivalent to a regular vector load instruction followed by a 'select' between the loaded and the passthru values, predicated on the same mask. However, using this intrinsic prevents exceptions on memory access to masked-off lanes.

```
%res = call <16 x float> @llvm.masked.load.v16f32.p0v16f32 (<16 x float>* %ptr, i32 4,
↳ <16 x i1>%mask, <16 x float> %passthru)

;; The result of the two following instructions is identical aside from potential_
↳ memory access exception
%loadl1 = load <16 x float>, <16 x float>* %ptr, align 4
%res = select <16 x i1> %mask, <16 x float> %loadl1, <16 x float> %passthru
```

'llvm.masked.store.*' Intrinsics

Syntax:

This is an overloaded intrinsic. The data stored in memory is a vector of any integer, floating-point or pointer data type.

```
declare void @llvm.masked.store.v8i32.p0v8i32 (<8 x i32> <value>, <8 x i32>*
↳ <ptr>, i32 <alignment>, <8 x i1> <mask>)
declare void @llvm.masked.store.v16f32.p0v16f32 (<16 x float> <value>, <16 x float>*
↳ <ptr>, i32 <alignment>, <16 x i1> <mask>)
;; The data is a vector of pointers to double
declare void @llvm.masked.store.v8p0f64.p0v8p0f64 (<8 x double*> <value>, <8 x_
↳ double*>* <ptr>, i32 <alignment>, <8 x i1> <mask>)
;; The data is a vector of function pointers
declare void @llvm.masked.store.v4p0f_i32f.p0v4p0f_i32f (<4 x i32 ()*> <value>, <4 x_
↳ i32 ()*>* <ptr>, i32 <alignment>, <4 x i1> <mask>)
```

Overview:

Writes a vector to memory according to the provided mask. The mask holds a bit for each vector lane, and is used to prevent memory accesses to the masked-off lanes.

Arguments:

The first operand is the vector value to be written to memory. The second operand is the base pointer for the store, it has the same underlying type as the value operand. The third operand is the alignment of the destination location. The fourth operand, mask, is a vector of boolean values. The types of the mask and the value operand must have the same number of vector elements.

Semantics:

The 'llvm.masked.store' intrinsic is designed for conditional writing of selected vector elements in a single IR operation. It is useful for targets that support vector masked store and allows vectorizing predicated basic blocks on these targets. Other targets may support this intrinsic differently, for example by lowering it into a sequence of branches that guard scalar store operations. The result of this operation is equivalent to a load-modify-store sequence. However, using this intrinsic prevents exceptions and data races on memory access to masked-off lanes.

```
call void @llvm.masked.store.v16f32.p0v16f32(<16 x float> %value, <16 x float>* %ptr,
    i32 4, <16 x i1> %mask)

;; The result of the following instructions is identical aside from potential data_
    races and memory access exceptions
%oldval = load <16 x float>, <16 x float>* %ptr, align 4
%res = select <16 x i1> %mask, <16 x float> %value, <16 x float> %oldval
store <16 x float> %res, <16 x float>* %ptr, align 4
```

Masked Vector Gather and Scatter Intrinsics

LLVM provides intrinsics for vector gather and scatter operations. They are similar to *Masked Vector Load and Store*, except they are designed for arbitrary memory accesses, rather than sequential memory accesses. Gather and scatter also employ a mask operand, which holds one bit per vector element, switching the associated vector lane on or off. The memory addresses corresponding to the "off" lanes are not accessed. When all bits are off, no memory is accessed.

'llvm.masked.gather.*' Intrinsics

Syntax:

This is an overloaded intrinsic. The loaded data are multiple scalar values of any integer, floating-point or pointer data type gathered together into one vector.

```
declare <16 x float> @llvm.masked.gather.v16f32.v16p0f32 (<16 x float*> <ptrs>, i32
    <alignment>, <16 x i1> <mask>, <16 x float> <passthru>)
declare <2 x double> @llvm.masked.gather.v2f64.v2p1f64 (<2 x double addrspace(1)*>
    <ptrs>, i32 <alignment>, <2 x i1> <mask>, <2 x double> <passthru>)
declare <8 x float*> @llvm.masked.gather.v8p0f32.v8p0p0f32 (<8 x float**> <ptrs>, i32
    <alignment>, <8 x i1> <mask>, <8 x float*> <passthru>)
```

Overview:

Reads scalar values from arbitrary memory locations and gathers them into one vector. The memory locations are provided in the vector of pointers 'ptrs'. The memory is accessed according to the provided mask. The mask holds a bit for each vector lane, and is used to prevent memory accesses to the masked-off lanes. The masked-off lanes in the result vector are taken from the corresponding lanes of the 'passthru' operand.

Arguments:

The first operand is a vector of pointers which holds all memory addresses to read. The second operand is an alignment of the source addresses. It must be a constant integer value. The third operand, mask, is a vector of boolean values with the same number of elements as the return type. The fourth is a pass-through value that is used to fill the masked-off lanes of the result. The return type, underlying type of the vector of pointers and the type of the 'passthru' operand are the same vector types.

Semantics:

The 'llvm.masked.gather' intrinsic is designed for conditional reading of multiple scalar values from arbitrary memory locations in a single IR operation. It is useful for targets that support vector masked gathers and allows vectorizing basic blocks with data and control divergence. Other targets may support this intrinsic differently, for example by lowering it into a sequence of scalar load operations. The semantics of this operation are equivalent to a sequence of conditional scalar loads with subsequent gathering all loaded values into a single vector. The mask restricts memory access to certain lanes and facilitates vectorization of predicated basic blocks.

```
%res = call <4 x double> @llvm.masked.gather.v4f64.v4p0f64 (<4 x double*> %ptrs, i32 8,
  ↪8, <4 x i1> <i1 true, i1 true, i1 true, i1 true>, <4 x double> undef)

;; The gather with all-true mask is equivalent to the following instruction sequence
%ptr0 = extractelement <4 x double*> %ptrs, i32 0
%ptr1 = extractelement <4 x double*> %ptrs, i32 1
%ptr2 = extractelement <4 x double*> %ptrs, i32 2
%ptr3 = extractelement <4 x double*> %ptrs, i32 3

%val0 = load double, double* %ptr0, align 8
%val1 = load double, double* %ptr1, align 8
%val2 = load double, double* %ptr2, align 8
%val3 = load double, double* %ptr3, align 8

%vec0   = insertelement <4 x double>undef, %val0, 0
%vec01  = insertelement <4 x double>%vec0, %val1, 1
%vec012 = insertelement <4 x double>%vec01, %val2, 2
%vec0123 = insertelement <4 x double>%vec012, %val3, 3
```

'llvm.masked.scatter.*' Intrinsics

Syntax:

This is an overloaded intrinsic. The data stored in memory is a vector of any integer, floating-point or pointer data type. Each vector element is stored in an arbitrary memory address. Scatter with overlapping addresses is guaranteed to be ordered from least-significant to most-significant element.

```
declare void @llvm.masked.scatter.v8i32.v8p0i32    (<8 x i32>    <value>, <8 x i32*>
→    <ptrs>, i32 <alignment>, <8 x i1> <mask>)
declare void @llvm.masked.scatter.v16f32.v16p1f32   (<16 x float> <value>, <16 x
→float> addrspace(1)*> <ptrs>, i32 <alignment>, <16 x i1> <mask>)
declare void @llvm.masked.scatter.v4p0f64.v4p0f64 (<4 x double*> <value>, <4 x
→double*> <ptrs>, i32 <alignment>, <4 x i1> <mask>)
```

Overview:

Writes each element from the value vector to the corresponding memory address. The memory addresses are represented as a vector of pointers. Writing is done according to the provided mask. The mask holds a bit for each vector lane, and is used to prevent memory accesses to the masked-off lanes.

Arguments:

The first operand is a vector value to be written to memory. The second operand is a vector of pointers, pointing to where the value elements should be stored. It has the same underlying type as the value operand. The third operand is an alignment of the destination addresses. The fourth operand, mask, is a vector of boolean values. The types of the mask and the value operand must have the same number of vector elements.

Semantics:

The 'llvm.masked.scatter' intrinsic is designed for writing selected vector elements to arbitrary memory addresses in a single IR operation. The operation may be conditional, when not all bits in the mask are switched on. It is useful for targets that support vector masked scatter and allows vectorizing basic blocks with data and control divergence. Other targets may support this intrinsic differently, for example by lowering it into a sequence of branches that guard scalar store operations.

```
;; This instruction unconditionally stores data vector in multiple addresses
call @llvm.masked.scatter.v8i32.v8p0i32 (<8 x i32> %value, <8 x i32*> %ptrs, i32 4,
→<8 x i1> <true, true, .. true>)

;; It is equivalent to a list of scalar stores
%val0 = extractelement <8 x i32> %value, i32 0
%val1 = extractelement <8 x i32> %value, i32 1
..
%val7 = extractelement <8 x i32> %value, i32 7
%ptr0 = extractelement <8 x i32*> %ptrs, i32 0
%ptr1 = extractelement <8 x i32*> %ptrs, i32 1
..
%ptr7 = extractelement <8 x i32*> %ptrs, i32 7
;; Note: the order of the following stores is important when they overlap:
store i32 %val0, i32* %ptr0, align 4
```

(continues on next page)

(continued from previous page)

```
store i32 %val1, i32* %ptr1, align 4
..
store i32 %val7, i32* %ptr7, align 4
```

Masked Vector Expanding Load and Compressing Store Intrinsics

LLVM provides intrinsics for expanding load and compressing store operations. Data selected from a vector according to a mask is stored in consecutive memory addresses (compressed store), and vice-versa (expanding load). These operations effective map to "if (cond.i) a[j++] = v.i" and "if (cond.i) v.i = a[j++]" patterns, respectively. Note that when the mask starts with '1' bits followed by '0' bits, these operations are identical to *llvm.masked.store* and *llvm.masked.load*.

'llvm.masked.expandload.*' Intrinsics

Syntax:

This is an overloaded intrinsic. Several values of integer, floating point or pointer data type are loaded from consecutive memory addresses and stored into the elements of a vector according to the mask.

```
declare <16 x float> @llvm.masked.expandload.v16f32 (float* <ptr>, <16 x i1> <mask>,
↳<16 x float> <passthru>)
declare <2 x i64> @llvm.masked.expandload.v2i64 (i64* <ptr>, <2 x i1> <mask>, <2_
↳x i64> <passthru>)
```

Overview:

Reads a number of scalar values sequentially from memory location provided in 'ptr' and spreads them in a vector. The 'mask' holds a bit for each vector lane. The number of elements read from memory is equal to the number of '1' bits in the mask. The loaded elements are positioned in the destination vector according to the sequence of '1' and '0' bits in the mask. E.g., if the mask vector is '10010001', "explandload" reads 3 values from memory addresses ptr, ptr+1, ptr+2 and places them in lanes 0, 3 and 7 accordingly. The masked-off lanes are filled by elements from the corresponding lanes of the 'passthru' operand.

Arguments:

The first operand is the base pointer for the load. It has the same underlying type as the element of the returned vector. The second operand, mask, is a vector of boolean values with the same number of elements as the return type. The third is a pass-through value that is used to fill the masked-off lanes of the result. The return type and the type of the 'passthru' operand have the same vector type.

Semantics:

The 'llvm.masked.expandload' intrinsic is designed for reading multiple scalar values from adjacent memory addresses into possibly non-adjacent vector lanes. It is useful for targets that support vector expanding loads and allows vectorizing loop with cross-iteration dependency like in the following example:

```
// In this loop we load from B and spread the elements into array A.
double *A, B; int *C;
for (int i = 0; i < size; ++i) {
    if (C[i] != 0)
        A[i] = B[j++];
}
```

```
; Load several elements from array B and expand them in a vector.
; The number of loaded elements is equal to the number of '1' elements in the Mask.
%Tmp = call <8 x double> @llvm.masked.expandload.v8f64(double* %Bptr, <8 x i1> %Mask,
↳<8 x double> undef)
; Store the result in A
call void @llvm.masked.store.v8f64.p0v8f64(<8 x double> %Tmp, <8 x double>* %Aptr,
↳i32 8, <8 x i1> %Mask)

; %Bptr should be increased on each iteration according to the number of '1' elements
↳in the Mask.
%MaskI = bitcast <8 x i1> %Mask to i8
%MaskIPopcnt = call i8 @llvm.ctpop.i8(i8 %MaskI)
%MaskI64 = zext i8 %MaskIPopcnt to i64
%BNextInd = add i64 %BInd, %MaskI64
```

Other targets may support this intrinsic differently, for example, by lowering it into a sequence of conditional scalar load operations and shuffles. If all mask elements are '1', the intrinsic behavior is equivalent to the regular unmasked vector load.

'llvm.masked.compressstore.*' Intrinsics

Syntax:

This is an overloaded intrinsic. A number of scalar values of integer, floating point or pointer data type are collected from an input vector and stored into adjacent memory addresses. A mask defines which elements to collect from the vector.

```
declare void @llvm.masked.compressstore.v8i32 (<8 x i32> <value>, i32* <ptr>,
↳<8 x i1> <mask>)
declare void @llvm.masked.compressstore.v16f32 (<16 x float> <value>, float* <ptr>,
↳<16 x i1> <mask>)
```

Overview:

Selects elements from input vector 'value' according to the 'mask'. All selected elements are written into adjacent memory addresses starting at address 'ptr', from lower to higher. The mask holds a bit for each vector lane, and is used to select elements to be stored. The number of elements to be stored is equal to the number of active bits in the mask.

Arguments:

The first operand is the input vector, from which elements are collected and written to memory. The second operand is the base pointer for the store, it has the same underlying type as the element of the input vector operand. The third operand is the mask, a vector of boolean values. The mask and the input vector must have the same number of vector elements.

Semantics:

The 'llvm.masked.compressstore' intrinsic is designed for compressing data in memory. It allows to collect elements from possibly non-adjacent lanes of a vector and store them contiguously in memory in one IR operation. It is useful for targets that support compressing store operations and allows vectorizing loops with cross-iteration dependences like in the following example:

```
// In this loop we load elements from A and store them consecutively in B
double *A, B; int *C;
for (int i = 0; i < size; ++i) {
    if (C[i] != 0)
        B[j++] = A[i]
}
```

```
; Load elements from A.
%Tmp = call <8 x double> @llvm.masked.load.v8f64.p0v8f64(<8 x double>* %Aptr, i32 8,
↳<8 x i1> %Mask, <8 x double> undef)
; Store all selected elements consecutively in array B
call <void> @llvm.masked.compressstore.v8f64(<8 x double> %Tmp, double* %Bptr, <8 x_
↳i1> %Mask)

; %Bptr should be increased on each iteration according to the number of '1' elements_
↳in the Mask.
%MaskI = bitcast <8 x i1> %Mask to i8
%MaskIPopcnt = call i8 @llvm.ctpop.i8(i8 %MaskI)
%MaskI64 = zext i8 %MaskIPopcnt to i64
%BNextInd = add i64 %BInd, %MaskI64
```

Other targets may support this intrinsic differently, for example, by lowering it into a sequence of branches that guard scalar store operations.

Memory Use Markers

This class of intrinsics provides information about the lifetime of memory objects and ranges where variables are immutable.

'`llvm.lifetime.start`' Intrinsic

Syntax:

```
declare void @llvm.lifetime.start(i64 <size>, i8* nocapture <ptr>)
```

Overview:

The '`llvm.lifetime.start`' intrinsic specifies the start of a memory object's lifetime.

Arguments:

The first argument is a constant integer representing the size of the object, or -1 if it is variable sized. The second argument is a pointer to the object.

Semantics:

This intrinsic indicates that before this point in the code, the value of the memory pointed to by `ptr` is dead. This means that it is known to never be used and has an undefined value. A load from the pointer that precedes this intrinsic can be replaced with '`undef`'.

'`llvm.lifetime.end`' Intrinsic

Syntax:

```
declare void @llvm.lifetime.end(i64 <size>, i8* nocapture <ptr>)
```

Overview:

The '`llvm.lifetime.end`' intrinsic specifies the end of a memory object's lifetime.

Arguments:

The first argument is a constant integer representing the size of the object, or -1 if it is variable sized. The second argument is a pointer to the object.

Semantics:

This intrinsic indicates that after this point in the code, the value of the memory pointed to by `ptr` is dead. This means that it is known to never be used and has an undefined value. Any stores into the memory object following this intrinsic may be removed as dead.

'llvm.invariant.start' Intrinsic**Syntax:**

This is an overloaded intrinsic. The memory object can belong to any address space.

```
declare {}* @llvm.invariant.start.p0i8(i64 <size>, i8* nocapture <ptr>)
```

Overview:

The `'llvm.invariant.start'` intrinsic specifies that the contents of a memory object will not change.

Arguments:

The first argument is a constant integer representing the size of the object, or -1 if it is variable sized. The second argument is a pointer to the object.

Semantics:

This intrinsic indicates that until an `llvm.invariant.end` that uses the return value, the referenced memory location is constant and unchanging.

'llvm.invariant.end' Intrinsic**Syntax:**

This is an overloaded intrinsic. The memory object can belong to any address space.

```
declare void @llvm.invariant.end.p0i8({}* <start>, i64 <size>, i8* nocapture <ptr>)
```

Overview:

The `'llvm.invariant.end'` intrinsic specifies that the contents of a memory object are mutable.

Arguments:

The first argument is the matching `llvm.invariant.start` intrinsic. The second argument is a constant integer representing the size of the object, or -1 if it is variable sized and the third argument is a pointer to the object.

Semantics:

This intrinsic indicates that the memory is mutable again.

'llvm.laundry.invariant.group' Intrinsic**Syntax:**

This is an overloaded intrinsic. The memory object can belong to any address space. The returned pointer must belong to the same address space as the argument.

```
declare i8* @llvm.laundry.invariant.group.p0i8(i8* <ptr>)
```

Overview:

The `'llvm.laundry.invariant.group'` intrinsic can be used when an invariant established by `invariant.group` metadata no longer holds, to obtain a new pointer value that carries fresh invariant group information. It is an experimental intrinsic, which means that its semantics might change in the future.

Arguments:

The `llvm.laundry.invariant.group` takes only one argument, which is a pointer to the memory.

Semantics:

Returns another pointer that aliases its argument but which is considered different for the purposes of `load/store invariant.group` metadata. It does not read any accessible memory and the execution can be speculated.

'llvm.strip.invariant.group' Intrinsic

Syntax:

This is an overloaded intrinsic. The memory object can belong to any address space. The returned pointer must belong to the same address space as the argument.

```
declare i8* @llvm.strip.invariant.group.p0i8(i8* <ptr>)
```

Overview:

The 'llvm.strip.invariant.group' intrinsic can be used when an invariant established by `invariant.group` metadata no longer holds, to obtain a new pointer value that does not carry the invariant information. It is an experimental intrinsic, which means that its semantics might change in the future.

Arguments:

The `llvm.strip.invariant.group` takes only one argument, which is a pointer to the memory.

Semantics:

Returns another pointer that aliases its argument but which has no associated `invariant.group` metadata. It does not read any memory and can be speculated.

Constrained Floating-Point Intrinsics

These intrinsics are used to provide special handling of floating-point operations when specific rounding mode or floating-point exception behavior is required. By default, LLVM optimization passes assume that the rounding mode is round-to-nearest and that floating-point exceptions will not be monitored. Constrained FP intrinsics are used to support non-default rounding modes and accurately preserve exception behavior without compromising LLVM's ability to optimize FP code when the default behavior is used.

Each of these intrinsics corresponds to a normal floating-point operation. The first two arguments and the return value are the same as the corresponding FP operation.

The third argument is a metadata argument specifying the rounding mode to be assumed. This argument must be one of the following strings:

```
"round.dynamic"
"round.tonearest"
"round.downward"
"round.upward"
"round.towardzero"
```

If this argument is "round.dynamic" optimization passes must assume that the rounding mode is unknown and may change at runtime. No transformations that depend on rounding mode may be performed in this case.

The other possible values for the rounding mode argument correspond to the similarly named IEEE rounding modes. If the argument is any of these values optimization passes may perform transformations as long as they are consistent with the specified rounding mode.

For example, 'x-0'-'>'x' is not a valid transformation if the rounding mode is "round.downward" or "round.dynamic" because if the value of 'x' is +0 then 'x-0' should evaluate to '-0' when rounding downward. However, this transformation is legal for all other rounding modes.

For values other than "round.dynamic" optimization passes may assume that the actual runtime rounding mode (as defined in a target-specific manner) matches the specified rounding mode, but this is not guaranteed. Using a specific non-dynamic rounding mode which does not match the actual rounding mode at runtime results in undefined behavior.

The fourth argument to the constrained floating-point intrinsics specifies the required exception behavior. This argument must be one of the following strings:

```
"fpexcept.ignore"  
"fpexcept.maytrap"  
"fpexcept.strict"
```

If this argument is "fpexcept.ignore" optimization passes may assume that the exception status flags will not be read and that floating-point exceptions will be masked. This allows transformations to be performed that may change the exception semantics of the original code. For example, FP operations may be speculatively executed in this case whereas they must not be for either of the other possible values of this argument.

If the exception behavior argument is "fpexcept.maytrap" optimization passes must avoid transformations that may raise exceptions that would not have been raised by the original code (such as speculatively executing FP operations), but passes are not required to preserve all exceptions that are implied by the original code. For example, exceptions may be potentially hidden by constant folding.

If the exception behavior argument is "fpexcept.strict" all transformations must strictly preserve the floating-point exception semantics of the original code. Any FP exception that would have been raised by the original code must be raised by the transformed code, and the transformed code must not raise any FP exceptions that would not have been raised by the original code. This is the exception behavior argument that will be used if the code being compiled reads the FP exception status flags, but this mode can also be used with code that unmask FP exceptions.

The number and order of floating-point exceptions is NOT guaranteed. For example, a series of FP operations that each may raise exceptions may be vectorized into a single instruction that raises each unique exception a single time.

'llvm.experimental.constrained.fadd' Intrinsic

Syntax:

```
declare <type>  
@llvm.experimental.constrained.fadd(<type> <op1>, <type> <op2>,  
                                     metadata <rounding mode>,  
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.fadd' intrinsic returns the sum of its two operands.

Arguments:

The first two arguments to the 'llvm.experimental.constrained.fadd' intrinsic must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

The third and fourth arguments specify the rounding mode and exception behavior as described above.

Semantics:

The value produced is the floating-point sum of the two value operands and has the same type as the operands.

'llvm.experimental.constrained.fsub' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.fsub(<type> <op1>, <type> <op2>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.fsub' intrinsic returns the difference of its two operands.

Arguments:

The first two arguments to the 'llvm.experimental.constrained.fsub' intrinsic must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

The third and fourth arguments specify the rounding mode and exception behavior as described above.

Semantics:

The value produced is the floating-point difference of the two value operands and has the same type as the operands.

'llvm.experimental.constrained.fmul' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.fmul(<type> <op1>, <type> <op2>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.fmul'` intrinsic returns the product of its two operands.

Arguments:

The first two arguments to the `'llvm.experimental.constrained.fmul'` intrinsic must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

The third and fourth arguments specify the rounding mode and exception behavior as described above.

Semantics:

The value produced is the floating-point product of the two value operands and has the same type as the operands.

'llvm.experimental.constrained.fdiv' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.fdiv(<type> <op1>, <type> <op2>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.fdiv'` intrinsic returns the quotient of its two operands.

Arguments:

The first two arguments to the `'llvm.experimental.constrained.fdiv'` intrinsic must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

The third and fourth arguments specify the rounding mode and exception behavior as described above.

Semantics:

The value produced is the floating-point quotient of the two value operands and has the same type as the operands.

'llvm.experimental.constrained.frem' Intrinsic

Syntax:

```
declare <type>
@llvm.experimental.constrained.frem(<type> <op1>, <type> <op2>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.frem' intrinsic returns the remainder from the division of its two operands.

Arguments:

The first two arguments to the 'llvm.experimental.constrained.frem' intrinsic must be *floating-point* or *vector* of floating-point values. Both arguments must have identical types.

The third and fourth arguments specify the rounding mode and exception behavior as described above. The rounding mode argument has no effect, since the result of frem is never rounded, but the argument is included for consistency with the other constrained floating-point intrinsics.

Semantics:

The value produced is the floating-point remainder from the division of the two value operands and has the same type as the operands. The remainder has the same sign as the dividend.

'llvm.experimental.constrained.fma' Intrinsic

Syntax:

```
declare <type>
@llvm.experimental.constrained.fma(<type> <op1>, <type> <op2>, <type> <op3>,
                                   metadata <rounding mode>,
                                   metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.fma' intrinsic returns the result of a fused-multiply-add operation on its operands.

Arguments:

The first three arguments to the `'llvm.experimental.constrained.fma'` intrinsic must be *floating-point* or *vector* of floating-point values. All arguments must have identical types.

The fourth and fifth arguments specify the rounding mode and exception behavior as described above.

Semantics:

The result produced is the product of the first two operands added to the third operand computed with infinite precision, and then rounded to the target precision.

'llvm.experimental.constrained.fptrunc' Intrinsic**Syntax:**

```
declare <ty2>
@llvm.experimental.constrained.fptrunc(<type> <value>,
                                       metadata <rounding mode>,
                                       metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.fptrunc'` intrinsic truncates value to type `ty2`.

Arguments:

The first argument to the `'llvm.experimental.constrained.fptrunc'` intrinsic must be *floating point* or *vector* of floating point values. This argument must be larger in size than the result.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

The result produced is a floating point value truncated to be smaller in size than the operand.

'llvm.experimental.constrained.fpext' Intrinsic**Syntax:**

```
declare <ty2>
@llvm.experimental.constrained.fpext(<type> <value>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.fpext'` intrinsic extends a floating-point value to a larger floating-point value.

Arguments:

The first argument to the `'llvm.experimental.constrained.fpext'` intrinsic must be *floating point* or *vector* of floating point values. This argument must be smaller in size than the result.

The second argument specifies the exception behavior as described above.

Semantics:

The result produced is a floating point value extended to be larger in size than the operand. All restrictions that apply to the `fpext` instruction also apply to this intrinsic.

Constrained libm-equivalent Intrinsics

In addition to the basic floating-point operations for which constrained intrinsics are described above, there are constrained versions of various operations which provide equivalent behavior to a corresponding libm function. These intrinsics allow the precise behavior of these operations with respect to rounding mode and exception behavior to be controlled.

As with the basic constrained floating-point intrinsics, the rounding mode and exception behavior arguments only control the behavior of the optimizer. They do not change the runtime floating-point environment.

'llvm.experimental.constrained.sqrt' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.sqrt(<type> <op1>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.sqrt'` intrinsic returns the square root of the specified value, returning the same value as the libm `'sqrt'` functions would, but without setting `errno`.

Arguments:

The first argument and the return type are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the nonnegative square root of the specified value. If the value is less than negative zero, a floating-point exception occurs and the return value is architecture specific.

'llvm.experimental.constrained.pow' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.pow(<type> <op1>, <type> <op2>,
                                   metadata <rounding mode>,
                                   metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.pow' intrinsic returns the first operand raised to the (positive or negative) power specified by the second operand.

Arguments:

The first two arguments and the return value are floating-point numbers of the same type. The second argument specifies the power to which the first argument should be raised.

The third and fourth arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the first value raised to the second power, returning the same values as the libm `pow` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained.powi' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.powi(<type> <op1>, i32 <op2>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.powi'` intrinsic returns the first operand raised to the (positive or negative) power specified by the second operand. The order of evaluation of multiplications is not defined. When a vector of floating-point type is used, the second argument remains a scalar integer value.

Arguments:

The first argument and the return value are floating-point numbers of the same type. The second argument is a 32-bit signed integer specifying the power to which the first argument should be raised.

The third and fourth arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the first value raised to the second power with an unspecified sequence of rounding operations.

'llvm.experimental.constrained.sin' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.sin(<type> <op1>,
                                   metadata <rounding mode>,
                                   metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.sin'` intrinsic returns the sine of the first operand.

Arguments:

The first argument and the return type are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the sine of the specified operand, returning the same values as the `libm sin` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained.cos' Intrinsic

Syntax:

```
declare <type>
@llvm.experimental.constrained.cos(<type> <op1>,
                                   metadata <rounding mode>,
                                   metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.cos' intrinsic returns the cosine of the first operand.

Arguments:

The first argument and the return type are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the cosine of the specified operand, returning the same values as the libm `cos` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained.exp' Intrinsic

Syntax:

```
declare <type>
@llvm.experimental.constrained.exp(<type> <op1>,
                                   metadata <rounding mode>,
                                   metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.exp' intrinsic computes the base-e exponential of the specified value.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the same values as the libm `exp` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained.exp2' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.exp2(<type> <op1>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.exp2' intrinsic computes the base-2 exponential of the specified value.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the same values as the libm `exp2` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained.log' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.log(<type> <op1>,
                                   metadata <rounding mode>,
                                   metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.log'` intrinsic computes the base-e logarithm of the specified value.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the same values as the `libm log` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained.log10' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.log10(<type> <op1>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.log10'` intrinsic computes the base-10 logarithm of the specified value.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the same values as the `libm log10` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained.log2' Intrinsic

Syntax:

```
declare <type>
@llvm.experimental.constrained.log2(<type> <op1>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.log2' intrinsic computes the base-2 logarithm of the specified value.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the same values as the libm `log2` functions would, and handles error conditions in the same way.

'llvm.experimental.constrained rint' Intrinsic

Syntax:

```
declare <type>
@llvm.experimental.constrained.rint(<type> <op1>,
                                    metadata <rounding mode>,
                                    metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.rint' intrinsic returns the first operand rounded to the nearest integer. It may raise an inexact floating-point exception if the operand is not an integer.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the same values as the `libm rint` functions would, and handles error conditions in the same way. The rounding mode is described, not determined, by the rounding mode argument. The actual rounding mode is determined by the runtime floating-point environment. The rounding mode argument is only intended as information to the compiler.

'llvm.experimental.constrained.nearbyint' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.nearbyint(<type> <op1>,
                                         metadata <rounding mode>,
                                         metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.nearbyint'` intrinsic returns the first operand rounded to the nearest integer. It will not raise an inexact floating-point exception if the operand is not an integer.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function returns the same values as the `libm nearbyint` functions would, and handles error conditions in the same way. The rounding mode is described, not determined, by the rounding mode argument. The actual rounding mode is determined by the runtime floating-point environment. The rounding mode argument is only intended as information to the compiler.

'llvm.experimental.constrained.maxnum' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.maxnum(<type> <op1>, <type> <op2>
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.maxnum' intrinsic returns the maximum of the two arguments.

Arguments:

The first two arguments and the return value are floating-point numbers of the same type.

The third and forth arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function follows the IEEE-754 semantics for maxNum. The rounding mode is described, not determined, by the rounding mode argument. The actual rounding mode is determined by the runtime floating-point environment. The rounding mode argument is only intended as information to the compiler.

'llvm.experimental.constrained.minnum' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.minnum(<type> <op1>, <type> <op2>
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.minnum' intrinsic returns the minimum of the two arguments.

Arguments:

The first two arguments and the return value are floating-point numbers of the same type.

The third and forth arguments specify the rounding mode and exception behavior as described above.

Semantics:

This function follows the IEEE-754 semantics for `minNum`. The rounding mode is described, not determined, by the rounding mode argument. The actual rounding mode is determined by the runtime floating-point environment. The rounding mode argument is only intended as information to the compiler.

'llvm.experimental.constrained.ceil' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.ceil(<type> <op1>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.ceil'` intrinsic returns the ceiling of the first operand.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above. The rounding mode is currently unused for this intrinsic.

Semantics:

This function returns the same values as the `libm ceil` functions would and handles error conditions in the same way.

'llvm.experimental.constrained.floor' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.floor(<type> <op1>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.floor'` intrinsic returns the floor of the first operand.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above. The rounding mode is currently unused for this intrinsic.

Semantics:

This function returns the same values as the `libm floor` functions would and handles error conditions in the same way.

'llvm.experimental.constrained.round' Intrinsic**Syntax:**

```
declare <type>
@llvm.experimental.constrained.round(<type> <op1>,
                                     metadata <rounding mode>,
                                     metadata <exception behavior>)
```

Overview:

The `'llvm.experimental.constrained.round'` intrinsic returns the first operand rounded to the nearest integer.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the rounding mode and exception behavior as described above. The rounding mode is currently unused for this intrinsic.

Semantics:

This function returns the same values as the `libm round` functions would and handles error conditions in the same way.

'llvm.experimental.constrained.trunc' Intrinsic

Syntax:

```
declare <type>
@llvm.experimental.constrained.trunc(<type> <op1>,
                                     metadata <truncing mode>,
                                     metadata <exception behavior>)
```

Overview:

The 'llvm.experimental.constrained.trunc' intrinsic returns the first operand rounded to the nearest integer not larger in magnitude than the operand.

Arguments:

The first argument and the return value are floating-point numbers of the same type.

The second and third arguments specify the truncing mode and exception behavior as described above. The truncing mode is currently unused for this intrinsic.

Semantics:

This function returns the same values as the libm `trunc` functions would and handles error conditions in the same way.

General Intrinsics

This class of intrinsics is designed to be generic and has no specific purpose.

'llvm.var.annotation' Intrinsic

Syntax:

```
declare void @llvm.var.annotation(i8* <val>, i8* <str>, i8* <str>, i32 <int>)
```

Overview:

The 'llvm.var.annotation' intrinsic.

Arguments:

The first argument is a pointer to a value, the second is a pointer to a global string, the third is a pointer to a global string which is the source file name, and the last argument is the line number.

Semantics:

This intrinsic allows annotation of local variables with arbitrary strings. This can be useful for special purpose optimizations that want to look for these annotations. These have no other defined use; they are ignored by code generation and optimization.

'llvm.ptr.annotation.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use 'llvm.ptr.annotation' on a pointer to an integer of any width. *NOTE* you must specify an address space for the pointer. The identifier for the default address space is the integer '0'.

```
declare i8* @llvm.ptr.annotation.p<address space>i8(i8* <val>, i8* <str>, i8* <str>,
↳ i32 <int>)
declare i16* @llvm.ptr.annotation.p<address space>i16(i16* <val>, i8* <str>, i8*
↳ <str>, i32 <int>)
declare i32* @llvm.ptr.annotation.p<address space>i32(i32* <val>, i8* <str>, i8*
↳ <str>, i32 <int>)
declare i64* @llvm.ptr.annotation.p<address space>i64(i64* <val>, i8* <str>, i8*
↳ <str>, i32 <int>)
declare i256* @llvm.ptr.annotation.p<address space>i256(i256* <val>, i8* <str>, i8*
↳ <str>, i32 <int>)
```

Overview:

The 'llvm.ptr.annotation' intrinsic.

Arguments:

The first argument is a pointer to an integer value of arbitrary bitwidth (result of some expression), the second is a pointer to a global string, the third is a pointer to a global string which is the source file name, and the last argument is the line number. It returns the value of the first argument.

Semantics:

This intrinsic allows annotation of a pointer to an integer with arbitrary strings. This can be useful for special purpose optimizations that want to look for these annotations. These have no other defined use; they are ignored by code generation and optimization.

'llvm.annotation.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use 'llvm.annotation' on any integer bit width.

```
declare i8 @llvm.annotation.i8(i8 <val>, i8* <str>, i8* <str>, i32 <int>)  
declare i16 @llvm.annotation.i16(i16 <val>, i8* <str>, i8* <str>, i32 <int>)  
declare i32 @llvm.annotation.i32(i32 <val>, i8* <str>, i8* <str>, i32 <int>)  
declare i64 @llvm.annotation.i64(i64 <val>, i8* <str>, i8* <str>, i32 <int>)  
declare i256 @llvm.annotation.i256(i256 <val>, i8* <str>, i8* <str>, i32 <int>)
```

Overview:

The 'llvm.annotation' intrinsic.

Arguments:

The first argument is an integer value (result of some expression), the second is a pointer to a global string, the third is a pointer to a global string which is the source file name, and the last argument is the line number. It returns the value of the first argument.

Semantics:

This intrinsic allows annotations to be put on arbitrary expressions with arbitrary strings. This can be useful for special purpose optimizations that want to look for these annotations. These have no other defined use; they are ignored by code generation and optimization.

'llvm.codeview.annotation' Intrinsic

Syntax:

This annotation emits a label at its program point and an associated S_ANNOTATION codeview record with some additional string metadata. This is used to implement MSVC's __annotation intrinsic. It is marked noduplicate, so calls to this intrinsic prevent inlining and should be considered expensive.

```
declare void @llvm.codeview.annotation(metadata)
```

Arguments:

The argument should be an MDTuple containing any number of MDStrings.

'llvm.trap' Intrinsic

Syntax:

```
declare void @llvm.trap() cold noreturn nounwind
```

Overview:

The 'llvm.trap' intrinsic.

Arguments:

None.

Semantics:

This intrinsic is lowered to the target dependent trap instruction. If the target does not have a trap instruction, this intrinsic will be lowered to a call of the `abort()` function.

'llvm.debugtrap' Intrinsic

Syntax:

```
declare void @llvm.debugtrap() nounwind
```

Overview:

The 'llvm.debugtrap' intrinsic.

Arguments:

None.

Semantics:

This intrinsic is lowered to code which is intended to cause an execution trap with the intention of requesting the attention of a debugger.

'llvm.stackprotector' Intrinsic

Syntax:

```
declare void @llvm.stackprotector(i8* <guard>, i8** <slot>)
```

Overview:

The `llvm.stackprotector` intrinsic takes the guard and stores it onto the stack at `slot`. The stack slot is adjusted to ensure that it is placed on the stack before local variables.

Arguments:

The `llvm.stackprotector` intrinsic requires two pointer arguments. The first argument is the value loaded from the stack guard `@__stack_chk_guard`. The second variable is an `alloca` that has enough space to hold the value of the guard.

Semantics:

This intrinsic causes the prologue/epilogue inserter to force the position of the `AllocaInst` stack slot to be before local variables on the stack. This is to ensure that if a local variable on the stack is overwritten, it will destroy the value of the guard. When the function exits, the guard on the stack is checked against the original guard by `llvm.stackprotectorcheck`. If they are different, then `llvm.stackprotectorcheck` causes the program to abort by calling the `__stack_chk_fail()` function.

'llvm.stackguard' Intrinsic

Syntax:

```
declare i8* @llvm.stackguard()
```

Overview:

The `llvm.stackguard` intrinsic returns the system stack guard value.

It should not be generated by frontends, since it is only for internal usage. The reason why we create this intrinsic is that we still support IR form Stack Protector in FastISel.

Arguments:

None.

Semantics:

On some platforms, the value returned by this intrinsic remains unchanged between loads in the same thread. On other platforms, it returns the same global variable value, if any, e.g. `@__stack_chk_guard`.

Currently some platforms have IR-level customized stack guard loading (e.g. X86 Linux) that is not handled by `llvm.stackguard()`, while they should be in the future.

'llvm.objectsize' Intrinsic**Syntax:**

```
declare i32 @llvm.objectsize.i32(i8* <object>, i1 <min>, i1 <nullunknown>, i1
↳<dynamic>)
declare i64 @llvm.objectsize.i64(i8* <object>, i1 <min>, i1 <nullunknown>, i1
↳<dynamic>)
```

Overview:

The `llvm.objectsize` intrinsic is designed to provide information to the optimizer to determine whether a) an operation (like `memcpy`) will overflow a buffer that corresponds to an object, or b) that a runtime check for overflow isn't necessary. An object in this context means an allocation of a specific class, structure, array, or other object.

Arguments:

The `llvm.objectsize` intrinsic takes four arguments. The first argument is a pointer to or into the object. The second argument determines whether `llvm.objectsize` returns 0 (if true) or -1 (if false) when the object size is unknown. The third argument controls how `llvm.objectsize` acts when null in address space 0 is used as its pointer argument. If it's false, `llvm.objectsize` reports 0 bytes available when given null. Otherwise, if the null is in a non-zero address space or if true is given for the third argument of `llvm.objectsize`, we assume its size is unknown. The fourth argument to `llvm.objectsize` determines if the value should be evaluated at runtime.

The second, third, and fourth arguments only accept constants.

Semantics:

The `llvm.objectsize` intrinsic is lowered to a value representing the size of the object concerned. If the size cannot be determined, `llvm.objectsize` returns i32/i64 -1 or 0 (depending on the min argument).

'llvm.expect' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.expect` on any integer bit width.

```
declare i1 @llvm.expect.i1(i1 <val>, i1 <expected_val>)  
declare i32 @llvm.expect.i32(i32 <val>, i32 <expected_val>)  
declare i64 @llvm.expect.i64(i64 <val>, i64 <expected_val>)
```

Overview:

The `llvm.expect` intrinsic provides information about expected (the most probable) value of `val`, which can be used by optimizers.

Arguments:

The `llvm.expect` intrinsic takes two arguments. The first argument is a value. The second argument is an expected value.

Semantics:

This intrinsic is lowered to the `val`.

'llvm.assume' Intrinsic

Syntax:

```
declare void @llvm.assume(i1 %cond)
```

Overview:

The `llvm.assume` allows the optimizer to assume that the provided condition is true. This information can then be used in simplifying other parts of the code.

Arguments:

The condition which the optimizer may assume is always true.

Semantics:

The intrinsic allows the optimizer to assume that the provided condition is always true whenever the control flow reaches the intrinsic call. No code is generated for this intrinsic, and instructions that contribute only to the provided condition are not used for code generation. If the condition is violated during execution, the behavior is undefined.

Note that the optimizer might limit the transformations performed on values used by the `llvm.assume` intrinsic in order to preserve the instructions only used to form the intrinsic's input argument. This might prove undesirable if the extra information provided by the `llvm.assume` intrinsic does not cause sufficient overall improvement in code quality. For this reason, `llvm.assume` should not be used to document basic mathematical invariants that the optimizer can otherwise deduce or facts that are of little use to the optimizer.

'llvm.ssa_copy' Intrinsic**Syntax:**

```
declare type @llvm.ssa_copy(type %operand) returned(1) readonly
```

Arguments:

The first argument is an operand which is used as the returned value.

Overview:

The `llvm.ssa_copy` intrinsic can be used to attach information to operations by copying them and giving them new names. For example, the `PredicateInfo` utility uses it to build Extended SSA form, and attach various forms of information to operands that dominate specific uses. It is not meant for general use, only for building temporary renaming forms that require value splits at certain points.

'llvm.type.test' Intrinsic**Syntax:**

```
declare i1 @llvm.type.test(i8* %ptr, metadata %type) nounwind readonly
```

Arguments:

The first argument is a pointer to be tested. The second argument is a metadata object representing a *type identifier*.

Overview:

The `llvm.type.test` intrinsic tests whether the given pointer is associated with the given type identifier.

'`llvm.type.checked.load`' Intrinsic

Syntax:

```
declare {i8*, i1} @llvm.type.checked.load(i8* %ptr, i32 %offset, metadata %type)␣  
→argmemonly nounwind readonly
```

Arguments:

The first argument is a pointer from which to load a function pointer. The second argument is the byte offset from which to load the function pointer. The third argument is a metadata object representing a *type identifier*.

Overview:

The `llvm.type.checked.load` intrinsic safely loads a function pointer from a virtual table pointer using type metadata. This intrinsic is used to implement control flow integrity in conjunction with virtual call optimization. The virtual call optimization pass will optimize away `llvm.type.checked.load` intrinsics associated with devirtualized calls, thereby removing the type check in cases where it is not needed to enforce the control flow integrity constraint.

If the given pointer is associated with a type metadata identifier, this function returns true as the second element of its return value. (Note that the function may also return true if the given pointer is not associated with a type metadata identifier.) If the function's return value's second element is true, the following rules apply to the first element:

- If the given pointer is associated with the given type metadata identifier, it is the function pointer loaded from the given byte offset from the given pointer.
- If the given pointer is not associated with the given type metadata identifier, it is one of the following (the choice of which is unspecified):
 1. The function pointer that would have been loaded from an arbitrarily chosen (through an unspecified mechanism) pointer associated with the type metadata.
 2. If the function has a non-void return type, a pointer to a function that returns an unspecified value without causing side effects.

If the function's return value's second element is false, the value of the first element is undefined.

'`llvm.donothing`' Intrinsic

Syntax:

```
declare void @llvm.donothing() nounwind readnone
```

Overview:

The `llvm.donothing` intrinsic doesn't perform any operation. It's one of only three intrinsics (besides `llvm.experimental.patchpoint` and `llvm.experimental.gc.statepoint`) that can be called with an `invoke` instruction.

Arguments:

None.

Semantics:

This intrinsic does nothing, and it's removed by optimizers and ignored by codegen.

'llvm.experimental.deoptimize' Intrinsic**Syntax:**

```
declare type @llvm.experimental.deoptimize(...) [ "deopt"(...) ]
```

Overview:

This intrinsic, together with *deoptimization operand bundles*, allow frontends to express transfer of control and frame-local state from the currently executing (typically more specialized, hence faster) version of a function into another (typically more generic, hence slower) version.

In languages with a fully integrated managed runtime like Java and JavaScript this intrinsic can be used to implement "uncommon trap" or "side exit" like functionality. In unmanaged languages like C and C++, this intrinsic can be used to represent the slow paths of specialized functions.

Arguments:

The intrinsic takes an arbitrary number of arguments, whose meaning is decided by the *lowering strategy*.

Semantics:

The `@llvm.experimental.deoptimize` intrinsic executes an attached deoptimization continuation (denoted using a *deoptimization operand bundle*) and returns the value returned by the deoptimization continuation. Defining the semantic properties of the continuation itself is out of scope of the language reference -- as far as LLVM is concerned, the deoptimization continuation can invoke arbitrary side effects, including reading from and writing to the entire heap.

Deoptimization continuations expressed using "deopt" operand bundles always continue execution to the end of the physical frame containing them, so all calls to `@llvm.experimental.deoptimize` must be in "tail position":

- `@llvm.experimental.deoptimize` cannot be invoked.
- The call must immediately precede a *ret* instruction.

- The `ret` instruction must return the value produced by the `@llvm.experimental.deoptimize` call if there is one, or `void`.

Note that the above restrictions imply that the return type for a call to `@llvm.experimental.deoptimize` will match the return type of its immediate caller.

The inliner composes the "deopt" continuations of the caller into the "deopt" continuations present in the inlined, and also updates calls to this intrinsic to return directly from the frame of the function it inlined into.

All declarations of `@llvm.experimental.deoptimize` must share the same calling convention.

Lowering:

Calls to `@llvm.experimental.deoptimize` are lowered to calls to the symbol `__llvm_deoptimize` (it is the frontend's responsibility to ensure that this symbol is defined). The call arguments to `@llvm.experimental.deoptimize` are lowered as if they were formal arguments of the specified types, and not as varargs.

'llvm.experimental.guard' Intrinsic

Syntax:

```
declare void @llvm.experimental.guard(i1, ...) [ "deopt"(...) ]
```

Overview:

This intrinsic, together with *deoptimization operand bundles*, allows frontends to express guards or checks on optimistic assumptions made during compilation. The semantics of `@llvm.experimental.guard` is defined in terms of `@llvm.experimental.deoptimize` -- its body is defined to be equivalent to:

```
define void @llvm.experimental.guard(i1 %pred, <args...>) {
    %realPred = and i1 %pred, undef
    br i1 %realPred, label %continue, label %leave [, !make.implicit !{}]

leave:
    call void @llvm.experimental.deoptimize(<args...>) [ "deopt"() ]
    ret void

continue:
    ret void
}
```

with the optional `[, !make.implicit !{}]` present if and only if it is present on the call site. For more details on `!make.implicit`, see *FaultMaps and implicit checks*.

In words, `@llvm.experimental.guard` executes the attached "deopt" continuation if (but **not** only if) its first argument is false. Since the optimizer is allowed to replace the `undef` with an arbitrary value, it can optimize guard to fail "spuriously", i.e. without the original condition being false (hence the "not only if"); and this allows for "check widening" type optimizations.

`@llvm.experimental.guard` cannot be invoked.

'llvm.experimental.widenable.condition' Intrinsic

Syntax:

```
declare i1 @llvm.experimental.widenable.condition()
```

Overview:

This intrinsic represents a "widenable condition" which is boolean expressions with the following property: whether this expression is *true* or *false*, the program is correct and well-defined.

Together with *deoptimization operand bundles*, `@llvm.experimental.widenable.condition` allows frontends to express guards or checks on optimistic assumptions made during compilation and represent them as branch instructions on special conditions.

While this may appear similar in semantics to *undef*, it is very different in that an invocation produces a particular, singular value. It is also intended to be lowered late, and remain available for specific optimizations and transforms that can benefit from its special properties.

Arguments:

None.

Semantics:

The intrinsic `@llvm.experimental.widenable.condition()` returns either *true* or *false*. For each evaluation of a call to this intrinsic, the program must be valid and correct both if it returns *true* and if it returns *false*. This allows transformation passes to replace evaluations of this intrinsic with either value whenever one is beneficial.

When used in a branch condition, it allows us to choose between two alternative correct solutions for the same problem, like in example below:

```
%cond = call i1 @llvm.experimental.widenable.condition()
br i1 %cond, label %solution_1, label %solution_2

label %fast_path:
; Apply memory-consuming but fast solution for a task.

label %slow_path:
; Cheap in memory but slow solution.
```

Whether the result of intrinsic's call is *true* or *false*, it should be correct to pick either solution. We can switch between them by replacing the result of `@llvm.experimental.widenable.condition` with different *il* expressions.

This is how it can be used to represent guards as widenable branches:

```
block:
; Unguarded instructions
call void @llvm.experimental.guard(i1 %cond, <args...>) ["deopt"(<deopt_args...>)]
; Guarded instructions
```

Can be expressed in an alternative equivalent form of explicit branch using `@llvm.experimental.widenable.condition`:

```
block:
; Unguarded instructions
%widenable_condition = call i1 @llvm.experimental.widenable.condition()
%guard_condition = and i1 %cond, %widenable_condition
br i1 %guard_condition, label %guarded, label %deopt

guarded:
; Guarded instructions

deopt:
call type @llvm.experimental.deoptimize(<args...>) [ "deopt"(<deopt_args...>) ]
```

So the block *guarded* is only reachable when *%cond* is *true*, and it should be valid to go to the block *deopt* whenever *%cond* is *true* or *false*.

@llvm.experimental.widenable.condition will never throw, thus it cannot be invoked.

Guard widening:

When @llvm.experimental.widenable.condition() is used in condition of a guard represented as explicit branch, it is legal to widen the guard's condition with any additional conditions.

Guard widening looks like replacement of

```
%widenable_cond = call i1 @llvm.experimental.widenable.condition()
%guard_cond = and i1 %cond, %widenable_cond
br i1 %guard_cond, label %guarded, label %deopt
```

with

```
%widenable_cond = call i1 @llvm.experimental.widenable.condition()
%new_cond = and i1 %any_other_cond, %widenable_cond
%new_guard_cond = and i1 %cond, %new_cond
br i1 %new_guard_cond, label %guarded, label %deopt
```

for this branch. Here *%any_other_cond* is an arbitrarily chosen well-defined *il* value. By making guard widening, we may impose stricter conditions on *guarded* block and bail to the *deopt* when the new condition is not met.

Lowering:

Default lowering strategy is replacing the result of call of `@llvm.experimental.widenable.condition` with constant `true`. However it is always correct to replace it with any other *il* value. Any pass can freely do it if it can benefit from non-default lowering.

'llvm.load.relative' Intrinsic**Syntax:**

```
declare i8* @llvm.load.relative.iN(i8* %ptr, iN %offset) argmemonly nounwind readonly
```

Overview:

This intrinsic loads a 32-bit value from the address `%ptr + %offset`, adds `%ptr` to that value and returns it. The constant folder specifically recognizes the form of this intrinsic and the constant initializers it may load from; if a loaded constant initializer is known to have the form `i32 trunc(x - %ptr)`, the intrinsic call is folded to `x`.

LLVM provides that the calculation of such a constant initializer will not overflow at link time under the medium code model if `x` is an `unnamed_addr` function. However, it does not provide this guarantee for a constant initializer folded into a function body. This intrinsic can be used to avoid the possibility of overflows when loading from such a constant.

'llvm.sideeffect' Intrinsic**Syntax:**

```
declare void @llvm.sideeffect() inaccessiblememonly nounwind
```

Overview:

The `llvm.sideeffect` intrinsic doesn't perform any operation. Optimizers treat it as having side effects, so it can be inserted into a loop to indicate that the loop shouldn't be assumed to terminate (which could potentially lead to the loop being optimized away entirely), even if it's an infinite loop with no other side effects.

Arguments:

None.

Semantics:

This intrinsic actually does nothing, but optimizers must assume that it has externally observable side effects.

'llvm.is.constant.*' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.is.constant` with any argument type.

```
declare i1 @llvm.is.constant.i32(i32 %operand) nounwind readnone
declare i1 @llvm.is.constant.f32(float %operand) nounwind readnone
declare i1 @llvm.is.constant.TYPENAME(TYPE %operand) nounwind readnone
```

Overview:

The `'llvm.is.constant'` intrinsic will return true if the argument is known to be a manifest compile-time constant. It is guaranteed to fold to either true or false before generating machine code.

Semantics:

This intrinsic generates no code. If its argument is known to be a manifest compile-time constant value, then the intrinsic will be converted to a constant true value. Otherwise, it will be converted to a constant false value.

In particular, note that if the argument is a constant expression which refers to a global (the address of which `_is_` a constant, but not manifest during the compile), then the intrinsic evaluates to false.

The result also intentionally depends on the result of optimization passes -- e.g., the result can change depending on whether a function gets inlined or not. A function's parameters are obviously not constant. However, a call like `llvm.is.constant.i32(i32 %param)` *can* return true after the function is inlined, if the value passed to the function parameter was a constant.

On the other hand, if constant folding is not run, it will never evaluate to true, even in simple cases.

Stack Map Intrinsics

LLVM provides experimental intrinsics to support runtime patching mechanisms commonly desired in dynamic language JITs. These intrinsics are described in *Stack maps and patch points in LLVM*.

Element Wise Atomic Memory Intrinsics

These intrinsics are similar to the standard library memory intrinsics except that they perform memory transfer as a sequence of atomic memory accesses.

'llvm.memcpy.element.unordered.atomic' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.memcpy.element.unordered.atomic` on any integer bit width and for different address spaces. Not all targets support all bit widths however.

```
declare void @llvm.memcpy.element.unordered.atomic.p0i8.p0i8.i32(i8* <dest>,
                                                                i8* <src>,
                                                                i32 <len>,
                                                                i32 <element_size>)
declare void @llvm.memcpy.element.unordered.atomic.p0i8.p0i8.i64(i8* <dest>,
                                                                i8* <src>,
                                                                i64 <len>,
                                                                i32 <element_size>)
```

Overview:

The `'llvm.memcpy.element.unordered.atomic.*'` intrinsic is a specialization of the `'llvm.memcpy.*'` intrinsic. It differs in that the `dest` and `src` are treated as arrays with elements that are exactly `element_size` bytes, and the copy between buffers uses a sequence of *unordered atomic* load/store operations that are a positive integer multiple of the `element_size` in size.

Arguments:

The first three arguments are the same as they are in the `@llvm.memcpy` intrinsic, with the added constraint that `len` is required to be a positive integer multiple of the `element_size`. If `len` is not a positive integer multiple of `element_size`, then the behaviour of the intrinsic is undefined.

`element_size` must be a compile-time constant positive power of two no greater than target-specific atomic access size limit.

For each of the input pointers `align` parameter attribute must be specified. It must be a power of two no less than the `element_size`. Caller guarantees that both the source and destination pointers are aligned to that boundary.

Semantics:

The `'llvm.memcpy.element.unordered.atomic.*'` intrinsic copies `len` bytes of memory from the source location to the destination location. These locations are not allowed to overlap. The memory copy is performed as a sequence of load/store operations where each access is guaranteed to be a multiple of `element_size` bytes wide and aligned at an `element_size` boundary.

The order of the copy is unspecified. The same value may be read from the source buffer many times, but only one write is issued to the destination buffer per element. It is well defined to have concurrent reads and writes to both source and destination provided those reads and writes are unordered atomic when specified.

This intrinsic does not provide any additional ordering guarantees over those provided by a set of unordered loads from the source location and stores to the destination.

Lowering:

In the most general case call to the `'llvm.memcpy.element.unordered.atomic.*'` is lowered to a call to the symbol `__llvm_memcpy_element_unordered_atomic_*`. Where `'*'` is replaced with an actual element size.

Optimizer is allowed to inline memory copy when it's profitable to do so.

'llvm.memmove.element.unordered.atomic' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.memmove.element.unordered.atomic` on any integer bit width and for different address spaces. Not all targets support all bit widths however.

```
declare void @llvm.memmove.element.unordered.atomic.p0i8.p0i8.i32(i8* <dest>,
                                                                    i8* <src>,
                                                                    i32 <len>,
                                                                    i32 <element_size>)
declare void @llvm.memmove.element.unordered.atomic.p0i8.p0i8.i64(i8* <dest>,
                                                                    i8* <src>,
                                                                    i64 <len>,
                                                                    i32 <element_size>)
```

Overview:

The `'llvm.memmove.element.unordered.atomic.*'` intrinsic is a specialization of the `'llvm.memmove.*'` intrinsic. It differs in that the `dest` and `src` are treated as arrays with elements that are exactly `element_size` bytes, and the copy between buffers uses a sequence of *unordered atomic* load/store operations that are a positive integer multiple of the `element_size` in size.

Arguments:

The first three arguments are the same as they are in the `@llvm.memmove` intrinsic, with the added constraint that `len` is required to be a positive integer multiple of the `element_size`. If `len` is not a positive integer multiple of `element_size`, then the behaviour of the intrinsic is undefined.

`element_size` must be a compile-time constant positive power of two no greater than a target-specific atomic access size limit.

For each of the input pointers the `align` parameter attribute must be specified. It must be a power of two no less than the `element_size`. Caller guarantees that both the source and destination pointers are aligned to that boundary.

Semantics:

The `'llvm.memmove.element.unordered.atomic.*'` intrinsic copies `len` bytes of memory from the source location to the destination location. These locations are allowed to overlap. The memory copy is performed as a sequence of load/store operations where each access is guaranteed to be a multiple of `element_size` bytes wide and aligned at an `element_size` boundary.

The order of the copy is unspecified. The same value may be read from the source buffer many times, but only one write is issued to the destination buffer per element. It is well defined to have concurrent reads and writes to both source and destination provided those reads and writes are unordered atomic when specified.

This intrinsic does not provide any additional ordering guarantees over those provided by a set of unordered loads from the source location and stores to the destination.

Lowering:

In the most general case call to the `'llvm.memmove.element.unordered.atomic.*'` is lowered to a call to the symbol `__llvm_memmove_element_unordered_atomic_*`. Where `'*'` is replaced with an actual element size.

The optimizer is allowed to inline the memory copy when it's profitable to do so.

'llvm.memset.element.unordered.atomic' Intrinsic

Syntax:

This is an overloaded intrinsic. You can use `llvm.memset.element.unordered.atomic` on any integer bit width and for different address spaces. Not all targets support all bit widths however.

```
declare void @llvm.memset.element.unordered.atomic.p0i8.i32(i8* <dest>,
                                                            i8 <value>,
                                                            i32 <len>,
                                                            i32 <element_size>)
declare void @llvm.memset.element.unordered.atomic.p0i8.i64(i8* <dest>,
                                                            i8 <value>,
                                                            i64 <len>,
                                                            i32 <element_size>)
```

Overview:

The `'llvm.memset.element.unordered.atomic.*'` intrinsic is a specialization of the `'llvm.memset.*'` intrinsic. It differs in that the `dest` is treated as an array with elements that are exactly `element_size` bytes, and the assignment to that array uses a sequence of *unordered atomic* store operations that are a positive integer multiple of the `element_size` in size.

Arguments:

The first three arguments are the same as they are in the `@llvm.memset` intrinsic, with the added constraint that `len` is required to be a positive integer multiple of the `element_size`. If `len` is not a positive integer multiple of `element_size`, then the behaviour of the intrinsic is undefined.

`element_size` must be a compile-time constant positive power of two no greater than target-specific atomic access size limit.

The `dest` input pointer must have the `align` parameter attribute specified. It must be a power of two no less than the `element_size`. Caller guarantees that the destination pointer is aligned to that boundary.

Semantics:

The `'llvm.memset.element.unordered.atomic.*'` intrinsic sets the `len` bytes of memory starting at the destination location to the given value. The memory is set with a sequence of store operations where each access is guaranteed to be a multiple of `element_size` bytes wide and aligned at an `element_size` boundary.

The order of the assignment is unspecified. Only one write is issued to the destination buffer per element. It is well defined to have concurrent reads and writes to the destination provided those reads and writes are unordered atomic when specified.

This intrinsic does not provide any additional ordering guarantees over those provided by a set of unordered stores to the destination.

Lowering:

In the most general case call to the `'llvm.memset.element.unordered.atomic.*'` is lowered to a call to the symbol `__llvm_memset_element_unordered_atomic_*`. Where `'*'` is replaced with an actual element size.

The optimizer is allowed to inline the memory assignment when it's profitable to do so.

Objective-C ARC Runtime Intrinsics

LLVM provides intrinsics that lower to Objective-C ARC runtime entry points. LLVM is aware of the semantics of these functions, and optimizes based on that knowledge. You can read more about the details of Objective-C ARC [here](#).

'llvm.objc.autorelease' Intrinsic

Syntax:

```
declare i8* @llvm.objc.autorelease(i8*)
```

Lowering:

Lowers to a call to `objc_autorelease`.

'llvm.objc.autoreleasePoolPop' Intrinsic**Syntax:**

```
declare void @llvm.objc.autoreleasePoolPop(i8*)
```

Lowering:

Lowers to a call to `objc_autoreleasePoolPop`.

'llvm.objc.autoreleasePoolPush' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.autoreleasePoolPush()
```

Lowering:

Lowers to a call to `objc_autoreleasePoolPush`.

'llvm.objc.autoreleaseReturnValue' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.autoreleaseReturnValue(i8*)
```

Lowering:

Lowers to a call to `objc_autoreleaseReturnValue`.

'llvm.objc.copyWeak' Intrinsic**Syntax:**

```
declare void @llvm.objc.copyWeak(i8**, i8**)
```

Lowering:

Lowers to a call to `objc_copyWeak`.

'llvm.objc.destroyWeak' Intrinsic**Syntax:**

```
declare void @llvm.objc.destroyWeak(i8**)
```

Lowering:

Lowers to a call to `objc_destroyWeak`.

'llvm.objc.initWeak' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.initWeak(i8**, i8*)
```

Lowering:

Lowers to a call to `objc_initWeak`.

'llvm.objc.loadWeak' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.loadWeak(i8**)
```

Lowering:

Lowers to a call to `objc_loadWeak`.

'llvm.objc.loadWeakRetained' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.loadWeakRetained(i8**)
```

Lowering:

Lowers to a call to `objc_loadWeakRetained`.

'llvm.objc.moveWeak' Intrinsic**Syntax:**

```
declare void @llvm.objc.moveWeak(i8**, i8**)
```

Lowering:

Lowers to a call to `objc_moveWeak`.

'llvm.objc.release' Intrinsic**Syntax:**

```
declare void @llvm.objc.release(i8*)
```

Lowering:

Lowers to a call to `objc_release`.

'llvm.objc.retain' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.retain(i8*)
```

Lowering:

Lowers to a call to `objc_retain`.

'llvm.objc.retainAutorelease' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.retainAutorelease(i8*)
```

Lowering:

Lowers to a call to `objc_retainAutorelease`.

'llvm.objc.retainAutoreleaseReturnValue' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.retainAutoreleaseReturnValue(i8*)
```

Lowering:

Lowers to a call to `objc_retainAutoreleaseReturnValue`.

'llvm.objc.retainAutoreleasedReturnValue' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.retainAutoreleasedReturnValue(i8*)
```

Lowering:

Lowers to a call to `objc_retainAutoreleasedReturnValue`.

'llvm.objc.retainBlock' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.retainBlock(i8*)
```

Lowering:

Lowers to a call to `objc_retainBlock`.

'llvm.objc.storeStrong' Intrinsic**Syntax:**

```
declare void @llvm.objc.storeStrong(i8**, i8*)
```

Lowering:

Lowers to a call to `objc_storeStrong`.

'llvm.objc.storeWeak' Intrinsic**Syntax:**

```
declare i8* @llvm.objc.storeWeak(i8**, i8*)
```

Lowering:

Lowers to a call to `objc_storeWeak`.

Preserving Debug Information Intrinsics

These intrinsics are used to carry certain debuginfo together with IR-level operations. For example, it may be desirable to know the structure/union name and the original user-level field indices. Such information got lost in IR `GetElementPtr` instruction since the IR types are different from `debugInfo` types and unions are converted to structs in IR.

'llvm.preserve.array.access.index' Intrinsic**Syntax:**

```
declare <ret_type>
@llvm.preserve.array.access.index.p0s_union.anons.p0a10s_union.anons(<type> base,
                                                                    i32 dim,
                                                                    i32 index)
```

Overview:

The `'llvm.preserve.array.access.index'` intrinsic returns the `getelementptr` address based on array base, array dimension `dim` and the last access index `index` into the array. The return type `ret_type` is a pointer type to the array element. The array `dim` and `index` are preserved which is more robust than `getelementptr` instruction which may be subject to compiler transformation.

Arguments:

The `base` is the array base address. The `dim` is the array dimension. The `base` is a pointer if `dim` equals 0. The `index` is the last access index into the array or pointer.

Semantics:

The `'llvm.preserve.array.access.index'` intrinsic produces the same result as a `getelementptr` with `base` and access operands `{dim's 0's, index}`.

'llvm.preserve.union.access.index' Intrinsic**Syntax:**

```
declare <type>
@llvm.preserve.union.access.index.p0s_union.anons.p0s_union.anons(<type> base,
                                                                    i32 di_index)
```

Overview:

The `'llvm.preserve.union.access.index'` intrinsic carries the debuginfo field index `di_index` and returns the base address. The `llvm.preserve.access.index` type of metadata is attached to this call instruction to provide union debuginfo type. The metadata is a `DICompositeType` representing the debuginfo version of type. The return type `type` is the same as the base type.

Arguments:

The `base` is the union base address. The `di_index` is the field index in debuginfo.

Semantics:

The `'llvm.preserve.union.access.index'` intrinsic returns the base address.

'llvm.preserve.struct.access.index' Intrinsic**Syntax:**

```
declare <ret_type>
@llvm.preserve.struct.access.index.p0i8.p0s_struct.anon.0s(<type> base,
                                                            i32 gep_index,
                                                            i32 di_index)
```

Overview:

The `'llvm.preserve.struct.access.index'` intrinsic returns the `getelementptr` address based on struct base and IR struct member index `gep_index`. The `llvm.preserve.access.index` type of metadata is attached to this call instruction to provide struct debuginfo type. The metadata is a `DICompositeType` representing the debuginfo version of type. The return type `ret_type` is a pointer type to the structure member.

Arguments:

The `base` is the structure base address. The `gep_index` is the struct member index based on IR structures. The `di_index` is the struct member index based on debuginfo.

Semantics:

The `'llvm.preserve.struct.access.index'` intrinsic produces the same result as a `getelementptr` with `base` and `access` operands `{0, gep_index}`.

2.1.1 Introduction

[CMake](#) is a cross-platform build-generator tool. CMake does not build the project, it generates the files needed by your build tool (GNU make, Visual Studio, etc.) for building LLVM.

If **you are a new contributor**, please start with the [Getting Started with the LLVM System](#) page. This page is geared for existing contributors moving from the legacy configure/make system.

If you are really anxious about getting a functional LLVM build, go to the [Quick start](#) section. If you are a CMake novice, start with [Basic CMake usage](#) and then go back to the [Quick start](#) section once you know what you are doing.

The *Options and variables* section is a reference for customizing your build. If you already have experience with CMake, this is the recommended starting point.

This page is geared towards users of the LLVM CMake build. If you're looking for information about modifying the LLVM CMake build system you may want to see the *CMake Primer* page. It has a basic overview of the CMake language.

2.1.2 Quick start

We use here the command-line, non-interactive CMake interface.

1. **Download** and install CMake. Version 3.4.3 is the minimum required.
2. Open a shell. Your development tools must be reachable from this shell through the PATH environment variable.
3. Create a build directory. Building LLVM in the source directory is not supported. cd to this directory:

```
$ mkdir mybuilddir
$ cd mybuilddir
```

4. Execute this command in the shell replacing *path/to/llvm/source/root* with the path to the root of your LLVM source tree:

```
$ cmake path/to/llvm/source/root
```

CMake will detect your development environment, perform a series of tests, and generate the files required for building LLVM. CMake will use default values for all build parameters. See the *Options and variables* section for a list of build parameters that you can modify.

This can fail if CMake can't detect your toolset, or if it thinks that the environment is not sane enough. In this case, make sure that the toolset that you intend to use is the only one reachable from the shell, and that the shell itself is the correct one for your development environment. CMake will refuse to build MinGW makefiles if you have a POSIX shell reachable through the PATH environment variable, for instance. You can force CMake to use a given build tool; for instructions, see the *Usage* section, below.

5. After CMake has finished running, proceed to use IDE project files, or start the build from the build directory:

```
$ cmake --build .
```

The `--build` option tells `cmake` to invoke the underlying build tool (`make`, `ninja`, `xcodebuild`, `msbuild`, etc.)

The underlying build tool can be invoked directly, of course, but the `--build` option is portable.

6. After LLVM has finished building, install it from the build directory:

```
$ cmake --build . --target install
```

The `--target` option with `install` parameter in addition to the `--build` option tells `cmake` to build the `install` target.

It is possible to set a different install prefix at installation time by invoking the `cmake_install.cmake` script generated in the build directory:

```
$ cmake -DCMAKE_INSTALL_PREFIX=/tmp/llvm -P cmake_install.cmake
```

2.1.3 Basic CMake usage

This section explains basic aspects of CMake which you may need in your day-to-day usage.

CMake comes with extensive documentation, in the form of html files, and as online help accessible via the `cmake` executable itself. Execute `cmake --help` for further help options.

CMake allows you to specify a build tool (e.g., GNU make, Visual Studio, or Xcode). If not specified on the command line, CMake tries to guess which build tool to use, based on your environment. Once it has identified your build tool, CMake uses the corresponding *Generator* to create files for your build tool (e.g., Makefiles or Visual Studio or Xcode project files). You can explicitly specify the generator with the command line option `-G "Name of the generator"`. To see a list of the available generators on your system, execute

```
$ cmake --help
```

This will list the generator names at the end of the help text.

Generators' names are case-sensitive, and may contain spaces. For this reason, you should enter them exactly as they are listed in the `cmake --help` output, in quotes. For example, to generate project files specifically for Visual Studio 12, you can execute:

```
$ cmake -G "Visual Studio 12" path/to/llvm/source/root
```

For a given development platform there can be more than one adequate generator. If you use Visual Studio, "NMake Makefiles" is a generator you can use for building with NMake. By default, CMake chooses the most specific generator supported by your development environment. If you want an alternative generator, you must tell this to CMake with the `-G` option.

2.1.4 Options and variables

Variables customize how the build will be generated. Options are boolean variables, with possible values ON/OFF. Options and variables are defined on the CMake command line like this:

```
$ cmake -DVARIBLE=value path/to/llvm/source
```

You can set a variable after the initial CMake invocation to change its value. You can also undefine a variable:

```
$ cmake -UVARIBLE path/to/llvm/source
```

Variables are stored in the CMake cache. This is a file named `CMakeCache.txt` stored at the root of your build directory that is generated by `cmake`. Editing it yourself is not recommended.

Variables are listed in the CMake cache and later in this document with the variable name and type separated by a colon. You can also specify the variable and type on the CMake command line:

```
$ cmake -DVARIBLE:TYPE=value path/to/llvm/source
```

Frequently-used CMake variables

Here are some of the CMake variables that are used often, along with a brief explanation and LLVM-specific notes. For full documentation, consult the CMake manual, or execute `cmake --help-variable VARIABLE_NAME`.

CMAKE_BUILD_TYPE:STRING Sets the build type for make-based generators. Possible values are Release, Debug, RelWithDebInfo and MinSizeRel. If you are using an IDE such as Visual Studio, you should use the IDE settings to set the build type. Be aware that Release and RelWithDebInfo use different optimization levels on most platforms.

CMAKE_INSTALL_PREFIX:PATH Path where LLVM will be installed if "make install" is invoked or the "install" target is built.

LLVM_LIBDIR_SUFFIX:STRING Extra suffix to append to the directory where libraries are to be installed. On a 64-bit architecture, one could use `-DLLVM_LIBDIR_SUFFIX=64` to install libraries to `/usr/lib64`.

CMAKE_C_FLAGS:STRING Extra flags to use when compiling C source files.

CMAKE_CXX_FLAGS:STRING Extra flags to use when compiling C++ source files.

LLVM-specific variables

LLVM_TARGETS_TO_BUILD:STRING Semicolon-separated list of targets to build, or *all* for building all targets. Case-sensitive. Defaults to *all*. Example: `-DLLVM_TARGETS_TO_BUILD="X86;PowerPC"`.

LLVM_BUILD_TOOLS:BOOL Build LLVM tools. Defaults to ON. Targets for building each tool are generated in any case. You can build a tool separately by invoking its target. For example, you can build *llvm-as* with a Makefile-based system by executing *make llvm-as* at the root of your build directory.

LLVM_INCLUDE_TOOLS:BOOL Generate build targets for the LLVM tools. Defaults to ON. You can use this option to disable the generation of build targets for the LLVM tools.

LLVM_INSTALL_BINUTILS_SYMLINKS:BOOL Install symlinks from the binutils tool names to the corresponding LLVM tools. For example, *ar* will be symlinked to *llvm-ar*.

LLVM_BUILD_EXAMPLES:BOOL Build LLVM examples. Defaults to OFF. Targets for building each example are generated in any case. See documentation for *LLVM_BUILD_TOOLS* above for more details.

LLVM_INCLUDE_EXAMPLES:BOOL Generate build targets for the LLVM examples. Defaults to ON. You can use this option to disable the generation of build targets for the LLVM examples.

LLVM_BUILD_TESTS:BOOL Build LLVM unit tests. Defaults to OFF. Targets for building each unit test are generated in any case. You can build a specific unit test using the targets defined under *unittests*, such as *ADTTests*, *IRTests*, *SupportTests*, etc. (Search for `add_llvm_unittest` in the subdirectories of *unittests* for a complete list of unit tests.) It is possible to build all unit tests with the target *UnitTests*.

LLVM_INCLUDE_TESTS:BOOL Generate build targets for the LLVM unit tests. Defaults to ON. You can use this option to disable the generation of build targets for the LLVM unit tests.

LLVM_BUILD_BENCHMARKS:BOOL Adds benchmarks to the list of default targets. Defaults to OFF.

LLVM_INCLUDE_BENCHMARKS:BOOL Generate build targets for the LLVM benchmarks. Defaults to ON.

LLVM_APPEND_VC_REV:BOOL Embed version control revision info (svn revision number or Git revision id). The version info is provided by the `LLVM_REVISION` macro in `llvm/include/llvm/Support/VCSRevision.h`. Developers using git who don't need revision info can disable this option to avoid re-linking most binaries after a branch switch. Defaults to ON.

LLVM_ENABLE_THREADS:BOOL Build with threads support, if available. Defaults to ON.

LLVM_ENABLE_UNWIND_TABLES:BOOL Enable unwind tables in the binary. Disabling unwind tables can reduce the size of the libraries. Defaults to ON.

LLVM_CXX_STD:STRING Build with the specified C++ standard. Defaults to "c++11".

LLVM_ENABLE_ASSERTIONS:BOOL Enables code assertions. Defaults to ON if and only if `CMAKE_BUILD_TYPE` is *Debug*.

LLVM_ENABLE_EH:BOOL Build LLVM with exception-handling support. This is necessary if you wish to link against LLVM libraries and make use of C++ exceptions in your own code that need to propagate through LLVM code. Defaults to OFF.

LLVM_ENABLE_EXPENSIVE_CHECKS:BOOL Enable additional time/memory expensive checking. Defaults to OFF.

LLVM_ENABLE_IDE:BOOL Tell the build system that an IDE is being used. This in turn disables the creation of certain convenience build system targets, such as the various `install-*` and `check-*` targets, since IDEs don't always deal well with a large number of targets. This is usually autodetected, but it can be configured manually to explicitly control the generation of those targets. One scenario where a manual override may be desirable is when using Visual Studio 2017's CMake integration, which would not be detected as an IDE otherwise.

LLVM_ENABLE_PIC:BOOL Add the `-fPIC` flag to the compiler command-line, if the compiler supports this flag. Some systems, like Windows, do not need this flag. Defaults to ON.

LLVM_ENABLE_RTTI:BOOL Build LLVM with run-time type information. Defaults to OFF.

LLVM_ENABLE_WARNINGS:BOOL Enable all compiler warnings. Defaults to ON.

LLVM_ENABLE_PEDANTIC:BOOL Enable pedantic mode. This disables compiler-specific extensions, if possible. Defaults to ON.

LLVM_ENABLE_WERROR:BOOL Stop and fail the build, if a compiler warning is triggered. Defaults to OFF.

LLVM_ABI_BREAKING_CHECKS:STRING Used to decide if LLVM should be built with ABI breaking checks or not. Allowed values are *WITH_ASSERTS* (default), *FORCE_ON* and *FORCE_OFF*. *WITH_ASSERTS* turns on ABI breaking checks in an assertion enabled build. *FORCE_ON* (*FORCE_OFF*) turns them on (off) irrespective of whether normal (*NDEBUG*-based) assertions are enabled or not. A version of LLVM built with ABI breaking checks is not ABI compatible with a version built without it.

LLVM_BUILD_32_BITS:BOOL Build 32-bit executables and libraries on 64-bit systems. This option is available only on some 64-bit Unix systems. Defaults to OFF.

LLVM_TARGET_ARCH:STRING LLVM target to use for native code generation. This is required for JIT generation. It defaults to "host", meaning that it shall pick the architecture of the machine where LLVM is being built. If you are cross-compiling, set it to the target architecture name.

LLVM_TABLEGEN:STRING Full path to a native TableGen executable (usually named `llvm-tblgen`). This is intended for cross-compiling: if the user sets this variable, no native TableGen will be created.

LLVM_LIT_ARGS:STRING Arguments given to `lit`. `make check` and `make clang-test` are affected. By default, `'-sv --no-progress-bar'` on Visual C++ and Xcode, `'-sv'` on others.

LLVM_LIT_TOOLS_DIR:PATH The path to GnuWin32 tools for tests. Valid on Windows host. Defaults to the empty string, in which case `lit` will look for tools needed for tests (e.g. `grep`, `sort`, etc.) in your `%PATH%`. If GnuWin32 is not in your `%PATH%`, then you can set this variable to the GnuWin32 directory so that `lit` can find tools needed for tests in that directory.

LLVM_ENABLE_FFI:BOOL Indicates whether the LLVM Interpreter will be linked with the Foreign Function Interface library (`libffi`) in order to enable calling external functions. If the library or its headers are installed in a custom location, you can also set the variables `FFI_INCLUDE_DIR` and `FFI_LIBRARY_DIR` to the directories where `ffi.h` and `libffi.so` can be found, respectively. Defaults to OFF.

LLVM_EXTERNAL_{CLANG,LLD,POLLY}_SOURCE_DIR:PATH These variables specify the path to the source directory for the external LLVM projects Clang, lld, and Polly, respectively, relative to the top-level

source directory. If the in-tree subdirectory for an external project exists (e.g., `llvm/tools/clang` for Clang), then the corresponding variable will not be used. If the variable for an external project does not point to a valid path, then that project will not be built.

LLVM_ENABLE_PROJECTS:STRING Semicolon-separated list of projects to build, or *all* for building all (clang, libcxx, libcxxabi, lldb, compiler-rt, lld, polly) projects. This flag assumes that projects are checked out side-by-side and not nested, i.e. clang needs to be in parallel of llvm instead of nested in *llvm/tools*. This feature allows to have one build for only LLVM and another for clang+llvm using the same source checkout.

LLVM_EXTERNAL_PROJECTS:STRING Semicolon-separated list of additional external projects to build as part of llvm. For each project `LLVM_EXTERNAL_<NAME>_SOURCE_DIR` have to be specified with the path for the source code of the project. Example: `-DLLVM_EXTERNAL_PROJECTS="Foo;Bar" -DLLVM_EXTERNAL_FOO_SOURCE_DIR=/src/foo -DLLVM_EXTERNAL_BAR_SOURCE_DIR=/src/bar`.

LLVM_USE_OPROFILE:BOOL Enable building OProfile JIT support. Defaults to OFF.

LLVM_PROFDATA_FILE:PATH Path to a profdata file to pass into clang's `-fprofile-instr-use` flag. This can only be specified if you're building with clang.

LLVM_USE_INTEL_JITEVENTS:BOOL Enable building support for Intel JIT Events API. Defaults to OFF.

LLVM_ENABLE_LIBPFM:BOOL Enable building with libpfm to support hardware counter measurements in LLVM tools. Defaults to ON.

LLVM_USE_PERF:BOOL Enable building support for Perf (linux profiling tool) JIT support. Defaults to OFF.

LLVM_ENABLE_ZLIB:BOOL Enable building with zlib to support compression/uncompression in LLVM tools. Defaults to ON.

LLVM_ENABLE_DIA_SDK:BOOL Enable building with MSVC DIA SDK for PDB debugging support. Available only with MSVC. Defaults to ON.

LLVM_USE_SANITIZER:STRING Define the sanitizer used to build LLVM binaries and tests. Possible values are Address, Memory, MemoryWithOrigins, Undefined, Thread, and Address;Undefined. Defaults to empty string.

LLVM_ENABLE_LTO:STRING Add `-flto` or `-flto=` flags to the compile and link command lines, enabling link-time optimization. Possible values are Off, On, Thin and Full. Defaults to OFF.

LLVM_USE_LINKER:STRING Add `-fuse-ld={name}` to the link invocation. The possible value depend on your compiler, for clang the value can be an absolute path to your custom linker, otherwise clang will prefix the name with `ld.` and apply its usual search. For example to link LLVM with the Gold linker, cmake can be invoked with `-DLLVM_USE_LINKER=gold`.

LLVM_ENABLE_LLD:BOOL This option is equivalent to `-DLLVM_USE_LINKER=lld`, except during a 2-stage build where a dependency is added from the first stage to the second ensuring that lld is built before stage2 begins.

LLVM_PARALLEL_COMPILE_JOBS:STRING Define the maximum number of concurrent compilation jobs.

LLVM_PARALLEL_LINK_JOBS:STRING Define the maximum number of concurrent link jobs.

LLVM_BUILD_DOCS:BOOL Adds all *enabled* documentation targets (i.e. Doxygen and Sphinx targets) as dependencies of the default build targets. This results in all of the (enabled) documentation targets being as part of a normal build. If the `install` target is run then this also enables all built documentation targets to be installed. Defaults to OFF. To enable a particular documentation target, see `LLVM_ENABLE_SPHINX` and `LLVM_ENABLE_DOXYGEN`.

LLVM_ENABLE_DOXYGEN:BOOL Enables the generation of browsable HTML documentation using doxygen. Defaults to OFF.

LLVM_ENABLE_DOXYGEN_QT_HELP:BOOL Enables the generation of a Qt Compressed Help file. Defaults to OFF. This affects the make target `doxygen-llvm`. When enabled, apart from the normal HTML output generated by doxygen, this will produce a QCH file named `org.llvm.qch`. You can then load this file into Qt Creator. This option is only useful in combination with `-DLLVM_ENABLE_DOXYGEN=ON`; otherwise this has no effect.

LLVM_DOXYGEN_QCH_FILENAME:STRING The filename of the Qt Compressed Help file that will be generated when `-DLLVM_ENABLE_DOXYGEN=ON` and `-DLLVM_ENABLE_DOXYGEN_QT_HELP=ON` are given. Defaults to `org.llvm.qch`. This option is only useful in combination with `-DLLVM_ENABLE_DOXYGEN_QT_HELP=ON`; otherwise it has no effect.

LLVM_DOXYGEN_QHP_NAMESPACE:STRING Namespace under which the intermediate Qt Help Project file lives. See [Qt Help Project](#) for more information. Defaults to `"org.llvm"`. This option is only useful in combination with `-DLLVM_ENABLE_DOXYGEN_QT_HELP=ON`; otherwise it has no effect.

LLVM_DOXYGEN_QHP_CUST_FILTER_NAME:STRING See [Qt Help Project](#) for more information. Defaults to the CMake variable `${PACKAGE_STRING}` which is a combination of the package name and version string. This filter can then be used in Qt Creator to select only documentation from LLVM when browsing through all the help files that you might have loaded. This option is only useful in combination with `-DLLVM_ENABLE_DOXYGEN_QT_HELP=ON`; otherwise it has no effect.

LLVM_DOXYGEN_QHELPGENERATOR_PATH:STRING The path to the `qhelpgenerator` executable. Defaults to whatever CMake's `find_program()` can find. This option is only useful in combination with `-DLLVM_ENABLE_DOXYGEN_QT_HELP=ON`; otherwise it has no effect.

LLVM_DOXYGEN_SVG:BOOL Uses `.svg` files instead of `.png` files for graphs in the Doxygen output. Defaults to OFF.

LLVM_INSTALL_DOXYGEN_HTML_DIR:STRING The path to install Doxygen-generated HTML documentation to. This path can either be absolute or relative to the `CMAKE_INSTALL_PREFIX`. Defaults to `share/doc/llvm/doxygen-html`.

LLVM_ENABLE_SPHINX:BOOL If specified, CMake will search for the `sphinx-build` executable and will make the `SPHINX_OUTPUT_HTML` and `SPHINX_OUTPUT_MAN` CMake options available. Defaults to OFF.

SPHINX_EXECUTABLE:STRING The path to the `sphinx-build` executable detected by CMake. For installation instructions, see <http://www.sphinx-doc.org/en/latest/install.html>

SPHINX_OUTPUT_HTML:BOOL If enabled (and `LLVM_ENABLE_SPHINX` is enabled) then the targets for building the documentation as html are added (but not built by default unless `LLVM_BUILD_DOCS` is enabled). There is a target for each project in the source tree that uses sphinx (e.g. `docs-llvm-html`, `docs-clang-html` and `docs-lld-html`). Defaults to ON.

SPHINX_OUTPUT_MAN:BOOL If enabled (and `LLVM_ENABLE_SPHINX` is enabled) the targets for building the man pages are added (but not built by default unless `LLVM_BUILD_DOCS` is enabled). Currently the only target added is `docs-llvm-man`. Defaults to ON.

SPHINX_WARNINGS_AS_ERRORS:BOOL If enabled then sphinx documentation warnings will be treated as errors. Defaults to ON.

LLVM_INSTALL_SPHINX_HTML_DIR:STRING The path to install Sphinx-generated HTML documentation to. This path can either be absolute or relative to the `CMAKE_INSTALL_PREFIX`. Defaults to `share/doc/llvm/html`.

LLVM_INSTALL_OCAMLDOC_HTML_DIR:STRING The path to install OCamlDoc-generated HTML documentation to. This path can either be absolute or relative to the `CMAKE_INSTALL_PREFIX`. Defaults to `share/doc/llvm/ocaml-html`.

LLVM_CREATE_XCODE_TOOLCHAIN:BOOL macOS Only: If enabled CMake will generate a target named `'install-xcode-toolchain'`. This target will create a directory at `$CMAKE_INSTALL_PREFIX/Toolchains` containing an `xctoolchain` directory which can be used to override the default system tools.

LLVM_BUILD_LLVM_DYLIB:BOOL If enabled, the target for building the libLLVM shared library is added. This library contains all of LLVM's components in a single shared library. Defaults to OFF. This cannot be used in conjunction with BUILD_SHARED_LIBS. Tools will only be linked to the libLLVM shared library if LLVM_LINK_LLVM_DYLIB is also ON. The components in the library can be customised by setting LLVM_DYLIB_COMPONENTS to a list of the desired components.

LLVM_LINK_LLVM_DYLIB:BOOL If enabled, tools will be linked with the libLLVM shared library. Defaults to OFF. Setting LLVM_LINK_LLVM_DYLIB to ON also sets LLVM_BUILD_LLVM_DYLIB to ON.

BUILD_SHARED_LIBS:BOOL Flag indicating if each LLVM component (e.g. Support) is built as a shared library (ON) or as a static library (OFF). Its default value is OFF. On Windows, shared libraries may be used when building with MinGW, including mingw-w64, but not when building with the Microsoft toolchain.

Note: BUILD_SHARED_LIBS is only recommended for use by LLVM developers. If you want to build LLVM as a shared library, you should use the LLVM_BUILD_LLVM_DYLIB option.

LLVM_OPTIMIZED_TABLEGEN:BOOL If enabled and building a debug or asserts build the CMake build system will generate a Release build tree to build a fully optimized tablegen for use during the build. Enabling this option can significantly speed up build times especially when building LLVM in Debug configurations.

LLVM_REVERSE_ITERATION:BOOL If enabled, all supported unordered llvm containers would be iterated in reverse order. This is useful for uncovering non-determinism caused by iteration of unordered containers.

LLVM_BUILD_INSTRUMENTED_COVERAGE:BOOL If enabled, [source-based code coverage](#) instrumentation is enabled while building llvm.

LLVM_CCACHE_BUILD:BOOL If enabled and the ccache program is available, then LLVM will be built using ccache to speed up rebuilds of LLVM and its components. Defaults to OFF. The size and location of the cache maintained by ccache can be adjusted via the LLVM_CCACHE_MAXSIZE and LLVM_CCACHE_DIR options, which are passed to the CCACHE_MAXSIZE and CCACHE_DIR environment variables, respectively.

LLVM_FORCE_USE_OLD_TOOLCHAIN:BOOL If enabled, the compiler and standard library versions won't be checked. LLVM may not compile at all, or might fail at runtime due to known bugs in these toolchains.

LLVM_TEMPORARILY_ALLOW_OLD_TOOLCHAIN:BOOL If enabled, the compiler version check will only warn when using a toolchain which is about to be deprecated, instead of emitting an error.

LLVM_USE_NEWPM:BOOL If enabled, use the experimental new pass manager.

LLVM_ENABLE_BINDINGS:BOOL If disabled, do not try to build the OCaml and go bindings.

2.1.5 CMake Caches

Recently LLVM and Clang have been adding some more complicated build system features. Utilizing these new features often involves a complicated chain of CMake variables passed on the command line. Clang provides a collection of CMake cache scripts to make these features more approachable.

CMake cache files are utilized using CMake's -C flag:

```
$ cmake -C <path to cache file> <path to sources>
```

CMake cache scripts are processed in an isolated scope, only cached variables remain set when the main configuration runs. CMake cached variables do not reset variables that are already set unless the FORCE option is specified.

A few notes about CMake Caches:

- Order of command line arguments is important
 - -D arguments specified before -C are set before the cache is processed and can be read inside the cache file

- -D arguments specified after -C are set after the cache is processed and are unset inside the cache file
- All -D arguments will override cache file settings
- CMAKE_TOOLCHAIN_FILE is evaluated after both the cache file and the command line arguments
- It is recommended that all -D options should be specified *before* -C

For more information about some of the advanced build configurations supported via Cache files see [Advanced Build Configurations](#).

2.1.6 Executing the Tests

Testing is performed when the *check-all* target is built. For instance, if you are using Makefiles, execute this command in the root of your build directory:

```
$ make check-all
```

On Visual Studio, you may run tests by building the project "check-all". For more information about testing, see the [LLVM Testing Infrastructure Guide](#).

2.1.7 Cross compiling

See [this wiki page](#) for generic instructions on how to cross-compile with CMake. It goes into detailed explanations and may seem daunting, but it is not. On the wiki page there are several examples including toolchain files. Go directly to [this section](#) for a quick solution.

Also see the [LLVM-specific variables](#) section for variables used when cross-compiling.

2.1.8 Embedding LLVM in your project

From LLVM 3.5 onwards the CMake build system exports LLVM libraries as importable CMake targets. This means that clients of LLVM can now reliably use CMake to develop their own LLVM-based projects against an installed version of LLVM regardless of how it was built.

Here is a simple example of a CMakeLists.txt file that imports the LLVM libraries and uses them to build a simple application *simple-tool*.

```
cmake_minimum_required(VERSION 3.4.3)
project(SimpleProject)

find_package(LLVM REQUIRED CONFIG)

message(STATUS "Found LLVM ${LLVM_PACKAGE_VERSION}")
message(STATUS "Using LLVMConfig.cmake in: ${LLVM_DIR}")

# Set your project compile flags.
# E.g. if using the C++ header files
# you will need to enable C++11 support
# for your compiler.

include_directories(${LLVM_INCLUDE_DIRS})
add_definitions(${LLVM_DEFINITIONS})

# Now build our tools
```

(continues on next page)

(continued from previous page)

```

add_executable(simple-tool tool.cpp)

# Find the libraries that correspond to the LLVM components
# that we wish to use
llvm_map_components_to_libnames(llvm_libs support core irreader)

# Link against LLVM libraries
target_link_libraries(simple-tool ${llvm_libs})

```

The `find_package(...)` directive when used in CONFIG mode (as in the above example) will look for the `LLVMConfig.cmake` file in various locations (see `cmake` manual for details). It creates a `LLVM_DIR` cache entry to save the directory where `LLVMConfig.cmake` is found or allows the user to specify the directory (e.g. by passing `-DLLVM_DIR=/usr/lib/cmake/llvm` to the `cmake` command or by setting it directly in `ccmake` or `cmake-gui`).

This file is available in two different locations.

- `<INSTALL_PREFIX>/lib/cmake/llvm/LLVMConfig.cmake` where `<INSTALL_PREFIX>` is the install prefix of an installed version of LLVM. On Linux typically this is `/usr/lib/cmake/llvm/LLVMConfig.cmake`.
- `<LLVM_BUILD_ROOT>/lib/cmake/llvm/LLVMConfig.cmake` where `<LLVM_BUILD_ROOT>` is the root of the LLVM build tree. **Note: this is only available when building LLVM with CMake.**

If LLVM is installed in your operating system's normal installation prefix (e.g. on Linux this is usually `/usr/`) `find_package(LLVM ...)` will automatically find LLVM if it is installed correctly. If LLVM is not installed or you wish to build directly against the LLVM build tree you can use `LLVM_DIR` as previously mentioned.

The `LLVMConfig.cmake` file sets various useful variables. Notable variables include

LLVM_CMAKE_DIR The path to the LLVM CMake directory (i.e. the directory containing `LLVMConfig.cmake`).

LLVM_DEFINITIONS A list of preprocessor defines that should be used when building against LLVM.

LLVM_ENABLE_ASSERTIONS This is set to ON if LLVM was built with assertions, otherwise OFF.

LLVM_ENABLE_EH This is set to ON if LLVM was built with exception handling (EH) enabled, otherwise OFF.

LLVM_ENABLE_RTTI This is set to ON if LLVM was built with run time type information (RTTI), otherwise OFF.

LLVM_INCLUDE_DIRS A list of include paths to directories containing LLVM header files.

LLVM_PACKAGE_VERSION The LLVM version. This string can be used with CMake conditionals, e.g., `if (${LLVM_PACKAGE_VERSION} VERSION_LESS "3.5")`.

LLVM_TOOLS_BINARY_DIR The path to the directory containing the LLVM tools (e.g. `llvm-as`).

Notice that in the above example we link `simple-tool` against several LLVM libraries. The list of libraries is determined by using the `llvm_map_components_to_libnames()` CMake function. For a list of available components look at the output of running `llvm-config --components`.

Note that for LLVM < 3.5 `llvm_map_components_to_libraries()` was used instead of `llvm_map_components_to_libnames()`. This is now deprecated and will be removed in a future version of LLVM.

Developing LLVM passes out of source

It is possible to develop LLVM passes out of LLVM's source tree (i.e. against an installed or built LLVM). An example of a project layout is provided below.

```
<project dir>/
|
|  CMakeLists.txt
|  <pass name>/
|  |
|  |  CMakeLists.txt
|  |  Pass.cpp
|  |  ...
|  ...
```

Contents of <project dir>/CMakeLists.txt:

```
find_package(LLVM REQUIRED CONFIG)

add_definitions(${LLVM_DEFINITIONS})
include_directories(${LLVM_INCLUDE_DIRS})

add_subdirectory(<pass name>)
```

Contents of <project dir>/<pass name>/CMakeLists.txt:

```
add_library(LLVMPassname MODULE Pass.cpp)
```

Note if you intend for this pass to be merged into the LLVM source tree at some point in the future it might make more sense to use LLVM's internal `add_llvm_library` function with the `MODULE` argument instead by...

Adding the following to <project dir>/CMakeLists.txt (after `find_package(LLVM ...)`)

```
list(APPEND CMAKE_MODULE_PATH "${LLVM_CMAKE_DIR}")
include(AddLLVM)
```

And then changing <project dir>/<pass name>/CMakeLists.txt to

```
add_llvm_library(LLVMPassname MODULE
  Pass.cpp
)
```

When you are done developing your pass, you may wish to integrate it into the LLVM source tree. You can achieve it in two easy steps:

1. Copying <pass name> folder into <LLVM root>/lib/Transform directory.
2. Adding `add_subdirectory(<pass name>)` line into <LLVM root>/lib/Transform/CMakeLists.txt.

2.1.9 Compiler/Platform-specific topics

Notes for specific compilers and/or platforms.

Microsoft Visual C++

LLVM_COMPILER_JOBS:STRING Specifies the maximum number of parallel compiler jobs to use per project when building with msbuild or Visual Studio. Only supported for the Visual Studio 2010 CMake generator. 0 means use all processors. Default is 0.

Warning: Disclaimer: This documentation is written by LLVM project contributors *not* anyone affiliated with the CMake project. This document may contain inaccurate terminology, phrasing, or technical details. It is provided with the best intentions.

2.2.1 Introduction

The LLVM project and many of the core projects built on LLVM build using CMake. This document aims to provide a brief overview of CMake for developers modifying LLVM projects or building their own projects on top of LLVM.

The official CMake language references is available in the [cmake-language manpage](#) and [cmake-language online documentation](#).

2.2.2 10,000 ft View

CMake is a tool that reads script files in its own language that describe how a software project builds. As CMake evaluates the scripts it constructs an internal representation of the software project. Once the scripts have been fully processed, if there are no errors, CMake will generate build files to actually build the project. CMake supports generating build files for a variety of command line build tools as well as for popular IDEs.

When a user runs CMake it performs a variety of checks similar to how autoconf worked historically. During the checks and the evaluation of the build description scripts CMake caches values into the CMakeCache. This is useful because it allows the build system to skip long-running checks during incremental development. CMake caching also has some drawbacks, but that will be discussed later.

2.2.3 Scripting Overview

CMake's scripting language has a very simple grammar. Every language construct is a command that matches the pattern `_name_(args_)`. Commands come in three primary types: language-defined (commands implemented in C++ in CMake), defined functions, and defined macros. The CMake distribution also contains a suite of CMake modules that contain definitions for useful functionality.

The example below is the full CMake build for building a C++ "Hello World" program. The example uses only CMake language-defined functions.

```
cmake_minimum_required(VERSION 3.2)
project(HelloWorld)
add_executable(HelloWorld HelloWorld.cpp)
```

The CMake language provides control flow constructs in the form of foreach loops and if blocks. To make the example above more complicated you could add an if block to define "APPLE" when targeting Apple platforms:

```
cmake_minimum_required(VERSION 3.2)
project(HelloWorld)
add_executable(HelloWorld HelloWorld.cpp)
if(APPLE)
    target_compile_definitions(HelloWorld PUBLIC APPLE)
endif()
```

2.2.4 Variables, Types, and Scope

Dereferencing

In CMake variables are "stringly" typed. All variables are represented as strings throughout evaluation. Wrapping a variable in `${ }` dereferences it and results in a literal substitution of the name for the value. CMake refers to this as "variable evaluation" in their documentation. Dereferences are performed *before* the command being called receives the arguments. This means dereferencing a list results in multiple separate arguments being passed to the command.

Variable dereferences can be nested and be used to model complex data. For example:

```
set(var_name var1)
set(${var_name} foo) # same as "set(var1 foo)"
set(${${var_name}}_var bar) # same as "set(foo_var bar)"
```

Dereferencing an unset variable results in an empty expansion. It is a common pattern in CMake to conditionally set variables knowing that it will be used in code paths that the variable isn't set. There are examples of this throughout the LLVM CMake build system.

An example of variable empty expansion is:

```
if(APPLE)
    set(extra_sources Apple.cpp)
endif()
add_executable(HelloWorld HelloWorld.cpp ${extra_sources})
```

In this example the `extra_sources` variable is only defined if you're targeting an Apple platform. For all other targets the `extra_sources` will be evaluated as empty before `add_executable` is given its arguments.

Lists

In CMake lists are semi-colon delimited strings, and it is strongly advised that you avoid using semi-colons in lists; it doesn't go smoothly. A few examples of defining lists:

```
# Creates a list with members a, b, c, and d
set(my_list a b c d)
set(my_list "a;b;c;d")

# Creates a string "a b c d"
set(my_string "a b c d")
```

Lists of Lists

One of the more complicated patterns in CMake is lists of lists. Because a list cannot contain an element with a semi-colon to construct a list of lists you make a list of variable names that refer to other lists. For example:

```
set(list_of_lists a b c)
set(a 1 2 3)
set(b 4 5 6)
set(c 7 8 9)
```

With this layout you can iterate through the list of lists printing each value with the following code:

```
foreach(list_name IN LISTS list_of_lists)
    foreach(value IN LISTS ${list_name})
        message("${value}")
    endforeach()
endforeach()
```

You'll notice that the inner `foreach` loop's list is doubly dereferenced. This is because the first dereference turns `list_name` into the name of the sub-list (a, b, or c in the example), then the second dereference is to get the value of the list.

This pattern is used throughout CMake, the most common example is the compiler flags options, which CMake refers to using the following variable expansions: `CMAKE_${LANGUAGE}_FLAGS` and `CMAKE_${LANGUAGE}_FLAGS_${CMAKE_BUILD_TYPE}`.

Other Types

Variables that are cached or specified on the command line can have types associated with them. The variable's type is used by CMake's UI tool to display the right input field. A variable's type generally doesn't impact evaluation, however CMake does have special handling for some variables such as `PATH`. You can read more about the special handling in [CMake's set documentation](#).

Scope

CMake inherently has a directory-based scoping. Setting a variable in a CMakeLists file, will set the variable for that file, and all subdirectories. Variables set in a CMake module that is included in a CMakeLists file will be set in the scope they are included from, and all subdirectories.

When a variable that is already set is set again in a subdirectory it overrides the value in that scope and any deeper subdirectories.

The CMake `set` command provides two scope-related options. `PARENT_SCOPE` sets a variable into the parent scope, and not the current scope. The `CACHE` option sets the variable in the CMakeCache, which results in it being set in all scopes. The `CACHE` option will not set a variable that already exists in the `CACHE` unless the `FORCE` option is specified.

In addition to directory-based scope, CMake functions also have their own scope. This means variables set inside functions do not bleed into the parent scope. This is not true of macros, and it is for this reason LLVM prefers functions over macros whenever reasonable.

Note: Unlike C-based languages, CMake's loop and control flow blocks do not have their own scopes.

2.2.5 Control Flow

CMake features the same basic control flow constructs you would expect in any scripting language, but there are a few quirks because, as with everything in CMake, control flow constructs are commands.

If, Elseif, Else

Note: For the full documentation on the CMake `if` command go [here](#). That resource is far more complete.

In general CMake `if` blocks work the way you'd expect:

```
if(<condition>)
  message("do stuff")
elseif(<condition>)
  message("do other stuff")
else()
  message("do other other stuff")
endif()
```

The single most important thing to know about CMake's `if` blocks coming from a C background is that they do not have their own scope. Variables set inside conditional blocks persist after the `endif()`.

Loops

The most common form of the CMake foreach block is:

```
foreach(var ...)  
  message("do stuff")  
endforeach()
```

The variable argument portion of the foreach block can contain dereferenced lists, values to iterate, or a mix of both:

```
foreach(var foo bar baz)  
  message(${var})  
endforeach()  
# prints:  
# foo  
# bar  
# baz  
  
set(my_list 1 2 3)  
foreach(var ${my_list})  
  message(${var})  
endforeach()  
# prints:  
# 1  
# 2  
# 3  
  
foreach(var ${my_list} out_of_bounds)  
  message(${var})  
endforeach()  
# prints:  
# 1  
# 2  
# 3  
# out_of_bounds
```

There is also a more modern CMake foreach syntax. The code below is equivalent to the code above:

```
foreach(var IN ITEMS foo bar baz)  
  message(${var})  
endforeach()  
# prints:  
# foo  
# bar  
# baz  
  
set(my_list 1 2 3)  
foreach(var IN LISTS my_list)  
  message(${var})  
endforeach()  
# prints:  
# 1  
# 2  
# 3  
  
foreach(var IN LISTS my_list ITEMS out_of_bounds)  
  message(${var})
```

(continues on next page)

(continued from previous page)

```
endforeach()
# prints:
# 1
# 2
# 3
# out_of_bounds
```

Similar to the conditional statements, these generally behave how you would expect, and they do not have their own scope.

CMake also supports `while` loops, although they are not widely used in LLVM.

2.2.6 Modules, Functions and Macros

Modules

Modules are CMake's vehicle for enabling code reuse. CMake modules are just CMake script files. They can contain code to execute on include as well as definitions for commands.

In CMake macros and functions are universally referred to as commands, and they are the primary method of defining code that can be called multiple times.

In LLVM we have several CMake modules that are included as part of our distribution for developers who don't build our project from source. Those modules are the fundamental pieces needed to build LLVM-based projects with CMake. We also rely on modules as a way of organizing the build system's functionality for maintainability and re-use within LLVM projects.

Argument Handling

When defining a CMake command handling arguments is very useful. The examples in this section will all use the CMake `function` block, but this all applies to the `macro` block as well.

CMake commands can have named arguments that are required at every call site. In addition, all commands will implicitly accept a variable number of extra arguments (In C parlance, all commands are varargs functions). When a command is invoked with extra arguments (beyond the named ones) CMake will store the full list of arguments (both named and unnamed) in a list named `ARGV`, and the sublist of unnamed arguments in `ARGN`. Below is a trivial example of providing a wrapper function for CMake's built in function `add_dependencies`.

```
function(add_deps target)
  add_dependencies(${target} ${ARGN})
endfunction()
```

This example defines a new macro named `add_deps` which takes a required first argument, and just calls another function passing through the first argument and all trailing arguments.

CMake provides a module `CMakeParseArguments` which provides an implementation of advanced argument parsing. We use this all over LLVM, and it is recommended for any function that has complex argument-based behaviors or optional arguments. CMake's official documentation for the module is in the `cmake-modules` manpage, and is also available at the [cmake-modules online documentation](#).

Note: As of CMake 3.5 the `cmake_parse_arguments` command has become a native command and the `CMakeParseArguments` module is empty and only left around for compatibility.

Functions Vs Macros

Functions and Macros look very similar in how they are used, but there is one fundamental difference between the two. Functions have their own scope, and macros don't. This means variables set in macros will bleed out into the calling scope. That makes macros suitable for defining very small bits of functionality only.

The other difference between CMake functions and macros is how arguments are passed. Arguments to macros are not set as variables, instead dereferences to the parameters are resolved across the macro before executing it. This can result in some unexpected behavior if using unreferenced variables. For example:

```
macro(print_list my_list)
  foreach(var IN LISTS my_list)
    message("${var}")
  endforeach()
endmacro()

set(my_list a b c d)
set(my_list_of_numbers 1 2 3 4)
print_list(my_list_of_numbers)
# prints:
# a
# b
# c
# d
```

Generally speaking this issue is uncommon because it requires using non-dereferenced variables with names that overlap in the parent scope, but it is important to be aware of because it can lead to subtle bugs.

2.2.7 LLVM Project Wrappers

LLVM projects provide lots of wrappers around critical CMake built-in commands. We use these wrappers to provide consistent behaviors across LLVM components and to reduce code duplication.

We generally (but not always) follow the convention that commands prefaced with `llvm_` are intended to be used only as building blocks for other commands. Wrapper commands that are intended for direct use are generally named following with the project in the middle of the command name (i.e. `add_llvm_executable` is the wrapper for `add_executable`). The LLVM `add_*` wrapper functions are all defined in `AddLLVM.cmake` which is installed as part of the LLVM distribution. It can be included and used by any LLVM sub-project that requires LLVM.

Note: Not all LLVM projects require LLVM for all use cases. For example `compiler-rt` can be built without LLVM, and the `compiler-rt` sanitizer libraries are used with GCC.

2.2.8 Useful Built-in Commands

CMake has a bunch of useful built-in commands. This document isn't going to go into details about them because The CMake project has excellent documentation. To highlight a few useful functions see:

- `add_custom_command`
- `add_custom_target`
- `file`
- `list`
- `math`

- `string`

The full documentation for CMake commands is in the `cmake-commands` manpage and available on [CMake's website](#)

2.3 Advanced Build Configurations

- *Introduction*
- *Bootstrap Builds*
- *Apple Clang Builds (A More Complex Bootstrap)*
- *Multi-stage PGO*
- *3-Stage Non-Determinism*

2.3.1 Introduction

CMake is a cross-platform build-generator tool. CMake does not build the project, it generates the files needed by your build tool (GNU make, Visual Studio, etc.) for building LLVM.

If **you are a new contributor**, please start with the *Getting Started with the LLVM System* or *Building LLVM with CMake* pages. This page is intended for users doing more complex builds.

Many of the examples below are written assuming specific CMake Generators. Unless otherwise explicitly called out these commands should work with any CMake generator.

2.3.2 Bootstrap Builds

The Clang CMake build system supports bootstrap (aka multi-stage) builds. At a high level a multi-stage build is a chain of builds that pass data from one stage into the next. The most common and simple version of this is a traditional bootstrap build.

In a simple two-stage bootstrap build, we build clang using the system compiler, then use that just-built clang to build clang again. In CMake this simplest form of a bootstrap build can be configured with a single option, `CLANG_ENABLE_BOOTSTRAP`.

```
$ cmake -G Ninja -DCLANG_ENABLE_BOOTSTRAP=On <path to source>
$ ninja stage2
```

This command itself isn't terribly useful because it assumes default configurations for each stage. The next series of examples utilize CMake cache scripts to provide more complex options.

By default, only a few CMake options will be passed between stages. The list, called `_BOOTSTRAP_DEFAULT_PASSTHROUGH`, is defined in `clang/CMakeLists.txt`. To force the passing of the variables between stages, use the `-DCLANG_BOOTSTRAP_PASSTHROUGH` CMake option, each variable separated by a `;`. As example:

```
$ cmake -G Ninja -DCLANG_ENABLE_BOOTSTRAP=On -DCLANG_BOOTSTRAP_PASSTHROUGH="CMAKE_
↪INSTALL_PREFIX;CMAKE_VERBOSE_MAKEFILE" <path to source>
$ ninja stage2
```

CMake options starting by `BOOTSTRAP_` will be passed only to the stage2 build. This gives the opportunity to use Clang specific build flags. For example, the following CMake call will enabled `'-fno-addrsig'` only during the stage2 build for C and C++.

```
$ cmake [...] -DBOOTSTRAP_CMAKE_CXX_FLAGS='-fno-addrsig' -DBOOTSTRAP_CMAKE_C_FLAGS='-fno-addrsig' [...]
```

The clang build system refers to builds as stages. A stage1 build is a standard build using the compiler installed on the host, and a stage2 build is built using the stage1 compiler. This nomenclature holds up to more stages too. In general a stage*n* build is built using the output from stage*n-1*.

2.3.3 Apple Clang Builds (A More Complex Bootstrap)

Apple's Clang builds are a slightly more complicated example of the simple bootstrapping scenario. Apple Clang is built using a 2-stage build.

The stage1 compiler is a host-only compiler with some options set. The stage1 compiler is a balance of optimization vs build time because it is a throwaway. The stage2 compiler is the fully optimized compiler intended to ship to users.

Setting up these compilers requires a lot of options. To simplify the configuration the Apple Clang build settings are contained in CMake Cache files. You can build an Apple Clang compiler using the following commands:

```
$ cmake -G Ninja -C <path to clang>/cmake/caches/Apple-stage1.cmake <path to source>
$ ninja stage2-distribution
```

This CMake invocation configures the stage1 host compiler, and sets `CLANG_BOOTSTRAP_CMAKE_ARGS` to pass the Apple-stage2.cmake cache script to the stage2 configuration step.

When you build the stage2-distribution target it builds the minimal stage1 compiler and required tools, then configures and builds the stage2 compiler based on the settings in Apple-stage2.cmake.

This pattern of using cache scripts to set complex settings, and specifically to make later stage builds include cache scripts is common in our more advanced build configurations.

2.3.4 Multi-stage PGO

Profile-Guided Optimizations (PGO) is a really great way to optimize the code clang generates. Our multi-stage PGO builds are a workflow for generating PGO profiles that can be used to optimize clang.

At a high level, the way PGO works is that you build an instrumented compiler, then you run the instrumented compiler against sample source files. While the instrumented compiler runs it will output a bunch of files containing performance counters (.profrac files). After generating all the profraw files you use `llvm-profdata` to merge the files into a single profdata file that you can feed into the `LLVM_PROFDATA_FILE` option.

Our PGO.cmake cache script automates that whole process. You can use it by running:

```
$ cmake -G Ninja -C <path_to_clang>/cmake/caches/PGO.cmake <source dir>
$ ninja stage2-instrumented-generate-profdata
```

If you let that run for a few hours or so, it will place a profdata file in your build directory. This takes a really long time because it builds clang twice, and you *must* have compiler-rt in your build tree.

This process uses any source files under the perf-training directory as training data as long as the source files are marked up with LIT-style RUN lines.

After it finishes you can use “`find . -name clang.profdata`” to find it, but it should be at a path something like:

```
<build_dir>/tools/clang/stage2-instrumented-bins/utils/perf-training/clang.profdata
```

You can feed that file into the LLVM_PROFDATA_FILE option when you build your optimized compiler.

The PGO came cache has a slightly different stage naming scheme than other multi-stage builds. It generates three stages; stage1, stage2-instrumented, and stage2. Both of the stage2 builds are built using the stage1 compiler.

The PGO came cache generates the following additional targets:

stage2-instrumented Builds a stage1 x86 compiler, runtime, and required tools (llvm-config, llvm-profdata) then uses that compiler to build an instrumented stage2 compiler.

stage2-instrumented-generate-profdata Depends on "stage2-instrumented" and will use the instrumented compiler to generate profdata based on the training files in <clang>/utils/perf-training

stage2 Depends of "stage2-instrumented-generate-profdata" and will use the stage1 compiler with the stage2 profdata to build a PGO-optimized compiler.

stage2-check-llvm Depends on stage2 and runs check-llvm using the stage2 compiler.

stage2-check-clang Depends on stage2 and runs check-clang using the stage2 compiler.

stage2-check-all Depends on stage2 and runs check-all using the stage2 compiler.

stage2-test-suite Depends on stage2 and runs the test-suite using the stage3 compiler (requires in-tree test-suite).

2.3.5 3-Stage Non-Determinism

In the ancient lore of compilers non-determinism is like the multi-headed hydra. Whenever its head pops up, terror and chaos ensue.

Historically one of the tests to verify that a compiler was deterministic would be a three stage build. The idea of a three stage build is you take your sources and build a compiler (stage1), then use that compiler to rebuild the sources (stage2), then you use that compiler to rebuild the sources a third time (stage3) with an identical configuration to the stage2 build. At the end of this, you have a stage2 and stage3 compiler that should be bit-for-bit identical.

You can perform one of these 3-stage builds with LLVM & clang using the following commands:

```
$ cmake -G Ninja -C <path_to_clang>/cmake/caches/3-stage.cmake <source_dir>
$ ninja stage3
```

After the build you can compare the stage2 & stage3 compilers. We have a bot setup [here](#) that runs this build and compare configuration.

2.4 How To Build On ARM

2.4.1 Introduction

This document contains information about building/testing LLVM and Clang on an ARM machine.

This document is *NOT* tailored to help you cross-compile LLVM/Clang to ARM on another architecture, for example an x86_64 machine. To find out more about cross-compiling, please check [How To Cross-Compile Clang/LLVM using Clang/LLVM](#).

2.4.2 Notes On Building LLVM/Clang on ARM

Here are some notes on building/testing LLVM/Clang on ARM. Note that ARM encompasses a wide variety of CPUs; this advice is primarily based on the ARMv6 and ARMv7 architectures and may be inapplicable to older chips.

1. The most popular Linaro/Ubuntu OS's for ARM boards, e.g., the Pandaboard, have become hard-float platforms. There are a number of choices when using CMake. Autoconf usage is deprecated as of 3.8.

Building LLVM/Clang in Release mode is preferred since it consumes a lot less memory. Otherwise, the building process will very likely fail due to insufficient memory. It's also a lot quicker to only build the relevant back-ends (ARM and AArch64), since it's very unlikely that you'll use an ARM board to cross-compile to other arches. If you're running Compiler-RT tests, also include the x86 back-end, or some tests will fail.

```
cmake $LLVM_SRC_DIR -DCMAKE_BUILD_TYPE=Release \
      -DLLVM_TARGETS_TO_BUILD="ARM;X86;AArch64"
```

Other options you can use are:

```
Use Ninja instead of Make: "-G Ninja"
Build with assertions on: "-DLLVM_ENABLE_ASSERTIONS=True"
Force Python2: "-DPYTHON_EXECUTABLE=/usr/bin/python2"
Local (non-sudo) install path: "-DCMAKE_INSTALL_PREFIX=$HOME/llvm/instal"
CPU flags: "DCMAKE_C_FLAGS=-mcpu=cortex-a15" (same for CXX_FLAGS)
```

After that, just typing `make -jN` or `ninja` will build everything. `make -jN check-all` or `ninja check-all` will run all compiler tests. For running the test suite, please refer to *LLVM Testing Infrastructure Guide*.

2. If you are building LLVM/Clang on an ARM board with 1G of memory or less, please use `gold` rather than `GNU ld`. In any case it is probably a good idea to set up a swap partition, too.

```
$ sudo ln -sf /usr/bin/ld /usr/bin/ld.gold
```

3. ARM development boards can be unstable and you may experience that cores are disappearing, caches being flushed on every big.LITTLE switch, and other similar issues. To help ease the effect of this, set the Linux scheduler to "performance" on **all** cores using this little script:

```
# The code below requires the package 'cpufrequtils' to be installed.
for ((cpu=0; cpu<`grep -c proc /proc/cpuinfo`; cpu++)); do
    sudo cpufreq-set -c $cpu -g performance
done
```

Remember to turn that off after the build, or you may risk burning your CPU. Most modern kernels don't need that, so only use it if you have problems.

4. Running the build on SD cards is ok, but they are more prone to failures than good quality USB sticks, and those are more prone to failures than external hard-drives (those are also a lot faster). So, at least, you should consider to buy a fast USB stick. On systems with a fast eMMC, that's a good option too.
5. Make sure you have a decent power supply (dozens of dollars worth) that can provide *at least* 4 amperes, this is especially important if you use USB devices with your board. Externally powered USB/SATA harddrives are even better than having a good power supply.

2.5 How To Build Clang and LLVM with Profile-Guided Optimizations

2.5.1 Introduction

PGO (Profile-Guided Optimization) allows your compiler to better optimize code for how it actually runs. Users report that applying this to Clang and LLVM can decrease overall compile time by 20%.

This guide walks you through how to build Clang with PGO, though it also applies to other subprojects, such as LLD.

2.5.2 Using the script

We have a script at `utils/collect_and_build_with_pgo.py`. This script is tested on a few Linux flavors, and requires a checkout of LLVM, Clang, and compiler-rt. Despite the the name, it performs four clean builds of Clang, so it can take a while to run to completion. Please see the script's `--help` for more information on how to run it, and the different options available to you. If you want to get the most out of PGO for a particular use-case (e.g. compiling a specific large piece of software), please do read the section below on 'benchmark' selection.

Please note that this script is only tested on a few Linux distros. Patches to add support for other platforms, as always, are highly appreciated. :)

This script also supports a `--dry-run` option, which causes it to print important commands instead of running them.

2.5.3 Selecting 'benchmarks'

PGO does best when the profiles gathered represent how the user plans to use the compiler. Notably, highly accurate profiles of `llc` building `x86_64` code aren't incredibly helpful if you're going to be targeting ARM.

By default, the script above does two things to get solid coverage. It:

- runs all of Clang and LLVM's lit tests, and
- uses the instrumented Clang to build Clang, LLVM, and all of the other LLVM subprojects available to it.

Together, these should give you:

- solid coverage of building C++,
- good coverage of building C,
- great coverage of running optimizations,
- great coverage of the backend for your host's architecture, and
- some coverage of other architectures (if other arches are supported backends).

Altogether, this should cover a diverse set of uses for Clang and LLVM. If you have very specific needs (e.g. your compiler is meant to compile a large browser for four different platforms, or similar), you may want to do something else. This is configurable in the script itself.

2.5.4 Building Clang with PGO

If you prefer to not use the script, this briefly goes over how to build Clang/LLVM with PGO.

First, you should have at least LLVM, Clang, and compiler-rt checked out locally.

Next, at a high level, you're going to need to do the following:

1. Build a standard Release Clang and the relevant `libclang_rt.profile` library
2. Build Clang using the Clang you built above, but with instrumentation
3. Use the instrumented Clang to generate profiles, which consists of two steps:
 - Running the instrumented Clang/LLVM/lld/etc. on tasks that represent how users will use said tools.
 - Using a tool to convert the "raw" profiles generated above into a single, final PGO profile.
4. Build a final release Clang (along with whatever other binaries you need) using the profile collected from your benchmark

In more detailed steps:

1. Configure a Clang build as you normally would. It's highly recommended that you use the Release configuration for this, since it will be used to build another Clang. Because you need Clang and supporting libraries, you'll want to build the `all` target (e.g. `ninja all` or `make -j4 all`).
2. Configure a Clang build as above, but add the following CMake args:
 - `-DLLVM_BUILD_INSTRUMENTED=IR` -- This causes us to build everything with instrumentation.
 - `-DLLVM_BUILD_RUNTIME=No` -- A few projects have bad interactions when built with profiling, and aren't necessary to build. This flag turns them off.
 - `-DCMAKE_C_COMPILER=/path/to/stage1/clang` - Use the Clang we built in step 1.
 - `-DCMAKE_CXX_COMPILER=/path/to/stage1/clang++` - Same as above.

In this build directory, you simply need to build the `clang` target (and whatever supporting tooling your benchmark requires).

3. As mentioned above, this has two steps: gathering profile data, and then massaging it into a useful form:
 - a. Build your benchmark using the Clang generated in step 2. The 'standard' benchmark recommended is to run `check-clang` and `check-llvm` in your instrumented Clang's build directory, and to do a full build of Clang/LLVM using your instrumented Clang. So, create yet another build directory, with the following CMake arguments:
 - `-DCMAKE_C_COMPILER=/path/to/stage2/clang` - Use the Clang we built in step 2.
 - `-DCMAKE_CXX_COMPILER=/path/to/stage2/clang++` - Same as above.

If your users are fans of debug info, you may want to consider using `-DCMAKE_BUILD_TYPE=RelWithDebInfo` instead of `-DCMAKE_BUILD_TYPE=Release`. This will grant better coverage of debug info pieces of clang, but will take longer to complete and will result in a much larger build directory.

It's recommended to build the `all` target with your instrumented Clang, since more coverage is often better.

- b. You should now have a few `*.profraw` files in `path/to/stage2/profiles/`. You need to merge these using `llvm-profdata` (even if you only have one! The profile merge transforms profraw into actual profile data, as well). This can be done with `/path/to/stage1/llvm-profdata merge -output=/path/to/output/profdata.prof path/to/stage2/profiles/*.profraw`.

4. Now, build your final, PGO-optimized Clang. To do this, you'll want to pass the following additional arguments to CMake.

- `-DLLVM_PROFDATA_FILE=/path/to/output/profdata.prof` - Use the PGO profile from the previous step.
- `-DCMAKE_C_COMPILER=/path/to/stage1/clang` - Use the Clang we built in step 1.
- `-DCMAKE_CXX_COMPILER=/path/to/stage1/clang++` - Same as above.

From here, you can build whatever targets you need.

Note: You may see warnings about a mismatched profile in the build output. These are generally harmless. To silence them, you can add `-DCMAKE_C_FLAGS='-Wno-backend-plugin'` `-DCMAKE_CXX_FLAGS='-Wno-backend-plugin'` to your CMake invocation.

Congrats! You now have a Clang built with profile-guided optimizations, and you can delete all but the final build directory if you'd like.

If this worked well for you and you plan on doing it often, there's a slight optimization that can be made: LLVM and Clang have a tool called `tblgen` that's built and run during the build process. While it's potentially nice to build this for coverage as part of step 3, none of your other builds should benefit from building it. You can pass the CMake options `-DCLANG_TABLEGEN=/path/to/stage1/bin/clang-tblgen` `-DLLVM_TABLEGEN=/path/to/stage1/bin/llvm-tblgen` to steps 2 and onward to avoid these useless rebuilds.

2.6 How to Cross Compile Compiler-rt Builtins For Arm

2.6.1 Introduction

This document contains information about building and testing the builtins part of `compiler-rt` for an Arm target, from an `x86_64` Linux machine.

While this document concentrates on Arm and Linux the general principles should apply to other targets supported by `compiler-rt`. Further contributions for other targets are welcome.

The instructions in this document depend on libraries and programs external to LLVM, there are many ways to install and configure these dependencies so you may need to adapt the instructions here to fit your own local situation.

2.6.2 Prerequisites

In this use case we'll be using `cmake` on a Debian-based Linux system, cross-compiling from an `x86_64` host to a hard-float Armv7-A target. We'll be using as many of the LLVM tools as we can, but it is possible to use GNU equivalents.

- A build of LLVM/clang for the `llvm-tools` and `llvm-config`
- A clang executable with support for the ARM target
- `compiler-rt` sources
- The `qemu-arm` user mode emulator
- An `arm-linux-gnueabi` sysroot

In this example we will be using `ninja`.

See <https://compiler-rt.llvm.org/> for more information about the dependencies on clang and LLVM.

See <https://llvm.org/docs/GettingStarted.html> for information about obtaining the source for LLVM and compiler-rt. Note that the getting started guide places compiler-rt in the projects subdirectory, but this is not essential and if you are using the BaremetalARM.cmake cache for v6-M, v7-M and v7-EM then compiler-rt must be placed in the runtimes directory.

qemu-arm should be available as a package for your Linux distribution.

The most complicated of the prerequisites to satisfy is the arm-linux-gnueabi sysroot. In theory it is possible to use the Linux distributions multiarch support to fulfill the dependencies for building but unfortunately due to /usr/local/include being added some host includes are selected. The easiest way to supply a sysroot is to download the arm-linux-gnueabi toolchain. This can be found at: * <https://developer.arm.com/open-source/gnu-toolchain/gnu-a/downloads> for gcc 8 and above * <https://releases.linaro.org/components/toolchain/binaries/> for gcc 4.9 to 7.3

2.6.3 Building compiler-rt builtins for Arm

We will be doing a standalone build of compiler-rt using the following cmake options.

- path/to/compiler-rt
- -G Ninja
- -DCOMPILER_RT_BUILD_BUILTINS=ON
- -DCOMPILER_RT_BUILD_SANITIZERS=OFF
- -DCOMPILER_RT_BUILD_XRAY=OFF
- -DCOMPILER_RT_BUILD_LIBFUZZER=OFF
- -DCOMPILER_RT_BUILD_PROFILE=OFF
- -DCMAKE_C_COMPILER=/path/to/clang
- -DCMAKE_AR=/path/to/llvm-ar
- -DCMAKE_NM=/path/to/llvm-nm
- -DCMAKE_RANLIB=/path/to/llvm-ranlib
- -DCMAKE_EXE_LINKER_FLAGS="-fuse-ld=lld"
- -DCMAKE_C_COMPILER_TARGET="arm-linux-gnueabi"
- -DCMAKE_ASM_COMPILER_TARGET="arm-linux-gnueabi"
- -DCOMPILER_RT_DEFAULT_TARGET_ONLY=ON
- -DLLVM_CONFIG_PATH=/path/to/llvm-config
- -DCMAKE_C_FLAGS="build-c-flags"
- -DCMAKE_ASM_FLAGS="build-c-flags"

The build-c-flags need to be sufficient to pass the C-make compiler check, compile compiler-rt, and if you are running the tests, compile and link the tests. When cross-compiling with clang we will need to pass sufficient information to generate code for the Arm architecture we are targeting. We will need to select the Arm target, select the Armv7-A architecture and choose between using Arm or Thumb instructions. For example:

- --target=arm-linux-gnueabi
- -march=armv7a
- -mthumb

When using a GCC arm-linux-gnueabi toolchain the following flags are needed to pick up the includes and libraries:

- `--gcc-toolchain=/path/to/dir/toolchain`
- `--sysroot=/path/to/toolchain/arm-linux-gnueabi/libc`

In this example we will be adding all of the command line options to both `CMAKE_C_FLAGS` and `CMAKE_ASM_FLAGS`. There are cmake flags to pass some of these options individually which can be used to simplify the `build-c-flags`:

- `-DCMAKE_C_COMPILER_TARGET="arm-linux-gnueabi"`
- `-DCMAKE_ASM_COMPILER_TARGET="arm-linux-gnueabi"`
- `-DCMAKE_C_COMPILER_EXTERNAL_TOOLCHAIN=/path/to/dir/toolchain`
- `-DCMAKE_SYSROOT=/path/to/dir/toolchain/arm-linux-gnueabi/libc`

Once cmake has completed the builtins can be built with `ninja builtins`

2.6.4 Testing compiler-rt builtins using qemu-arm

To test the builtins library we need to add a few more cmake flags to enable testing and set up the compiler and flags for test case. We must also tell cmake that we wish to run the tests on `qemu-arm`.

- `-DCOMPILER_RT_EMULATOR="qemu-arm -L /path/to/armhf/sysroot"`
- `-DCOMPILER_RT_INCLUDE_TESTS=ON`
- `-DCOMPILER_RT_TEST_COMPILER="/path/to/clang"`
- `-DCOMPILER_RT_TEST_COMPILER_CFLAGS="test-c-flags"`

The `/path/to/armhf/sysroot` should be the same as the one passed to `--sysroot` in the `"build-c-flags"`.

The `"test-c-flags"` need to include the target, architecture, gcc-toolchain, sysroot and arm/thumb state. The additional cmake defines such as `CMAKE_C_COMPILER_EXTERNAL_TOOLCHAIN` do not apply when building the tests. If you have put all of these in `"build-c-flags"` then these can be repeated. If you wish to use `lld` to link the tests then add `"-fuse-ld=lld"`.

Once cmake has completed the tests can be built and run using `ninja check-builtins`

2.6.5 Troubleshooting

The cmake try compile stage fails

At an early stage cmake will attempt to compile and link a simple C program to test if the toolchain is working.

This stage can often fail at link time if the `--sysroot` and `--gcc-toolchain` options are not passed to the compiler. Check the `CMAKE_C_FLAGS` and `CMAKE_C_COMPILER_TARGET` flags.

It can be useful to build a simple example outside of cmake with your toolchain to make sure it is working. For example: `clang --target=arm-linux-gnueabi -march=armv7a --gcc-toolchain=/path/to/gcc-toolchain --sysroot=/path/to/gcc-toolchain/arm-linux-gnueabi/libc helloworld.c`

Clang uses the host header files

On debian based systems it is possible to install multiarch support for arm-linux-gnueabi and arm-linux-gnueabihf. In many cases clang can successfully use this multiarch support when `-gcc-toolchain` and `--sysroot` are not supplied. Unfortunately clang adds `/usr/local/include` before `/usr/include/arm-linux-gnueabihf` leading to errors when compiling the hosts header files.

The multiarch support is not sufficient to build the builtins you will need to use a separate arm-linux-gnueabihf toolchain.

No target passed to clang

If clang is not given a target it will typically use the host target, this will not understand the Arm assembly language files resulting in error messages such as `error: unknown directive .syntax unified`.

You can check the clang invocation in the error message to see if there is no `--target` or if it is set incorrectly. The cause is usually `CMAKE_ASM_FLAGS` not containing `--target` or `CMAKE_ASM_COMPILER_TARGET` not being present.

Arm architecture not given

The `--target=arm-linux-gnueabihf` will default to arm architecture v4t which cannot assemble the barrier instructions used in the `synch_and_fetch` source files.

The cause is usually a missing `-march=armv7a` from the `CMAKE_ASM_FLAGS`.

Compiler-rt builds but the tests fail to build

The flags used to build the tests are not the same as those used to build the builtins. The `c` flags are provided by `COMPILER_RT_TEST_COMPILE_CFLAGS` and the `CMAKE_C_COMPILER_TARGET`, `CMAKE_ASM_COMPILER_TARGET`, `CMAKE_C_COMPILER_EXTERNAL_TOOLCHAIN` and `CMAKE_SYSROOT` flags are not applied.

Make sure that `COMPILER_RT_TEST_COMPILE_CFLAGS` contains all the necessary information.

2.6.6 Modifications for other Targets

Arm Soft-Float Target

The instructions for the Arm hard-float target can be used for the soft-float target by substituting soft-float equivalents for the `sysroot` and `target`. The target to use is:

- `-DCMAKE_C_COMPILER_TARGET=arm-linux-gnueabi`

Depending on whether you want to use floating point instructions or not you may need extra `c`-flags such as `-mfloat-abi=softfp` for use of floating-point instructions, and `-mfloat-abi=soft -mfpu=none` for software floating-point emulation.

You will need to use an arm-linux-gnueabi GNU toolchain for soft-float.

AArch64 Target

The instructions for Arm can be used for AArch64 by substituting AArch64 equivalents for the sysroot, emulator and target.

- `-DCMAKE_C_COMPILER_TARGET=aarch64-linux-gnu`
- `-DCOMPILER_RT_EMULATOR="qemu-aarch64 -L /path/to/aarch64/sysroot"`

The `CMAKE_C_FLAGS` and `COMPILER_RT_TEST_COMPILER_CFLAGS` may also need: `"--sysroot=/path/to/aarch64/sysroot --gcc-toolchain=/path/to/gcc-toolchain"`

Armv6-m, Armv7-m and Armv7E-M targets

To build and test the libraries using a similar method to Armv7-A is possible but more difficult. The main problems are:

- There isn't a `qemu-arm` user-mode emulator for bare-metal systems. The `qemu-system-arm` can be used but this is significantly more difficult to setup.
- The targets to compile compiler-rt have the suffix `-none-eabi`. This uses the BareMetal driver in clang and by default won't find the libraries needed to pass the cmake compiler check.

As the Armv6-M, Armv7-M and Armv7E-M builds of compiler-rt only use instructions that are supported on Armv7-A we can still get most of the value of running the tests using the same `qemu-arm` that we used for Armv7-A by building and running the test cases for Armv7-A but using the builtins compiled for Armv6-M, Armv7-M or Armv7E-M. This will test that the builtins can be linked into a binary and execute the tests correctly but it will not catch if the builtins use instructions that are supported on Armv7-A but not Armv6-M, Armv7-M and Armv7E-M.

To get the cmake compile test to pass you will need to pass the libraries needed to successfully link the cmake test via `CMAKE_CFLAGS`. It is strongly recommended that you use version 3.6 or above of cmake so you can use `CMAKE_TRY_COMPILE_TARGET_TYPE=STATIC_LIBRARY` to skip the link step.

- `-DCMAKE_TRY_COMPILE_TARGET_TYPE=STATIC_LIBRARY`
- `-DCOMPILER_RT_OS_DIR="baremetal"`
- `-DCOMPILER_RT_BUILD_BUILTINS=ON`
- `-DCOMPILER_RT_BUILD_SANITIZERS=OFF`
- `-DCOMPILER_RT_BUILD_XRAY=OFF`
- `-DCOMPILER_RT_BUILD_LIBFUZZER=OFF`
- `-DCOMPILER_RT_BUILD_PROFILE=OFF`
- `-DCMAKE_C_COMPILER=${host_install_dir}/bin/clang`
- `-DCMAKE_C_COMPILER_TARGET="your *-none-eabi target"`
- `-DCMAKE_ASM_COMPILER_TARGET="your *-none-eabi target"`
- `-DCMAKE_AR=/path/to/llvm-ar`
- `-DCMAKE_NM=/path/to/llvm-nm`
- `-DCMAKE_RANLIB=/path/to/llvm-ranlib`
- `-DCOMPILER_RT_BAREMETAL_BUILD=ON`
- `-DCOMPILER_RT_DEFAULT_TARGET_ONLY=ON`
- `-DLLVM_CONFIG_PATH=/path/to/llvm-config`

- `-DCMAKE_C_FLAGS="build-c-flags"`
- `-DCMAKE_ASM_FLAGS="build-c-flags"`
- `-DCOMPILER_RT_EMULATOR="qemu-arm -L /path/to/armv7-A/sysroot"`
- `-DCOMPILER_RT_INCLUDE_TESTS=ON`
- `-DCOMPILER_RT_TEST_COMPILER="/path/to/clang"`
- `-DCOMPILER_RT_TEST_COMPILER_CFLAGS="test-c-flags"`

The Armv6-M builtins will use the soft-float ABI. When compiling the tests for Armv7-A we must include `"-mthumb -mfloat-abi=soft -mfpu=none"` in the `test-c-flags`. We must use an Armv7-A soft-float abi sysroot for `qemu-arm`.

Depending on the linker used for the test cases you may encounter BuildAttribute mismatches between the M-profile objects from `compiler-rt` and the A-profile objects from the test. The `lld` linker does not check the profile BuildAttribute so it can be used to link the tests by adding `-fuse-ld=lld` to the `COMPILER_RT_TEST_COMPILER_CFLAGS`.

Alternative using a cmake cache

If you wish to build, but not test `compiler-rt` for Armv6-M, Armv7-M or Armv7E-M the easiest way is to use the `BaremetalARM.cmake` recipe in `clang/cmake/caches`.

You will need a bare metal sysroot such as that provided by the GNU ARM Embedded toolchain.

The libraries can be built with the cmake options:

- `-DBAREMETAL_ARMV6M_SYSROOT=/path/to/bare/metal/toolchain/arm-none-eabi`
- `-DBAREMETAL_ARMV7M_SYSROOT=/path/to/bare/metal/toolchain/arm-none-eabi`
- `-DBAREMETAL_ARMV7EM_SYSROOT=/path/to/bare/metal/toolchain/arm-none-eabi`
- `-C /path/to/llvm/source/tools/clang/cmake/caches/BaremetalARM.cmake`
- `/path/to/llvm`

Note that for the recipe to work the `compiler-rt` source must be checked out into the directory `llvm/runtimes`. You will also need `clang` and `lld` checked out.

2.7 How To Cross-Compile Clang/LLVM using Clang/LLVM

2.7.1 Introduction

This document contains information about building LLVM and Clang on host machine, targeting another platform.

For more information on how to use Clang as a cross-compiler, please check <http://clang.llvm.org/docs/CrossCompilation.html>.

TODO: Add MIPS and other platforms to this document.

2.7.2 Cross-Compiling from x86_64 to ARM

In this use case, we'll be using CMake and Ninja, on a Debian-based Linux system, cross-compiling from an x86_64 host (most Intel and AMD chips nowadays) to a hard-float ARM target (most ARM targets nowadays).

The packages you'll need are:

- `cmake`
- `ninja-build` (from backports in Ubuntu)
- `gcc-4.7-arm-linux-gnueabi`
- `gcc-4.7-multilib-arm-linux-gnueabi`
- `binutils-arm-linux-gnueabi`
- `libgcc1-armhf-cross`
- `libstdc++6-armhf-cross`
- `libstdc++6-4.7-dev-armhf-cross`

Configuring CMake

For more information on how to configure CMake for LLVM/Clang, see *Building LLVM with CMake*.

The CMake options you need to add are:

- `-DCMAKE_CROSSCOMPILING=True`
- `-DCMAKE_INSTALL_PREFIX=<install-dir>`
- `-DLLVM_TABLEGEN=<path-to-host-bin>/llvm-tblgen`
- `-DCLANG_TABLEGEN=<path-to-host-bin>/clang-tblgen`
- `-DLLVM_DEFAULT_TARGET_TRIPLE=arm-linux-gnueabi`
- `-DLLVM_TARGET_ARCH=ARM`
- `-DLLVM_TARGETS_TO_BUILD=ARM`

If you're compiling with GCC, you can use architecture options for your target, and the compiler driver will detect everything that it needs:

- `-DCMAKE_CXX_FLAGS='-march=armv7-a -mcpu=cortex-a9 -mfloat-abi=hard'`

However, if you're using Clang, the driver might not be up-to-date with your specific Linux distribution, version or GCC layout, so you'll need to fudge.

In addition to the ones above, you'll also need:

- `'-target arm-linux-gnueabi'` or whatever is the triple of your cross GCC.
- `'--sysroot=/usr/arm-linux-gnueabi'`, `'--sysroot=/opt/gcc/arm-linux-gnueabi'` or whatever is the location of your GCC's sysroot (where `/lib`, `/bin` etc are).
- Appropriate use of `-I` and `-L`, depending on how the cross GCC is installed, and where are the libraries and headers.

The TableGen options are required to compile it with the host compiler, so you'll need to compile LLVM (or at least `llvm-tblgen`) to your host platform before you start. The CXX flags define the target, `cpu` (which in this case defaults to `fpv=VFP3` with NEON), and forcing the hard-float ABI. If you're using Clang as a cross-compiler, you will *also* have to set `--sysroot` to make sure it picks the correct linker.

When using Clang, it's important that you choose the triple to be *identical* to the GCC triple and the sysroot. This will make it easier for Clang to find the correct tools and include headers. But that won't mean all headers and libraries will be found. You'll still need to use `-I` and `-L` to locate those extra ones, depending on your distribution.

Most of the time, what you want is to have a native compiler to the platform itself, but not others. So there's rarely a point in compiling all back-ends. For that reason, you should also set the `TARGETS_TO_BUILD` to only build the back-end you're targeting to.

You must set the `CMAKE_INSTALL_PREFIX`, otherwise a `ninja install` will copy ARM binaries to your root filesystem, which is not what you want.

Hacks

There are some bugs in current LLVM, which require some fiddling before running CMake:

1. If you're using Clang as the cross-compiler, there is a problem in the LLVM ARM back-end that is producing absolute relocations on position-independent code (`R_ARM_THM_MOVW_ABS_NC`), so for now, you should disable PIC:

```
-DLLVM_ENABLE_PIC=False
```

This is not a problem, since Clang/LLVM libraries are statically linked anyway, it shouldn't affect much.

2. The ARM libraries won't be installed in your system. But the CMake prepare step, which checks for dependencies, will check the *host* libraries, not the *target* ones. Below there's a list of some dependencies, but your project could have more, or this document could be outdated. You'll see the errors while linking as an indication of that.

Debian based distros have a way to add `multiarch`, which adds a new architecture and allows you to install packages for those systems. See <https://wiki.debian.org/Multiarch/HOWTO> for more info.

But not all distros will have that, and possibly not an easy way to install them in any anyway, so you'll have to build/download them separately.

A quick way of getting the libraries is to download them from a distribution repository, like Debian (<http://packages.debian.org/jessie/>), and download the missing libraries. Note that the `libXXX` will have the shared objects (`.so`) and the `libXXX-dev` will give you the headers and the static (`.a`) library. Just in case, download both.

The ones you need for ARM are: `libtinfo`, `zlib1g`, `libxml2` and `liblzma`. In the Debian repository you'll find downloads for all architectures.

After you download and unpack all `.deb` packages, copy all `.so` and `.a` to a directory, make the appropriate symbolic links (if necessary), and add the relevant `-L` and `-I` paths to `-DCMAKE_CXX_FLAGS` above.

Running CMake and Building

Finally, if you're using your platform compiler, run:

```
$ cmake -G Ninja <source-dir> <options above>
```

If you're using Clang as the cross-compiler, run:

```
$ CC='clang' CXX='clang++' cmake -G Ninja <source-dir> <options above>
```

If you have `clang/clang++` on the path, it should just work, and special Ninja files will be created in the build directory. I strongly suggest you to run `cmake` on a separate build directory, *not* inside the source tree.

To build, simply type:

```
$ ninja
```

It should automatically find out how many cores you have, what are the rules that needs building and will build the whole thing.

You can't run `ninja check-all` on this tree because the created binaries are targeted to ARM, not `x86_64`.

Installing and Using

After the LLVM/Clang has built successfully, you should install it via:

```
$ ninja install
```

which will create a sysroot on the `install-dir`. You can then tar that directory into a binary with the full triple name (for easy identification), like:

```
$ ln -sf <install-dir> arm-linux-gnueabi-hf-clang
$ tar zchf arm-linux-gnueabi-hf-clang.tar.gz arm-linux-gnueabi-hf-clang
```

If you copy that tarball to your target board, you'll be able to use it for running the test-suite, for example. Follow the guidelines at <http://llvm.org/docs/ln/quickstart.html>, unpack the tarball in the test directory, and use options:

```
$ ./sandbox/bin/python sandbox/bin/ln runtest nt \
  --sandbox sandbox \
  --test-suite `pwd`/test-suite \
  --cc `pwd`/arm-linux-gnueabi-hf-clang/bin/clang \
  --cxx `pwd`/arm-linux-gnueabi-hf-clang/bin/clang++
```

Remember to add the `-jN` options to `ln` to the number of CPUs on your board. Also, the path to your clang has to be absolute, so you'll need the `pwd` trick above.

2.8 LLVM Command Guide

The following documents are command descriptions for all of the LLVM tools. These pages describe how to use the LLVM commands and what their options are. Note that these pages do not describe all of the options available for all tools. To get a complete listing, pass the `--help` (general options) or `--help-hidden` (general and debugging options) arguments to the tool you are interested in.

2.8.1 Basic Commands

llvm-as - LLVM assembler

SYNOPSIS

llvm-as [*options*] [*filename*]

DESCRIPTION

llvm-as is the LLVM assembler. It reads a file containing human-readable LLVM assembly language, translates it to LLVM bitcode, and writes the result into a file or to standard output.

If *filename* is omitted or is `-`, then **llvm-as** reads its input from standard input.

If an output file is not specified with the **-o** option, then **llvm-as** sends its output to a file or standard output by following these rules:

- If the input is standard input, then the output is standard output.
- If the input is a file that ends with `.ll`, then the output file is of the same name, except that the suffix is changed to `.bc`.
- If the input is a file that does not end with the `.ll` suffix, then the output file has the same name as the input file, except that the `.bc` suffix is appended.

OPTIONS

-f Enable binary output on terminals. Normally, **llvm-as** will refuse to write raw bitcode output if the output stream is a terminal. With this option, **llvm-as** will write raw bitcode regardless of the output device.

-help Print a summary of command line options.

-o filename Specify the output file name. If *filename* is `-`, then **llvm-as** sends its output to standard output.

EXIT STATUS

If **llvm-as** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

SEE ALSO

llvm-dis (1), *as* (1)

llvm-dis - LLVM disassembler

SYNOPSIS

llvm-dis [*options*] [*filename*]

DESCRIPTION

The **llvm-dis** command is the LLVM disassembler. It takes an LLVM bitcode file and converts it into human-readable LLVM assembly language.

If *filename* is omitted or specified as `-`, **llvm-dis** reads its input from standard input.

If the input is being read from standard input, then **llvm-dis** will send its output to standard output by default. Otherwise, the output will be written to a file named after the input file, with a `.ll` suffix added (any existing `.bc` suffix will first be removed). You can override the choice of output file using the **-o** option.

OPTIONS

-f

Enable binary output on terminals. Normally, **llvm-dis** will refuse to write raw bitcode output if the output stream is a terminal. With this option, **llvm-dis** will write raw bitcode regardless of the output device.

-help

Print a summary of command line options.

-o filename

Specify the output file name. If *filename* is `-`, then the output is sent to standard output.

EXIT STATUS

If **llvm-dis** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

SEE ALSO

llvm-as (1)

opt - LLVM optimizer

SYNOPSIS

opt [*options*] [*filename*]

DESCRIPTION

The **opt** command is the modular LLVM optimizer and analyzer. It takes LLVM source files as input, runs the specified optimizations or analyses on it, and then outputs the optimized file or the analysis results. The function of **opt** depends on whether the *-analyze* option is given.

When *-analyze* is specified, **opt** performs various analyses of the input source. It will usually print the results on standard output, but in a few cases, it will print output to standard error or generate a file with the analysis output, which is usually done when the output is meant for another program.

While *-analyze* is *not* given, **opt** attempts to produce an optimized output file. The optimizations available via **opt** depend upon what libraries were linked into it as well as any additional libraries that have been loaded with the *-load* option. Use the *-help* option to determine what optimizations you can use.

If *filename* is omitted from the command line or is "-", **opt** reads its input from standard input. Inputs can be in either the LLVM assembly language format (.ll) or the LLVM bitcode format (.bc).

If an output filename is not specified with the *-o* option, **opt** writes its output to the standard output.

OPTIONS

-f

Enable binary output on terminals. Normally, **opt** will refuse to write raw bitcode output if the output stream is a terminal. With this option, **opt** will write raw bitcode regardless of the output device.

-help

Print a summary of command line options.

-o <filename>

Specify the output filename.

-S

Write output in LLVM intermediate language (instead of bitcode).

-{passname}

opt provides the ability to run any of LLVM's optimization or analysis passes in any order. The *-help* option lists all the passes available. The order in which the options occur on the command line are the order in which they are executed (within pass constraints).

-disable-inlining

This option simply removes the inlining pass from the standard list.

-disable-opt

This option is only meaningful when *-std-link-opts* is given. It disables most passes.

-strip-debug

This option causes **opt** to strip debug information from the module before applying other optimizations. It is essentially the same as *-strip* but it ensures that stripping of debug information is done first.

-verify-each

This option causes **opt** to add a verify pass after every pass otherwise specified on the command line (including *-verify*). This is useful for cases where it is suspected that a pass is creating an invalid module but it is not clear which pass is doing it.

-stats

Print statistics.

-time-passes

Record the amount of time needed for each pass and print it to standard error.

-debug

If this is a debug build, this option will enable debug printouts from passes which use the `LLVM_DEBUG()` macro. See the [LLVM Programmer's Manual](#), section `#DEBUG` for more information.

-load=<plugin>

Load the dynamic object `plugin`. This object should register new optimization or analysis passes. Once loaded, the object will add new command line options to enable various optimizations or analyses. To see the new complete list of optimizations, use the `-help` and `-load` options together. For example:

```
opt -load=plugin.so -help
```

-p

Print module after each transformation.

EXIT STATUS

If **opt** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

llc - LLVM static compiler**SYNOPSIS**

llc [*options*] [*filename*]

DESCRIPTION

The **llc** command compiles LLVM source inputs into assembly language for a specified architecture. The assembly language output can then be passed through a native assembler and linker to generate a native executable.

The choice of architecture for the output assembly code is automatically determined from the input file, unless the `-march` option is used to override the default.

OPTIONS

If *filename* is "-" or omitted, **llc** reads from standard input. Otherwise, it will from *filename*. Inputs can be in either the LLVM assembly language format (`.ll`) or the LLVM bitcode format (`.bc`).

If the `-o` option is omitted, then **llc** will send its output to standard output if the input is from standard input. If the `-o` option specifies "-", then the output will also be sent to standard output.

If no `-o` option is specified and an input file other than "-" is specified, then **llc** creates the output filename by taking the input filename, removing any existing `.bc` extension, and adding a `.s` suffix.

Other **llc** options are described below.

End-user Options

-help

Print a summary of command line options.

-o <filename>

Use <filename> as the output filename. See the summary above for more details.

-O=uint

Generate code at different optimization levels. These correspond to the `-O0`, `-O1`, `-O2`, and `-O3` optimization levels used by **clang**.

-mtriple=<target triple>

Override the target triple specified in the input file with the specified string.

-march=<arch>

Specify the architecture for which to generate assembly, overriding the target encoded in the input file. See the output of `llc -help` for a list of valid architectures. By default this is inferred from the target triple or autodetected to the current architecture.

-mcpu=<cpuname>

Specify a specific chip in the current architecture to generate code for. By default this is inferred from the target triple and autodetected to the current architecture. For a list of available CPUs, use:

```
llvm-as < /dev/null | llc -march=xyz -mcpu=help
```

-filetype=<output file type>

Specify what kind of output `llc` should generated. Options are: `asm` for textual assembly (`'.s'`), `obj` for native object files (`'.o'`) and `null` for not emitting anything (for performance testing).

Note that not all targets support all options.

-mattr=a1,+a2,-a3,...

Override or control specific attributes of the target, such as whether SIMD operations are enabled or not. The default set of attributes is set by the current CPU. For a list of available attributes, use:

```
llvm-as < /dev/null | llc -march=xyz -mattr=help
```

--frame-pointer

Specify effect of frame pointer elimination optimization (all,non-leaf,none).

--disable-excess-fp-precision

Disable optimizations that may produce excess precision for floating point. Note that this option can dramatically slow down code on some systems (e.g. X86).

--enable-no-infs-fp-math

Enable optimizations that assume no Inf values.

--enable-no-nans-fp-math

Enable optimizations that assume no NAN values.

--enable-unsafe-fp-math

Enable optimizations that make unsafe assumptions about IEEE math (e.g. that addition is associative) or may not work for all input ranges. These optimizations allow the code generator to make use of some instructions which would otherwise not be usable (such as `fsin` on X86).

--stats

Print statistics recorded by code-generation passes.

--time-passes

Record the amount of time needed for each pass and print a report to standard error.

--load=<dso_path>

Dynamically load `dso_path` (a path to a dynamically shared object) that implements an LLVM target. This will permit the target name to be used with the `-march` option so that code can be generated for that target.

-meabi=[default|gnu|4|5]

Specify which EABI version should conform to. Valid EABI versions are *gnu*, 4 and 5. Default value (*default*) depends on the triple.

-stack-size-section

Emit the `.stack_sizes` section which contains stack size metadata. The section contains an array of pairs of function symbol values (pointer size) and stack sizes (unsigned LEB128). The stack size values only include the space allocated in the function prologue. Functions with dynamic stack allocations are not included.

-remarks-section

Emit the `.remarks` (ELF) / `__remarks` (MachO) section which contains metadata about remark diagnostics.

Tuning/Configuration Options

--print-machineinstrs

Print generated machine code between compilation phases (useful for debugging).

--regalloc=<allocator>

Specify the register allocator to use. Valid register allocators are:

basic

Basic register allocator.

fast

Fast register allocator. It is the default for unoptimized code.

greedy

Greedy register allocator. It is the default for optimized code.

pbqp

Register allocator based on 'Partitioned Boolean Quadratic Programming'.

--spiller=<spiller>

Specify the spiller to use for register allocators that support it. Currently this option is used only by the linear scan register allocator. The default `spiller` is *local*. Valid spillers are:

simple

Simple spiller

local

Local spiller

Intel IA-32-specific Options

--x86-asm-syntax=[att|intel]

Specify whether to emit assembly code in AT&T syntax (the default) or Intel syntax.

EXIT STATUS

If **lli** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

SEE ALSO

lli (1)

lli - directly execute programs from LLVM bitcode

SYNOPSIS

lli [*options*] [*filename*] [*program args*]

DESCRIPTION

lli directly executes programs in LLVM bitcode format. It takes a program in LLVM bitcode format and executes it using a just-in-time compiler or an interpreter.

lli is *not* an emulator. It will not execute IR of different architectures and it can only interpret (or JIT-compile) for the host architecture.

The JIT compiler takes the same arguments as other tools, like **llc**, but they don't necessarily work for the interpreter.

If *filename* is not specified, then **lli** reads the LLVM bitcode for the program from standard input.

The optional *args* specified on the command line are passed to the program as arguments.

GENERAL OPTIONS

-fake-argv0=executable

Override the `argv[0]` value passed into the executing program.

-force-interpreter={false,true}

If set to true, use the interpreter even if a just-in-time compiler is available for this architecture. Defaults to false.

-help

Print a summary of command line options.

-load=pluginfilename

Causes **lli** to load the plugin (shared object) named *pluginfilename* and use it for optimization.

-stats

Print statistics from the code-generation passes. This is only meaningful for the just-in-time compiler, at present.

-time-passes

Record the amount of time needed for each code-generation pass and print it to standard error.

-version

Print out the version of **lli** and exit without doing anything else.

TARGET OPTIONS**-mtriple**=target triple

Override the target triple specified in the input bitcode file with the specified string. This may result in a crash if you pick an architecture which is not compatible with the current system.

-march=arch

Specify the architecture for which to generate assembly, overriding the target encoded in the bitcode file. See the output of **llc -help** for a list of valid architectures. By default this is inferred from the target triple or autodetected to the current architecture.

-mcpu=cpuname

Specify a specific chip in the current architecture to generate code for. By default this is inferred from the target triple and autodetected to the current architecture. For a list of available CPUs, use: **llvm-as < /dev/null | llc**

-march=xyz -mcpu=help

-mattr=a1, +a2, -a3, ...

Override or control specific attributes of the target, such as whether SIMD operations are enabled or not. The default set of attributes is set by the current CPU. For a list of available attributes, use: **llvm-as < /dev/null | llc**

-march=xyz -mattr=help

FLOATING POINT OPTIONS**-disable-excess-fp-precision**

Disable optimizations that may increase floating point precision.

-enable-no-infs-fp-math

Enable optimizations that assume no Inf values.

-enable-no-nans-fp-math

Enable optimizations that assume no NAN values.

-enable-unsafe-fp-math

Causes **lli** to enable optimizations that may decrease floating point precision.

-soft-float

Causes **lli** to generate software floating point library calls instead of equivalent hardware instructions.

CODE GENERATION OPTIONS**-code-model**=model

Choose the code model from:

```
default: Target default code model
tiny: Tiny code model
small: Small code model
kernel: Kernel code model
medium: Medium code model
large: Large code model
```

-disable-post-RA-scheduler

Disable scheduling after register allocation.

-disable-spill-fusing

Disable fusing of spill code into instructions.

-jit-enable-eh

Exception handling should be enabled in the just-in-time compiler.

-join-liveintervals

Coalesce copies (default=true).

-nozero-initialized-in-bss

Don't place zero-initialized symbols into the BSS section.

-pre-RA-sched=scheduler

Instruction schedulers available (before register allocation):

```
=default: Best scheduler for the target
=none: No scheduling: breadth first sequencing
=simple: Simple two pass scheduling: minimize critical path and maximize ↵
↵processor utilization
=simple-noitin: Simple two pass scheduling: Same as simple except using generic ↵
↵latency
=list-burr: Bottom-up register reduction list scheduling
=list-tdrr: Top-down register reduction list scheduling
=list-td: Top-down list scheduler -print-machineinstrs - Print generated machine ↵
↵code
```

-regalloc=allocator

Register allocator to use (default=linearscan)

```
=bigblock: Big-block register allocator
=linearscan: linear scan register allocator =local - local register allocator
=simple: simple register allocator
```

-relocation-model=model

Choose relocation model from:

```
=default: Target default relocation model
=static: Non-relocatable code =pic - Fully relocatable, position independent ↵
↵code
=dynamic-no-pic: Relocatable external references, non-relocatable code
```

-spiller

Spiller to use (default=local)

```
=simple: simple spiller
=local: local spiller
```

-x86-asm-syntax=syntax

Choose style of code to emit from X86 backend:

```
=att: Emit AT&T-style assembly
=intel: Emit Intel-style assembly
```

EXIT STATUS

If **lli** fails to load the program, it will exit with an exit code of 1. Otherwise, it will return the exit code of the program it executes.

SEE ALSO

llc(1)

llvm-link - LLVM bitcode linker

SYNOPSIS

llvm-link [*options*] *filename* ...

DESCRIPTION

llvm-link takes several LLVM bitcode files and links them together into a single LLVM bitcode file. It writes the output file to standard output, unless the **-o** option is used to specify a filename.

OPTIONS

- f**
Enable binary output on terminals. Normally, **llvm-link** will refuse to write raw bitcode output if the output stream is a terminal. With this option, **llvm-link** will write raw bitcode regardless of the output device.
- o filename**
Specify the output file name. If *filename* is "-", then **llvm-link** will write its output to standard output.
- S**
Write output in LLVM intermediate language (instead of bitcode).
- d**
If specified, **llvm-link** prints a human-readable version of the output bitcode file to standard error.
- help**
Print a summary of command line options.
- v**
Verbose mode. Print information about what **llvm-link** is doing. This typically includes a message for each bitcode file linked in and for each library found.

EXIT STATUS

If **llvm-link** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

llvm-lib - LLVM lib.exe compatible library tool

SYNOPSIS

llvm-lib [/libpath:<path>] [/out:<output>] [/llvmlibthin] [/ignore] [/machine] [/nologo] [files...]

DESCRIPTION

The **llvm-lib** command is intended to be a `lib.exe` compatible tool. See <https://msdn.microsoft.com/en-us/library/7ykb2k5f> for the general description.

llvm-lib has the following extensions:

- Bitcode files in symbol tables. **llvm-lib** includes symbols from both bitcode files and regular object files in the symbol table.
- Creating thin archives. The `/llvmlibthin` option causes **llvm-lib** to create thin archive that contain only the symbol table and the header for the various members. These files are much smaller, but are not compatible with `link.exe` (`lld` can handle them).

llvm-lipo - LLVM tool for manipulating universal binaries

SYNOPSIS

llvm-lipo [filenames...] [options]

DESCRIPTION

llvm-lipo can create universal binaries from Mach-O files, extract regular object files from universal binaries, and display architecture information about both universal and regular files.

COMMANDS

llvm-lipo supports the following mutually exclusive commands:

-help, -h

Display usage information and exit.

-version

Display the version of this program.

-verify_arch <architecture 1> [<architecture 2> ...]

Take a single input file and verify the specified architectures are present in the file. If so then exit with a status of 0 else exit with a status of 1.

-archs

Take a single input file and display the architectures present in the file. Each architecture is separated by a single whitespace. Unknown architectures are displayed as `unknown(CPUtype,CPUsubtype)`.

BUGS

To report bugs, please visit <http://llvm.org/bugs/>.

llvm-config - Print LLVM compilation options

SYNOPSIS

llvm-config *option* [*components...*]

DESCRIPTION

llvm-config makes it easier to build applications that use LLVM. It can print the compiler flags, linker flags and object libraries needed to link against LLVM.

EXAMPLES

To link against the JIT:

```
g++ `llvm-config --cxxflags` -o HowToUseJIT.o -c HowToUseJIT.cpp
g++ `llvm-config --ldflags` -o HowToUseJIT HowToUseJIT.o \
    `llvm-config --libs engine bcreader scalaropts`
```

OPTIONS

--version

Print the version number of LLVM.

-help

Print a summary of **llvm-config** arguments.

--prefix

Print the installation prefix for LLVM.

--src-root

Print the source root from which LLVM was built.

--obj-root

Print the object root used to build LLVM.

--bindir

Print the installation directory for LLVM binaries.

--includedir

Print the installation directory for LLVM headers.

--libdir

Print the installation directory for LLVM libraries.

--cxxflags

Print the C++ compiler flags needed to use LLVM headers.

--ldflags

Print the flags needed to link against LLVM libraries.

--libs

Print all the libraries needed to link against the specified LLVM *components*, including any dependencies.

--libnames

Similar to **--libs**, but prints the bare filenames of the libraries without **-l** or pathnames. Useful for linking against a not-yet-installed copy of LLVM.

--libfiles

Similar to **--libs**, but print the full path to each library file. This is useful when creating makefile dependencies, to ensure that a tool is relinked if any library it uses changes.

--components

Print all valid component names.

--targets-built

Print the component names for all targets supported by this copy of LLVM.

--build-mode

Print the build mode used when LLVM was built (e.g. Debug or Release)

COMPONENTS

To print a list of all available components, run **llvm-config --components**. In most cases, components correspond directly to LLVM libraries. Useful "virtual" components include:

all

Includes all LLVM libraries. The default if no components are specified.

backend

Includes either a native backend or the C backend.

engine

Includes either a native JIT or the bitcode interpreter.

EXIT STATUS

If **llvm-config** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

llvm-cxxmap - Mangled name remapping tool

SYNOPSIS

```
llvm-cxxmap [options] symbol-file-1 symbol-file-2
```

DESCRIPTION

The **llvm-cxxmap** tool performs fuzzy matching of C++ mangled names, based on a file describing name components that should be considered equivalent.

The symbol files should contain a list of C++ mangled names (one per line). Blank lines and lines starting with # are ignored. The output is a list of pairs of equivalent symbols, one per line, of the form

```
<symbol-1> <symbol-2>
```

where <symbol-1> is a symbol from *symbol-file-1* and <symbol-2> is a symbol from *symbol-file-2*. Mappings for which the two symbols are identical are omitted.

OPTIONS

-remapping-file=file, -r=file

Specify a file containing a list of equivalence rules that should be used to determine whether two symbols are equivalent. Required. See [REMAPPING FILE](#).

-output=file, -o=file

Specify a file to write the list of matched names to. If unspecified, the list will be written to stdout.

-Wambiguous

Produce a warning if there are multiple equivalent (but distinct) symbols in *symbol-file-2*.

-Wincomplete

Produce a warning if *symbol-file-1* contains a symbol for which there is no equivalent symbol in *symbol-file-2*.

REMAPPING FILE

The remapping file is a text file containing lines of the form

```
fragmentkind fragment1 fragment2
```

where fragmentkind is one of name, type, or encoding, indicating whether the following mangled name fragments are <name>s, <type>s, or <encoding>s, respectively. Blank lines and lines starting with # are ignored.

For convenience, built-in <substitution>s such as St and Ss are accepted as <name>s (even though they technically are not <name>s).

For example, to specify that `absl::string_view` and `std::string_view` should be treated as equivalent, the following remapping file could be used:

```
# absl::string_view is considered equivalent to std::string_view
type N4absl11string_viewE St17basic_string_viewIcSt11char_traitsIcEE

# std:: might be std::__1:: in libc++ or std::__cxx11:: in libstdc++
name St St3__1
name St St7__cxx11
```

Note: Symbol remapping is currently only supported for C++ mangled names following the Itanium C++ ABI mangling scheme. This covers all C++ targets supported by Clang other than Windows targets.

llvm-diff - LLVM structural 'diff'

SYNOPSIS

llvm-diff [*options*] *module 1 module 2* [*global name ...*]

DESCRIPTION

llvm-diff compares the structure of two LLVM modules, primarily focusing on differences in function definitions. Insignificant differences, such as changes in the ordering of globals or in the names of local values, are ignored.

An input module will be interpreted as an assembly file if its name ends in '.ll'; otherwise it will be read in as a bitcode file.

If a list of global names is given, just the values with those names are compared; otherwise, all global values are compared, and diagnostics are produced for globals which only appear in one module or the other.

llvm-diff compares two functions by comparing their basic blocks, beginning with the entry blocks. If the terminators seem to match, then the corresponding successors are compared; otherwise they are ignored. This algorithm is very sensitive to changes in control flow, which tend to stop any downstream changes from being detected.

llvm-diff is intended as a debugging tool for writers of LLVM passes and frontends. It does not have a stable output format.

EXIT STATUS

If **llvm-diff** finds no differences between the modules, it will exit with 0 and produce no output. Otherwise it will exit with a non-zero value.

BUGS

Many important differences, like changes in linkage or function attributes, are not diagnosed.

Changes in memory behavior (for example, coalescing loads) can cause massive detected differences in blocks.

llvm-cov - emit coverage information

SYNOPSIS

llvm-cov *command* [*args...*]

DESCRIPTION

The **llvm-cov** tool shows code coverage information for programs that are instrumented to emit profile data. It can be used to work with `gcov`-style coverage or with `clang`'s instrumentation based profiling.

If the program is invoked with a base name of `gcov`, it will behave as if the **llvm-cov gcov** command were called. Otherwise, a command should be provided.

COMMANDS

- *gcov*
- *show*
- *report*
- *export*

GCOV COMMAND

SYNOPSIS

```
llvm-cov gcov [options] SOURCEFILE
```

DESCRIPTION

The **llvm-cov gcov** tool reads code coverage data files and displays the coverage information for a specified source file. It is compatible with the `gcov` tool from version 4.2 of GCC and may also be compatible with some later versions of `gcov`.

To use **llvm-cov gcov**, you must first build an instrumented version of your application that collects coverage data as it runs. Compile with the `-fprofile-arcs` and `-ftest-coverage` options to add the instrumentation. (Alternatively, you can use the `--coverage` option, which includes both of those other options.) You should compile with debugging information (`-g`) and without optimization (`-O0`); otherwise, the coverage data cannot be accurately mapped back to the source code.

At the time you compile the instrumented code, a `.gcno` data file will be generated for each object file. These `.gcno` files contain half of the coverage data. The other half of the data comes from `.gda` files that are generated when you run the instrumented program, with a separate `.gda` file for each object file. Each time you run the program, the execution counts are summed into any existing `.gda` files, so be sure to remove any old files if you do not want their contents to be included.

By default, the `.gda` files are written into the same directory as the object files, but you can override that by setting the `GCOV_PREFIX` and `GCOV_PREFIX_STRIP` environment variables. The `GCOV_PREFIX_STRIP` variable specifies a number of directory components to be removed from the start of the absolute path to the object file directory. After stripping those directories, the prefix from the `GCOV_PREFIX` variable is added. These environment variables allow you to run the instrumented program on a machine where the original object file directories are not accessible, but you will then need to copy the `.gda` files back to the object file directories where **llvm-cov gcov** expects to find them.

Once you have generated the coverage data files, run **llvm-cov gcov** for each main source file where you want to examine the coverage results. This should be run from the same directory where you previously ran the compiler. The results for the specified source file are written to a file named by appending a `.gcov` suffix. A separate output file is also created for each file included by the main source file, also with a `.gcov` suffix added.

The basic content of an `.gcov` output file is a copy of the source file with an execution count and line number prepended to every line. The execution count is shown as `-` if a line does not contain any executable code. If a line contains code but that code was never executed, the count is displayed as `#####`.

OPTIONS

-a, --all-blocks

Display all basic blocks. If there are multiple blocks for a single line of source code, this option causes `llvm-cov` to show the count for each block instead of just one count for the entire line.

-b, --branch-probabilities

Display conditional branch probabilities and a summary of branch information.

-c, --branch-counts

Display branch counts instead of probabilities (requires `-b`).

-f, --function-summaries

Show a summary of coverage for each function instead of just one summary for an entire source file.

--help

Display available options (`--help-hidden` for more).

-l, --long-file-names

For coverage output of files included from the main source file, add the main file name followed by `##` as a prefix to the output file names. This can be combined with the `--preserve-paths` option to use complete paths for both the main file and the included file.

-n, --no-output

Do not output any `.gcov` files. Summary information is still displayed.

-o=<DIR|FILE>, --object-directory=<DIR>, --object-file=<FILE>

Find objects in `DIR` or based on `FILE`'s path. If you specify a particular object file, the coverage data files are expected to have the same base name with `.gcno` and `.gcda` extensions. If you specify a directory, the files are expected in that directory with the same base name as the source file.

-p, --preserve-paths

Preserve path components when naming the coverage output files. In addition to the source file name, include the directories from the path to that file. The directories are separate by `#` characters, with `.` directories removed and `..` directories replaced by `^` characters. When used with the `--long-file-names` option, this applies to both the main file name and the included file name.

-u, --unconditional-branches

Include unconditional branches in the output for the `--branch-probabilities` option.

-version

Display the version of `llvm-cov`.

-x, --hash-filenames

Use md5 hash of file name when naming the coverage output files. The source file name will be suffixed by `##` followed by MD5 hash calculated for it.

EXIT STATUS

llvm-cov gcov returns 1 if it cannot read input files. Otherwise, it exits with zero.

SHOW COMMAND

SYNOPSIS

```
llvm-cov show [options] -instr-profile PROFILE BIN [-object BIN,...] [[-object BIN]] [SOURCES]
```

DESCRIPTION

The **llvm-cov show** command shows line by line coverage of the binaries *BIN*,... using the profile data *PROFILE*. It can optionally be filtered to only show the coverage for the files listed in *SOURCES*.

BIN may be an executable, object file, dynamic library, or archive (thin or otherwise).

To use **llvm-cov show**, you need a program that is compiled with instrumentation to emit profile and coverage data. To build such a program with `clang` use the `-fprofile-instr-generate` and `-fcoverage-mapping` flags. If linking with the `clang` driver, pass `-fprofile-instr-generate` to the link stage to make sure the necessary runtime libraries are linked in.

The coverage information is stored in the built executable or library itself, and this is what you should pass to **llvm-cov show** as a *BIN* argument. The profile data is generated by running this instrumented program normally. When the program exits it will write out a raw profile file, typically called `default.profraw`, which can be converted to a format that is suitable for the *PROFILE* argument using the **llvm-profdata merge** tool.

OPTIONS

-show-line-counts

Show the execution counts for each line. Defaults to true, unless another `-show` option is used.

-show-expansions

Expand inclusions, such as preprocessor macros or textual inclusions, inline in the display of the source file. Defaults to false.

-show-instantiations

For source regions that are instantiated multiple times, such as templates in C++, show each instantiation separately as well as the combined summary. Defaults to true.

-show-regions

Show the execution counts for each region by displaying a caret that points to the character where the region starts. Defaults to false.

-show-line-counts-or-regions

Show the execution counts for each line if there is only one region on the line, but show the individual regions if there are multiple on the line. Defaults to false.

-use-color

Enable or disable color output. By default this is autodetected.

-arch= [**NAMES**]

Specify a list of architectures such that the Nth entry in the list corresponds to the Nth specified binary. If the covered object is a universal binary, this specifies the architecture to use. It is an error to specify an architecture that is not included in the universal binary or to use an architecture that does not match a non-universal binary.

-name=<NAME>

Show code coverage only for functions with the given name.

-name-whitelist=<FILE>

Show code coverage only for functions listed in the given file. Each line in the file should start with *whitelist_fun:*, immediately followed by the name of the function to accept. This name can be a wildcard expression.

-name-regex=<PATTERN>

Show code coverage only for functions that match the given regular expression.

-ignore-filename-regex=<PATTERN>

Skip source code files with file paths that match the given regular expression.

-format=<FORMAT>

Use the specified output format. The supported formats are: "text", "html".

-tab-size=<TABSIZ>

Replace tabs with <TABSIZ> spaces when preparing reports. Currently, this is only supported for the html format.

-output-dir=PATH

Specify a directory to write coverage reports into. If the directory does not exist, it is created. When used in function view mode (i.e when -name or -name-regex are used to select specific functions), the report is written to PATH/functions.EXTENSION. When used in file view mode, a report for each file is written to PATH/REL_PATH_TO_FILE.EXTENSION.

-Xdemangler=<TOOL> | <TOOL-OPTION>

Specify a symbol demangler. This can be used to make reports more human-readable. This option can be specified multiple times to supply arguments to the demangler (e.g *-Xdemangler c++filt -Xdemangler -n* for C++). The demangler is expected to read a newline-separated list of symbols from stdin and write a newline-separated list of the same length to stdout.

-num-threads=N, -j=N

Use N threads to write file reports (only applicable when -output-dir is specified). When N=0, llvm-cov auto-detects an appropriate number of threads to use. This is the default.

-line-coverage-gt=<N>

Show code coverage only for functions with line coverage greater than the given threshold.

-line-coverage-lt=<N>

Show code coverage only for functions with line coverage less than the given threshold.

-region-coverage-gt=<N>

Show code coverage only for functions with region coverage greater than the given threshold.

-region-coverage-lt=<N>

Show code coverage only for functions with region coverage less than the given threshold.

-path-equivalence=<from>, <to>

Map the paths in the coverage data to local source file paths. This allows you to generate the coverage data on one machine, and then use llvm-cov on a different machine where you have the same files on a different path.

REPORT COMMAND

SYNOPSIS

```
llvm-cov report [options] -instr-profile PROFILE BIN [-object BIN,...] [[-object BIN]] [SOURCES]
```

DESCRIPTION

The **llvm-cov report** command displays a summary of the coverage of the binaries *BIN*,... using the profile data *PROFILE*. It can optionally be filtered to only show the coverage for the files listed in *SOURCES*.

BIN may be an executable, object file, dynamic library, or archive (thin or otherwise).

If no source files are provided, a summary line is printed for each file in the coverage data. If any files are provided, summaries can be shown for each function in the listed files if the `-show-functions` option is enabled.

For information on compiling programs for coverage and generating profile data, see [SHOW COMMAND](#).

OPTIONS

-use-color[=*VALUE*]

Enable or disable color output. By default this is autodetected.

-arch=<*name*>

If the covered binary is a universal binary, select the architecture to use. It is an error to specify an architecture that is not included in the universal binary or to use an architecture that does not match a non-universal binary.

-show-functions

Show coverage summaries for each function. Defaults to false.

-show-instantiation-summary

Show statistics for all function instantiations. Defaults to false.

-ignore-filename-regex=<*PATTERN*>

Skip source code files with file paths that match the given regular expression.

EXPORT COMMAND

SYNOPSIS

```
llvm-cov export [options] -instr-profile PROFILE BIN [-object BIN,...] [[-object BIN]] [SOURCES]
```

DESCRIPTION

The **llvm-cov export** command exports coverage data of the binaries *BIN*,... using the profile data *PROFILE* in either JSON or lcov trace file format.

When exporting JSON, the regions, functions, expansions, and summaries of the coverage data will be exported. When exporting an lcov trace file, the line-based coverage and summaries will be exported.

The exported data can optionally be filtered to only export the coverage for the files listed in *SOURCES*.

For information on compiling programs for coverage and generating profile data, see [SHOW COMMAND](#).

OPTIONS

-arch=<name>

If the covered binary is a universal binary, select the architecture to use. It is an error to specify an architecture that is not included in the universal binary or to use an architecture that does not match a non-universal binary.

-format=<FORMAT>

Use the specified output format. The supported formats are: "text" (JSON), "lcov".

-summary-only

Export only summary information for each file in the coverage data. This mode will not export coverage information for smaller units such as individual functions or regions. The result will contain the same information as produced by the **llvm-cov report** command, but presented in JSON or lcov format rather than text.

-ignore-filename-regex=<PATTERN>

Skip source code files with file paths that match the given regular expression.

-skip-expansions

Skip exporting macro expansion coverage data.

-skip-functions

Skip exporting per-function coverage data.

-num-threads=N, **-j**=N

Use N threads to export coverage data. When N=0, llvm-cov auto-detects an appropriate number of threads to use. This is the default.

llvm-profdata - Profile data tool

SYNOPSIS

llvm-profdata *command* [*args...*]

DESCRIPTION

The **llvm-profdata** tool is a small utility for working with profile data files.

COMMANDS

- *merge*
- *show*
- *overlap*

MERGE

SYNOPSIS

```
llvm-profdata merge [options] [filename...]
```

DESCRIPTION

llvm-profdata merge takes several profile data files generated by PGO instrumentation and merges them together into a single indexed profile data file.

By default profile data is merged without modification. This means that the relative importance of each input file is proportional to the number of samples or counts it contains. In general, the input from a longer training run will be interpreted as relatively more important than a shorter run. Depending on the nature of the training runs it may be useful to adjust the weight given to each input file by using the `-weighted-input` option.

Profiles passed in via `-weighted-input`, `-input-files`, or via positional arguments are processed once for each time they are seen.

OPTIONS

-help

Print a summary of command line options.

-output=output, -o=output

Specify the output file name. *Output* cannot be `-` as the resulting indexed profile data can't be written to standard output.

-weighted-input=weight, filename

Specify an input file name along with a weight. The profile counts of the supplied *filename* will be scaled (multiplied) by the supplied *weight*, where *weight* is a decimal integer ≥ 1 . Input files specified without using this option are assigned a default weight of 1. Examples are shown below.

-input-files=path, -f=path

Specify a file which contains a list of files to merge. The entries in this file are newline-separated. Lines starting with '#' are skipped. Entries may be of the form `<filename>` or `<weight>,<filename>`.

-remapping-file=path, -r=path

Specify a file which contains a remapping from symbol names in the input profile to the symbol names that should be used in the output profile. The file should consist of lines of the form `<input-symbol> <output-symbol>`. Blank lines and lines starting with # are skipped.

The *llvm-cxxmap* tool can be used to generate the symbol remapping file.

-instr (default)

Specify that the input profile is an instrumentation-based profile.

-sample

Specify that the input profile is a sample-based profile.

The format of the generated file can be generated in one of three ways:

-binary (default)

Emit the profile using a binary encoding. For instrumentation-based profile the output format is the indexed binary format.

-text

Emit the profile in text mode. This option can also be used with both sample-based and instrumentation-based profile. When this option is used the profile will be dumped in the text format that is parsable by the profile reader.

-gcc

Emit the profile using GCC's gcov format (Not yet supported).

-sparse [=true|false]

Do not emit function records with 0 execution count. Can only be used in conjunction with -instr. Defaults to false, since it can inhibit compiler optimization during PGO.

-num-threads=N, **-j**=N

Use N threads to perform profile merging. When N=0, llvm-profdata auto-detects an appropriate number of threads to use. This is the default.

EXAMPLES

Basic Usage

Merge three profiles:

```
llvm-profdata merge foo.profdata bar.profdata baz.profdata -output merged.profdata
```

Weighted Input

The input file *foo.profdata* is especially important, multiply its counts by 10:

```
llvm-profdata merge -weighted-input=10,foo.profdata bar.profdata baz.profdata -output merged.profdata
```

Exactly equivalent to the previous invocation (explicit form; useful for programmatic invocation):

```
llvm-profdata merge -weighted-input=10,foo.profdata -weighted-input=1,bar.profdata -weighted-input=1,baz.profdata -output merged.profdata
```

SHOW

SYNOPSIS

```
llvm-profdata show [options] [filename]
```

DESCRIPTION

llvm-profdata show takes a profile data file and displays the information about the profile counters for this file and for any of the specified function(s).

If *filename* is omitted or is -, then **llvm-profdata show** reads its input from standard input.

OPTIONS

-all-functions

Print details for every function.

-counts

Print the counter values for the displayed functions.

-function=string

Print details for a function if the function's name contains the given string.

-help

Print a summary of command line options.

-output=output, -o=output

Specify the output file name. If *output* is `-` or it isn't specified, then the output is sent to standard output.

-instr (default)

Specify that the input profile is an instrumentation-based profile.

-text

Instruct the profile dumper to show profile counts in the text format of the instrumentation-based profile data representation. By default, the profile information is dumped in a more human readable form (also in text) with annotations.

-topn=n

Instruct the profile dumper to show the top *n* functions with the hottest basic blocks in the summary section. By default, the top *n* functions are not dumped.

-sample

Specify that the input profile is a sample-based profile.

-memop-sizes

Show the profiled sizes of the memory intrinsic calls for shown functions.

-value-cutoff=n

Show only those functions whose max count values are greater or equal to *n*. By default, the value-cutoff is set to 0.

-list-below-cutoff

Only output names of functions whose max count value are below the cutoff value.

-showcs

Only show context sensitive profile counts. The default is to filter all context sensitive profile counts.

OVERLAP

SYNOPSIS

```
llvm-profdata overlap [options] [base profile file] [test profile file]
```

DESCRIPTION

llvm-profdata overlap takes two profile data files and displays the *overlap* of counter distribution between the whole files and between any of the specified functions.

In this command, *overlap* is defined as follows: Suppose *base profile file* has the following counts: {c1_1, c1_2, ..., c1_n, c1_u_1, c2_u_2, ..., c2_u_s}, and *test profile file* has {c2_1, c2_2, ..., c2_n, c2_v_1, c2_v_2, ..., c2_v_t}. Here c{1|2}_i (i = 1 .. n) are matched counters and c1_u_i (i = 1 .. s) and c2_v_i (i = 1 .. v) are unmatched counters (or counters only existing in) *base profile file* and *test profile file*, respectively. Let sum_1 = c1_1 + c1_2 + ... + c1_n + c1_u_1 + c2_u_2 + ... + c2_u_s, and sum_2 = c2_1 + c2_2 + ... + c2_n + c2_v_1 + c2_v_2 + ... + c2_v_t. *overlap* = min(c1_1/sum_1, c2_1/sum_2) + min(c1_2/sum_1, c2_2/sum_2) + ... + min(c1_n/sum_1, c2_n/sum_2).

The result overlap distribution is a percentage number, ranging from 0.0% to 100.0%, where 0.0% means there is no overlap and 100.0% means a perfect overlap.

Here is an example, if *base profile file* has counts of {400, 600}, and *test profile file* has matched counts of {60000, 40000}. The *overlap* is 80%.

OPTIONS

-function=string

Print details for a function if the function's name contains the given string.

-help

Print a summary of command line options.

-o=output or **-o output**

Specify the output file name. If *output* is - or it isn't specified, then the output is sent to standard output.

-value-cutoff=n

Show only those functions whose max count values are greater or equal to n. By default, the value-cutoff is set to max of unsigned long long.

-cs

Only show overlap for the context sensitive profile counts. The default is to show non-context sensitive profile counts.

EXIT STATUS

llvm-profdata returns 1 if the command is omitted or is invalid, if it cannot read input files, or if there is a mismatch between their data.

llvm-stress - generate random .ll files

SYNOPSIS

llvm-stress [-size=filesize] [-seed=initialseed] [-o=outfile]

DESCRIPTION

The **llvm-stress** tool is used to generate random `.ll` files that can be used to test different components of LLVM.

OPTIONS

- o** *filename*
Specify the output filename.
- size** *size*
Specify the size of the generated `.ll` file.
- seed** *seed*
Specify the seed to be used for the randomly generated instructions.

EXIT STATUS

llvm-stress returns 0.

llvm-symbolizer - convert addresses into source code locations

SYNOPSIS

llvm-symbolizer [*options*] [*addresses...*]

DESCRIPTION

llvm-symbolizer reads object file names and addresses from the command-line and prints corresponding source code locations to standard output.

If no address is specified on the command-line, it reads the addresses from standard input. If no object file is specified on the command-line, but addresses are, or if at any time an input value is not recognized, the input is simply echoed to the output.

A positional argument or standard input value can be preceded by "DATA" or "CODE" to indicate that the address should be symbolized as data or executable code respectively. If neither is specified, "CODE" is assumed. DATA is symbolized as address and symbol size rather than line number.

Object files can be specified together with the addresses either on standard input or as positional arguments on the command-line, following any "DATA" or "CODE" prefix.

EXAMPLES

All of the following examples use the following two source files as input. They use a mixture of C-style and C++-style linkage to illustrate how these names are printed differently (see `--demangle`).

```
// test.h
extern "C" inline int foz() {
    return 1234;
}
```

```
// test.cpp
#include "test.h"
int bar=42;

int foo() {
    return bar;
}

int baz() {
    volatile int k = 42;
    return foz() + k;
}

int main() {
    return foo() + baz();
}
```

These files are built as follows:

```
$ clang -g test.cpp -o test.elf
$ clang -g -O2 test.cpp -o inlined.elf
```

Example 1 - addresses and object on command-line:

```
$ llvm-symbolizer --obj=test.elf 0x4004d0 0x400490
foz
/tmp/test.h:1:0

baz()
/tmp/test.cpp:11:0
```

Example 2 - addresses on standard input:

```
$ cat addr.txt
0x4004a0
0x400490
0x4004d0
$ llvm-symbolizer --obj=test.elf < addr.txt
main
/tmp/test.cpp:15:0

baz()
/tmp/test.cpp:11:0

foz
/tmp/./test.h:1:0
```

Example 3 - object specified with address:

```
$ llvm-symbolizer "test.elf 0x400490" "inlined.elf 0x400480"
baz()
/tmp/test.cpp:11:0

foo()
/tmp/test.cpp:8:10

$ cat addr2.txt
```

(continues on next page)

(continued from previous page)

```
test.elf 0x4004a0
inlined.elf 0x400480

$ llvm-symbolizer < addr2.txt
main
/tmp/test.cpp:15:0

foo()
/tmp/test.cpp:8:10
```

Example 4 - CODE and DATA prefixes:

```
$ llvm-symbolizer --obj=test.elf "CODE 0x400490" "DATA 0x601028"
baz()
/tmp/test.cpp:11:0

bar
6295592 4

$ cat addr3.txt
CODE test.elf 0x4004a0
DATA inlined.elf 0x601028

$ llvm-symbolizer < addr3.txt
main
/tmp/test.cpp:15:0

bar
6295592 4
```

OPTIONS**--adjust-vma** <offset>

Add the specified offset to object file addresses when performing lookups. This can be used to perform lookups as if the object were relocated by the offset.

--basenames, -s

Strip directories when printing the file path.

--demangle, -C

Print demangled function names, if the names are mangled (e.g. the mangled name `_Z3bazv` becomes `baz()`, whilst the non-mangled name `foz` is printed as is). Defaults to true.

--dwp <path>

Use the specified DWP file at <path> for any CUs that have split DWARF debug data.

--fallback-debug-path <path>

When a separate file contains debug data, and is referenced by a GNU debug link section, use the specified path as a basis for locating the debug data if it cannot be found relative to the object.

--functions [<none|short|linkage>], **-f**

Specify the way function names are printed (omit function name, print short function name, or print full linkage name, respectively). Defaults to `linkage`.

--help, -h

Show help and usage for this command.

--help-list

Show help and usage for this command without grouping the options into categories.

--inlining, --inlines, -i

If a source code location is in an inlined function, prints all the inlined frames. Defaults to true.

--no-demangle

Don't print demangled function names.

--obj <path>, --exe, -e

Path to object file to be symbolized. If - is specified, read the object directly from the standard input stream.

--output-style <LLVM|GNU>

Specify the preferred output style. Defaults to LLVM. When the output style is set to GNU, the tool follows the style of GNU's **addr2line**. The differences from the LLVM style are:

- Does not print the column of a source code location.
- Does not add an empty line after the report for an address.
- Does not replace the name of an inlined function with the name of the topmost caller when inlined frames are not shown and `--use-symbol-table` is on.

```
$ llvm-symbolizer --obj=inlined.elf 0x4004be 0x400486 -p
baz() at /tmp/test.cpp:11:18
(inlined by) main at /tmp/test.cpp:15:0

foo() at /tmp/test.cpp:6:3

$ llvm-symbolizer --output-style=LLVM --obj=inlined.elf 0x4004be 0x400486 -p -i=0
main at /tmp/test.cpp:11:18

foo() at /tmp/test.cpp:6:3

$ llvm-symbolizer --output-style=GNU --obj=inlined.elf 0x4004be 0x400486 -p -i=0
baz() at /tmp/test.cpp:11
foo() at /tmp/test.cpp:6
```

--pretty-print, -p

Print human readable output. If `--inlining` is specified, the enclosing scope is prefixed by (inlined by).

```
$ llvm-symbolizer --obj=inlined.elf 0x4004be --inlining --pretty-print
baz() at /tmp/test.cpp:11:18
(inlined by) main at /tmp/test.cpp:15:0
```

--print-address, --addresses, -a

Print address before the source code location. Defaults to false.

```
$ llvm-symbolizer --obj=inlined.elf --print-address 0x4004be
0x4004be
baz()
/tmp/test.cpp:11:18
main
/tmp/test.cpp:15:0

$ llvm-symbolizer --obj=inlined.elf 0x4004be --pretty-print --print-address
0x4004be: baz() at /tmp/test.cpp:11:18
(inlined by) main at /tmp/test.cpp:15:0
```

--print-source-context-lines <N>

Print N lines of source context for each symbolized address.

```
$ llvm-symbolizer --obj=test.elf 0x400490 --print-source-context-lines=2
baz()
/tmp/test.cpp:11:0
10 :   volatile int k = 42;
11 >:   return foz() + k;
12 : }
```

--use-symbol-table

Prefer function names stored in symbol table to function names in debug info sections. Defaults to true.

--verbose

Print verbose line and column information.

```
$ llvm-symbolizer --obj=inlined.elf --verbose 0x4004be
baz()
  Filename: /tmp/test.cpp
Function start line: 9
  Line: 11
  Column: 18
main
  Filename: /tmp/test.cpp
Function start line: 14
  Line: 15
  Column: 0
```

--version

Print version information for the tool.

@<FILE>

Read command-line options from response file <FILE>.

MACH-O SPECIFIC OPTIONS**--default-arch <arch>**

If a binary contains object files for multiple architectures (e.g. it is a Mach-O universal binary), symbolize the object file for a given architecture. You can also specify the architecture by writing `binary_name:arch_name` in the input (see example below). If the architecture is not specified in either way, the address will not be symbolized. Defaults to empty string.

```
$ cat addr.txt
/tmp/mach_universal_binary:i386 0x1f84
/tmp/mach_universal_binary:x86_64 0x100000f24

$ llvm-symbolizer < addr.txt
__main
/tmp/source_i386.cc:8

__main
/tmp/source_x86_64.cc:8
```

--dsym-hint <path/to/file.dSYM>

If the debug info for a binary isn't present in the default location, look for the debug info at the .dSYM path provided via this option. This flag can be used multiple times.

EXIT STATUS

llvm-symbolizer returns 0. Other exit codes imply an internal program error.

llvm-addr2line(1)

llvm-dwarfdump - dump and verify DWARF debug information

SYNOPSIS

llvm-dwarfdump [*options*] [*filename ...*]

DESCRIPTION

llvm-dwarfdump parses DWARF sections in object files, archives, and *.dSYM* bundles and prints their contents in human-readable form. Only the *.debug_info* section is printed unless one of the section-specific options or *--all* is specified.

If no input file is specified, *a.out* is used instead. If *-* is used as the input file, **llvm-dwarfdump** reads the input from its standard input stream.

OPTIONS

-a, --all

Dump all supported DWARF sections.

--arch=<arch>

Dump DWARF debug information for the specified CPU architecture. Architectures may be specified by name or by number. This option can be specified multiple times, once for each desired architecture. All CPU architectures will be printed by default.

-c, --show-children

Show a debug info entry's children when selectively printing with the *=<offset>* argument of *--debug-info*, or options such as *--find* or *--name*.

--color

Use colors in output.

-f <name>, --find=<name>

Search for the exact text *<name>* in the accelerator tables and print the matching debug information entries. When there is no accelerator tables or the name of the DIE you are looking for is not found in the accelerator tables, try using the slower but more complete *--name* option.

-F, --show-form

Show DWARF form types after the DWARF attribute types.

-h, --help

Show help and usage for this command.

--help-list

Show help and usage for this command without grouping the options into categories.

- i, --ignore-case**
Ignore case distinctions when using `--name`.
- n <name>, --name=<name>**
Find and print all debug info entries whose name (`DW_AT_name` attribute) is `<name>`.
- lookup=<address>**
Look up `<address>` in the debug information and print out the file, function, block, and line table details.
- o <path>**
Redirect output to a file specified by `<path>`, where `-` is the standard output stream.
- p, --show-parents**
Show a debug info entry's parents when selectively printing with the `=<offset>` argument of `--debug-info`, or options such as `--find` or `--name`.
- parent-recurse-depth=<N>**
When displaying debug info entry parents, only show them to a maximum depth of `<N>`.
- quiet**
Use with `--verify` to not emit to `STDOUT`.
- r <N>, --recurse-depth=<N>**
When displaying debug info entries, only show children to a maximum depth of `<N>`.
- statistics**
Collect debug info quality metrics and print the results as machine-readable single-line JSON output.
- summarize-types**
Abbreviate the description of type unit entries.
- x, --regex**
Treat any `<name>` strings as regular expressions when searching with `--name`. If `--ignore-case` is also specified, the regular expression becomes case-insensitive.
- u, --uuid**
Show the UUID for each architecture.
- diff**
Dump the output in a format that is more friendly for comparing DWARF output from two different files.
- v, --verbose**
Display verbose information when dumping. This can help to debug DWARF issues.
- verify**
Verify the structure of the DWARF information by verifying the compile unit chains, DIE relationships graph, address ranges, and more.
- version**
Display the version of the tool.
- debug-abbrev, --debug-addr, --debug-aranges, --debug-cu-index, --debug-frame [=<offset>]**
Dump the specified DWARF section by name. Only the `.debug_info` section is shown by default. Some entries support adding an `=<offset>` as a way to provide an optional offset of the exact entry to dump within the respective section. When an offset is provided, only the entry at that offset will be dumped, else the entire section will be dumped.
- @<FILE>**
Read command-line options from `<FILE>`.

EXIT STATUS

llvm-dwarfdump returns 0 if the input files were parsed and dumped successfully. Otherwise, it returns 1.

SEE ALSO

dsymutil(1)

dsymutil - manipulate archived DWARF debug symbol files

SYNOPSIS

dsymutil [*options*] *executable*

DESCRIPTION

dsymutil links the DWARF debug information found in the object files for an executable *executable* by using debug symbols information contained in its symbol table. By default, the linked debug information is placed in a `.dSYM` bundle with the same name as the executable.

OPTIONS

--arch=<arch>

Link DWARF debug information only for specified CPU architecture types. Architectures may be specified by name. When using this option, an error will be returned if any architectures can not be properly linked. This option can be specified multiple times, once for each desired architecture. All CPU architectures will be linked by default and any architectures that can't be properly linked will cause **dsymutil** to return an error.

--dump-debug-map

Dump the *executable*'s debug-map (the list of the object files containing the debug information) in YAML format and exit. Not DWARF link will take place.

-f, --flat

Produce a flat dSYM file. A `.dwarf` extension will be appended to the executable name unless the output file is specified using the `-o` option.

-z, --minimize

When used when creating a dSYM file, this option will suppress the emission of the `.debug_inlines`, `.debug_pubnames`, and `.debug_pubtypes` sections since **dsymutil** currently has better equivalents: `.apple_names` and `.apple_types`. When used in conjunction with `--update` option, this option will cause redundant accelerator tables to be removed.

--no-odr

Do not use ODR (One Definition Rule) for uniquing C++ types.

--no-output

Do the link in memory, but do not emit the result file.

--no-swiftmodule-timestamp

Don't check the timestamp for swiftmodule files.

-j <n>, --num-threads=<n>

Specifies the maximum number (*n*) of simultaneous threads to use when linking multiple architectures.

- o** <filename>
Specifies an alternate `path` to place the dSYM bundle. The default dSYM bundle path is created by appending `.dSYM` to the executable name.
- oso-prepend-path**=<path>
Specifies a `path` to prepend to all debug symbol object file paths.
- papertrail**
When running `dsymutil` as part of your build system, it can be desirable for warnings to be part of the end product, rather than just being emitted to the output stream. When enabled warnings are embedded in the linked DWARF debug information.
- s, --syntab**
Dumps the symbol table found in *executable* or object file(s) and exits.
- toolchain**
Embed the toolchain in the dSYM bundle's property list.
- u, --update**
Update an existing dSYM file to contain the latest accelerator tables and other DWARF optimizations. This option will rebuild the `'apple_names'` and `'apple_types'` hashed accelerator tables.
- v, --verbose**
Display verbose information when linking.
- version**
Display the version of the tool.
- y**
Treat *executable* as a YAML debug-map rather than an executable.

EXIT STATUS

dsymutil returns 0 if the DWARF debug information was linked successfully. Otherwise, it returns 1.

llvm-mca - LLVM Machine Code Analyzer

SYNOPSIS

llvm-mca [*options*] [input]

DESCRIPTION

llvm-mca is a performance analysis tool that uses information available in LLVM (e.g. scheduling models) to statically measure the performance of machine code in a specific CPU.

Performance is measured in terms of throughput as well as processor resource consumption. The tool currently works for processors with an out-of-order backend, for which there is a scheduling model available in LLVM.

The main goal of this tool is not just to predict the performance of the code when run on the target, but also help with diagnosing potential performance issues.

Given an assembly code sequence, **llvm-mca** estimates the Instructions Per Cycle (IPC), as well as hardware resource pressure. The analysis and reporting style were inspired by the IACA tool from Intel.

For example, you can compile code with clang, output assembly, and pipe it directly into **llvm-mca** for analysis:

```
$ clang foo.c -O2 -target x86_64-unknown-unknown -S -o - | llvm-mca -mcpu=btver2
```

Or for Intel syntax:

```
$ clang foo.c -O2 -target x86_64-unknown-unknown -mllvm -x86-asm-syntax=intel -S -o - |  
↪ | llvm-mca -mcpu=btver2
```

Scheduling models are not just used to compute instruction latencies and throughput, but also to understand what processor resources are available and how to simulate them.

By design, the quality of the analysis conducted by **llvm-mca** is inevitably affected by the quality of the scheduling models in LLVM.

If you see that the performance report is not accurate for a processor, please [file a bug](#) against the appropriate backend.

OPTIONS

If input is "-" or omitted, **llvm-mca** reads from standard input. Otherwise, it will read from the specified filename.

If the `-o` option is omitted, then **llvm-mca** will send its output to standard output if the input is from standard input.

If the `-o` option specifies "-", then the output will also be sent to standard output.

-help

Print a summary of command line options.

-o <filename>

Use <filename> as the output filename. See the summary above for more details.

-mtriple=<target triple>

Specify a target triple string.

-march=<arch>

Specify the architecture for which to analyze the code. It defaults to the host default target.

-mcpu=<cpu name>

Specify the processor for which to analyze the code. By default, the cpu name is autodetected from the host.

-output-asm-variant=<variant id>

Specify the output assembly variant for the report generated by the tool. On x86, possible values are [0, 1]. A value of 0 (vic. 1) for this flag enables the AT&T (vic. Intel) assembly format for the code printed out by the tool in the analysis report.

- dispatch=<width>**
Specify a different dispatch width for the processor. The dispatch width defaults to field 'IssueWidth' in the processor scheduling model. If width is zero, then the default dispatch width is used.
- register-file-size=<size>**
Specify the size of the register file. When specified, this flag limits how many physical registers are available for register renaming purposes. A value of zero for this flag means "unlimited number of physical registers".
- iterations=<number of iterations>**
Specify the number of iterations to run. If this flag is set to 0, then the tool sets the number of iterations to a default value (i.e. 100).
- noalias=<bool>**
If set, the tool assumes that loads and stores don't alias. This is the default behavior.
- lqueue=<load queue size>**
Specify the size of the load queue in the load/store unit emulated by the tool. By default, the tool assumes an unbound number of entries in the load queue. A value of zero for this flag is ignored, and the default load queue size is used instead.
- squeue=<store queue size>**
Specify the size of the store queue in the load/store unit emulated by the tool. By default, the tool assumes an unbound number of entries in the store queue. A value of zero for this flag is ignored, and the default store queue size is used instead.
- timeline**
Enable the timeline view.
- timeline-max-iterations=<iterations>**
Limit the number of iterations to print in the timeline view. By default, the timeline view prints information for up to 10 iterations.
- timeline-max-cycles=<cycles>**
Limit the number of cycles in the timeline view. By default, the number of cycles is set to 80.
- resource-pressure**
Enable the resource pressure view. This is enabled by default.
- register-file-stats**
Enable register file usage statistics.
- dispatch-stats**
Enable extra dispatch statistics. This view collects and analyzes instruction dispatch events, as well as static/dynamic dispatch stall events. This view is disabled by default.
- scheduler-stats**
Enable extra scheduler statistics. This view collects and analyzes instruction issue events. This view is disabled by default.
- retire-stats**
Enable extra retire control unit statistics. This view is disabled by default.
- instruction-info**
Enable the instruction info view. This is enabled by default.
- all-stats**
Print all hardware statistics. This enables extra statistics related to the dispatch logic, the hardware schedulers, the register file(s), and the retire control unit. This option is disabled by default.
- all-views**
Enable all the view.

-instruction-tables

Prints resource pressure information based on the static information available from the processor model. This differs from the resource pressure view because it doesn't require that the code is simulated. It instead prints the theoretical uniform distribution of resource pressure for every instruction in sequence.

-bottleneck-analysis

Print information about bottlenecks that affect the throughput. This analysis can be expensive, and it is disabled by default. Bottlenecks are highlighted in the summary view.

EXIT STATUS

llvm-mca returns 0 on success. Otherwise, an error message is printed to standard error, and the tool returns 1.

USING MARKERS TO ANALYZE SPECIFIC CODE BLOCKS

llvm-mca allows for the optional usage of special code comments to mark regions of the assembly code to be analyzed. A comment starting with substring `LLVM-MCA-BEGIN` marks the beginning of a code region. A comment starting with substring `LLVM-MCA-END` marks the end of a code region. For example:

```
# LLVM-MCA-BEGIN
...
# LLVM-MCA-END
```

If no user-defined region is specified, then **llvm-mca** assumes a default region which contains every instruction in the input file. Every region is analyzed in isolation, and the final performance report is the union of all the reports generated for every code region.

Code regions can have names. For example:

```
# LLVM-MCA-BEGIN A simple example
add %eax, %eax
# LLVM-MCA-END
```

The code from the example above defines a region named "A simple example" with a single instruction in it. Note how the region name doesn't have to be repeated in the `LLVM-MCA-END` directive. In the absence of overlapping regions, an anonymous `LLVM-MCA-END` directive always ends the currently active user defined region.

Example of nesting regions:

```
# LLVM-MCA-BEGIN foo
add %eax, %edx
# LLVM-MCA-BEGIN bar
sub %eax, %edx
# LLVM-MCA-END bar
# LLVM-MCA-END foo
```

Example of overlapping regions:

```
# LLVM-MCA-BEGIN foo
add %eax, %edx
# LLVM-MCA-BEGIN bar
sub %eax, %edx
# LLVM-MCA-END foo
add %eax, %edx
# LLVM-MCA-END bar
```

Note that multiple anonymous regions cannot overlap. Also, overlapping regions cannot have the same name.

There is no support for marking regions from high-level source code, like C or C++. As a workaround, inline assembly directives may be used:

```
int foo(int a, int b) {
  __asm volatile("# LLVM-MCA-BEGIN foo");
  a += 42;
  __asm volatile("# LLVM-MCA-END");
  a *= b;
  return a;
}
```

However, this interferes with optimizations like loop vectorization and may have an impact on the code generated. This is because the `__asm` statements are seen as real code having important side effects, which limits how the code around them can be transformed. If users want to make use of inline assembly to emit markers, then the recommendation is to always verify that the output assembly is equivalent to the assembly generated in the absence of markers. The [Clang options to emit optimization reports](#) can also help in detecting missed optimizations.

HOW LLVM-MCA WORKS

`llvm-mca` takes assembly code as input. The assembly code is parsed into a sequence of MCInst with the help of the existing LLVM target assembly parsers. The parsed sequence of MCInst is then analyzed by a Pipeline module to generate a performance report.

The Pipeline module simulates the execution of the machine code sequence in a loop of iterations (default is 100). During this process, the pipeline collects a number of execution related statistics. At the end of this process, the pipeline generates and prints a report from the collected statistics.

Here is an example of a performance report generated by the tool for a dot-product of two packed float vectors of four elements. The analysis is conducted for target x86, cpu btver2. The following result can be produced via the following command using the example located at `test/tools/llvm-mca/X86/BtVer2/dot-product.s`:

```
$ llvm-mca -mtriple=x86_64-unknown-unknown -mcpu=btver2 -iterations=300 dot-product.s
```

```
Iterations:      300
Instructions:    900
Total Cycles:    610
Total uOps:      900
```

```
Dispatch Width:  2
uOps Per Cycle:  1.48
IPC:              1.48
Block RThroughput: 2.0
```

Instruction Info:

```

According to this report, the dot-product kernel has been executed 300 times, for a total of 900 simulated instructions. The total number of simulated micro opcodes (uOps) is also 900.

The report is structured in three main sections. The first section collects a few performance numbers; the goal of this section is to give a very quick overview of the performance throughput. Important performance indicators are **IPC**, **uOps Per Cycle**, and **Block RThroughput** (Block Reciprocal Throughput).

IPC is computed dividing the total number of simulated instructions by the total number of cycles. In the absence of loop-carried data dependencies, the observed IPC tends to a theoretical maximum which can be computed by dividing the number of instructions of a single iteration by the *Block RThroughput*.

Field 'uOps Per Cycle' is computed dividing the total number of simulated micro opcodes by the total number of cycles. A delta between Dispatch Width and this field is an indicator of a performance issue. In the absence of loop-carried data dependencies, the observed 'uOps Per Cycle' should tend to a theoretical maximum throughput which can be computed by dividing the number of uOps of a single iteration by the *Block RThroughput*.

Field *uOps Per Cycle* is bounded from above by the dispatch width. That is because the dispatch width limits the maximum size of a dispatch group. Both IPC and 'uOps Per Cycle' are limited by the amount of hardware parallelism. The availability of hardware resources affects the resource pressure distribution, and it limits the number of instructions that can be executed in parallel every cycle. A delta between Dispatch Width and the theoretical maximum uOps per Cycle (computed by dividing the number of uOps of a single iteration by the *Block RThroughput*) is an indicator of a

performance bottleneck caused by the lack of hardware resources. In general, the lower the Block RThroughput, the better.

In this example, `uOps per iteration/Block RThroughput` is 1.50. Since there are no loop-carried dependencies, the observed *uOps Per Cycle* is expected to approach 1.50 when the number of iterations tends to infinity. The delta between the Dispatch Width (2.00), and the theoretical maximum uOp throughput (1.50) is an indicator of a performance bottleneck caused by the lack of hardware resources, and the *Resource pressure view* can help to identify the problematic resource usage.

The second section of the report shows the latency and reciprocal throughput of every instruction in the sequence. That section also reports extra information related to the number of micro opcodes, and opcode properties (i.e., 'MayLoad', 'MayStore', and 'HasSideEffects').

The third section is the *Resource pressure view*. This view reports the average number of resource cycles consumed every iteration by instructions for every processor resource unit available on the target. Information is structured in two tables. The first table reports the number of resource cycles spent on average every iteration. The second table correlates the resource cycles to the machine instruction in the sequence. For example, every iteration of the instruction `vmulps` always executes on resource unit [6] (JFPU1 - floating point pipeline #1), consuming an average of 1 resource cycle per iteration. Note that on AMD Jaguar, vector floating-point multiply can only be issued to pipeline JFPU1, while horizontal floating-point additions can only be issued to pipeline JFPU0.

The resource pressure view helps with identifying bottlenecks caused by high usage of specific hardware resources. Situations with resource pressure mainly concentrated on a few resources should, in general, be avoided. Ideally, pressure should be uniformly distributed between multiple resources.

Timeline View

The timeline view produces a detailed report of each instruction's state transitions through an instruction pipeline. This view is enabled by the command line option `-timeline`. As instructions transition through the various stages of the pipeline, their states are depicted in the view report. These states are represented by the following characters:

- D : Instruction dispatched.
- e : Instruction executing.
- E : Instruction executed.
- R : Instruction retired.
- = : Instruction already dispatched, waiting to be executed.
- - : Instruction executed, waiting to be retired.

Below is the timeline view for a subset of the dot-product example located in `test/tools/llvm-mca/X86/BtVer2/dot-product.s` and processed by **llvm-mca** using the following command:

```
$ llvm-mca -mtriple=x86_64-unknown-unknown -mcpu=btver2 -iterations=3 -timeline dot-
↳ product.s
```

```
Timeline view:
                                012345
Index      0123456789
[0,0]      DeeER.      .      .      vmulps    %xmm0, %xmm1, %xmm2

Average Wait times (based on the timeline view):

[0]: Executions

[1]: Average time spent waiting in a scheduler's queue

[2]: Average time spent waiting in a scheduler's queue while ready

[3]: Average time elapsed from WB until retire stage

	[0]	[1]	[2]	[3]	
0.	3	1.0	1.0	3.3	vmulps %xmm0, %xmm1, %xmm2
1.	3	3.3	0.7	1.0	vhaddps %xmm2, %xmm2, %xmm3
2.	3	5.7	0.0	0.0	vhaddps %xmm3, %xmm3, %xmm4

The timeline view is interesting because it shows instruction state changes during execution. It also gives an idea of how the tool processes instructions executed on the target, and how their timing information might be calculated.

The timeline view is structured in two tables. The first table shows instructions changing state over time (measured in cycles); the second table (named *Average Wait times*) reports useful timing statistics, which should help diagnose performance bottlenecks caused by long data dependencies and sub-optimal usage of hardware resources.

An instruction in the timeline view is identified by a pair of indices, where the first index identifies an iteration, and the second index is the instruction index (i.e., where it appears in the code sequence). Since this example was generated using 3 iterations: `-iterations=3`, the iteration indices range from 0-2 inclusively.

Excluding the first and last column, the remaining columns are in cycles. Cycles are numbered sequentially starting from 0.

From the example output above, we know the following:

- Instruction [1,0] was dispatched at cycle 1.
- Instruction [1,0] started executing at cycle 2.
- Instruction [1,0] reached the write back stage at cycle 4.
- Instruction [1,0] was retired at cycle 10.

Instruction [1,0] (i.e., `vmulps` from iteration #1) does not have to wait in the scheduler's queue for the operands to become available. By the time `vmulps` is dispatched, operands are already available, and pipeline JFPU1 is ready to serve another instruction. So the instruction can be immediately issued on the JFPU1 pipeline. That is demonstrated by the fact that the instruction only spent 1cy in the scheduler's queue.

There is a gap of 5 cycles between the write-back stage and the retire event. That is because instructions must retire in program order, so [1,0] has to wait for [0,2] to be retired first (i.e., it has to wait until cycle 10).

In the example, all instructions are in a RAW (Read After Write) dependency chain. Register `%xmm2` written by `vmulps` is immediately used by the first `vhaddps`, and register `%xmm3` written by the first `vhaddps` is used by the second `vhaddps`. Long data dependencies negatively impact the ILP (Instruction Level Parallelism).

In the dot-product example, there are anti-dependencies introduced by instructions from different iterations. However, those dependencies can be removed at register renaming stage (at the cost of allocating register aliases, and therefore consuming physical registers).

Table *Average Wait times* helps diagnose performance issues that are caused by the presence of long latency instructions and potentially long data dependencies which may limit the ILP. Note that `llvm-mca`, by default, assumes at least 1cy between the dispatch event and the issue event.

When the performance is limited by data dependencies and/or long latency instructions, the number of cycles spent while in the *ready* state is expected to be very small when compared with the total number of cycles spent in the scheduler's queue. The difference between the two counters is a good indicator of how large of an impact data dependencies had on the execution of the instructions. When performance is mostly limited by the lack of hardware resources, the delta between the two counters is small. However, the number of cycles spent in the queue tends to be larger (i.e., more than 1-3cy), especially when compared to other low latency instructions.

Extra Statistics to Further Diagnose Performance Issues

The `-all-stats` command line option enables extra statistics and performance counters for the dispatch logic, the reorder buffer, the retire control unit, and the register file.

Below is an example of `-all-stats` output generated by `llvm-mca` for 300 iterations of the dot-product example discussed in the previous sections.

```
Dynamic Dispatch Stall Cycles:
RAT      - Register unavailable:          0
RCU      - Retire tokens unavailable:      0
SCHEDQ   - Scheduler full:                272   (44.6%)
LQ       - Load queue full:              0
SQ       - Store queue full:              0
GROUP    - Static restrictions on the dispatch group: 0

Dispatch Logic - number of cycles where we saw N micro opcodes dispatched:
[# dispatched], [# cycles]
0,          24   (3.9%)
1,          272  (44.6%)
2,          314  (51.5%)

Schedulers - number of cycles where we saw N micro opcodes issued:
[# issued], [# cycles]
0,           7   (1.1%)
1,          306  (50.2%)
2,          297  (48.7%)

Scheduler's queue usage:
[1] Resource name.
[2] Average number of used buffer entries.
[3] Maximum number of used buffer entries.
[4] Total number of buffer entries.

   [1]          [2]          [3]          [4]
JALU01          0           0           20
JFPU01          17          18           18
JLSAGU          0           0           12

Retire Control Unit - number of cycles where we saw N instructions retired:
[# retired], [# cycles]
0,          109  (17.9%)
1,          102  (16.7%)
2,          399  (65.4%)

Total ROB Entries:          64
```

(continues on next page)

(continued from previous page)

```

Max Used ROB Entries:          35  ( 54.7% )
Average Used ROB Entries per cy: 32  ( 50.0% )

Register File statistics:
Total number of mappings created: 900
Max number of mappings used:    35

* Register File #1 -- JFpuPRF:
  Number of physical registers: 72
  Total number of mappings created: 900
  Max number of mappings used: 35

* Register File #2 -- JIntegerPRF:
  Number of physical registers: 64
  Total number of mappings created: 0
  Max number of mappings used: 0

```

If we look at the *Dynamic Dispatch Stall Cycles* table, we see the counter for SCHEDQ reports 272 cycles. This counter is incremented every time the dispatch logic is unable to dispatch a full group because the scheduler's queue is full.

Looking at the *Dispatch Logic* table, we see that the pipeline was only able to dispatch two micro opcodes 51.5% of the time. The dispatch group was limited to one micro opcode 44.6% of the cycles, which corresponds to 272 cycles. The dispatch statistics are displayed by either using the command option `-all-stats` or `-dispatch-stats`.

The next table, *Schedulers*, presents a histogram displaying a count, representing the number of micro opcodes issued on some number of cycles. In this case, of the 610 simulated cycles, single opcodes were issued 306 times (50.2%) and there were 7 cycles where no opcodes were issued.

The *Scheduler's queue usage* table shows that the average and maximum number of buffer entries (i.e., scheduler queue entries) used at runtime. Resource JFPU01 reached its maximum (18 of 18 queue entries). Note that AMD Jaguar implements three schedulers:

- JALU01 - A scheduler for ALU instructions.
- JFPU01 - A scheduler floating point operations.
- JLSAGU - A scheduler for address generation.

The dot-product is a kernel of three floating point instructions (a vector multiply followed by two horizontal adds). That explains why only the floating point scheduler appears to be used.

A full scheduler queue is either caused by data dependency chains or by a sub-optimal usage of hardware resources. Sometimes, resource pressure can be mitigated by rewriting the kernel using different instructions that consume different scheduler resources. Schedulers with a small queue are less resilient to bottlenecks caused by the presence of long data dependencies. The scheduler statistics are displayed by using the command option `-all-stats` or `-scheduler-stats`.

The next table, *Retire Control Unit*, presents a histogram displaying a count, representing the number of instructions retired on some number of cycles. In this case, of the 610 simulated cycles, two instructions were retired during the same cycle 399 times (65.4%) and there were 109 cycles where no instructions were retired. The retire statistics are displayed by using the command option `-all-stats` or `-retire-stats`.

The last table presented is *Register File statistics*. Each physical register file (PRF) used by the pipeline is presented in this table. In the case of AMD Jaguar, there are two register files, one for floating-point registers (JFpuPRF) and one for integer registers (JIntegerPRF). The table shows that of the 900 instructions processed, there were 900 mappings created. Since this dot-product example utilized only floating point registers, the JFpuPRF was responsible for creating the 900 mappings. However, we see that the pipeline only used a maximum of 35 of 72 available register slots at any

given time. We can conclude that the floating point PRF was the only register file used for the example, and that it was never resource constrained. The register file statistics are displayed by using the command option `-all-stats` or `-register-file-stats`.

In this example, we can conclude that the IPC is mostly limited by data dependencies, and not by resource pressure.

Instruction Flow

This section describes the instruction flow through the default pipeline of **llvm-mca**, as well as the functional units involved in the process.

The default pipeline implements the following sequence of stages used to process instructions.

- Dispatch (Instruction is dispatched to the schedulers).
- Issue (Instruction is issued to the processor pipelines).
- Write Back (Instruction is executed, and results are written back).
- Retire (Instruction is retired; writes are architecturally committed).

The default pipeline only models the out-of-order portion of a processor. Therefore, the instruction fetch and decode stages are not modeled. Performance bottlenecks in the frontend are not diagnosed. **llvm-mca** assumes that instructions have all been decoded and placed into a queue before the simulation start. Also, **llvm-mca** does not model branch prediction.

Instruction Dispatch

During the dispatch stage, instructions are picked in program order from a queue of already decoded instructions, and dispatched in groups to the simulated hardware schedulers.

The size of a dispatch group depends on the availability of the simulated hardware resources. The processor dispatch width defaults to the value of the `IssueWidth` in LLVM's scheduling model.

An instruction can be dispatched if:

- The size of the dispatch group is smaller than processor's dispatch width.
- There are enough entries in the reorder buffer.
- There are enough physical registers to do register renaming.
- The schedulers are not full.

Scheduling models can optionally specify which register files are available on the processor. **llvm-mca** uses that information to initialize register file descriptors. Users can limit the number of physical registers that are globally available for register renaming by using the command option `-register-file-size`. A value of zero for this option means *unbounded*. By knowing how many registers are available for renaming, the tool can predict dispatch stalls caused by the lack of physical registers.

The number of reorder buffer entries consumed by an instruction depends on the number of micro-opcodes specified for that instruction by the target scheduling model. The reorder buffer is responsible for tracking the progress of instructions that are "in-flight", and retiring them in program order. The number of entries in the reorder buffer defaults to the value specified by field `MicroOpBufferSize` in the target scheduling model.

Instructions that are dispatched to the schedulers consume scheduler buffer entries. **llvm-mca** queries the scheduling model to determine the set of buffered resources consumed by an instruction. Buffered resources are treated like scheduler resources.

Instruction Issue

Each processor scheduler implements a buffer of instructions. An instruction has to wait in the scheduler's buffer until input register operands become available. Only at that point, does the instruction becomes eligible for execution and may be issued (potentially out-of-order) for execution. Instruction latencies are computed by **llvm-mca** with the help of the scheduling model.

llvm-mca's scheduler is designed to simulate multiple processor schedulers. The scheduler is responsible for tracking data dependencies, and dynamically selecting which processor resources are consumed by instructions. It delegates the management of processor resource units and resource groups to a resource manager. The resource manager is responsible for selecting resource units that are consumed by instructions. For example, if an instruction consumes 1cy of a resource group, the resource manager selects one of the available units from the group; by default, the resource manager uses a round-robin selector to guarantee that resource usage is uniformly distributed between all units of a group.

llvm-mca's scheduler internally groups instructions into three sets:

- WaitSet: a set of instructions whose operands are not ready.
- ReadySet: a set of instructions ready to execute.
- IssuedSet: a set of instructions executing.

Depending on the operands availability, instructions that are dispatched to the scheduler are either placed into the WaitSet or into the ReadySet.

Every cycle, the scheduler checks if instructions can be moved from the WaitSet to the ReadySet, and if instructions from the ReadySet can be issued to the underlying pipelines. The algorithm prioritizes older instructions over younger instructions.

Write-Back and Retire Stage

Issued instructions are moved from the ReadySet to the IssuedSet. There, instructions wait until they reach the write-back stage. At that point, they get removed from the queue and the retire control unit is notified.

When instructions are executed, the retire control unit flags the instruction as "ready to retire."

Instructions are retired in program order. The register file is notified of the retirement so that it can free the physical registers that were allocated for the instruction during the register renaming stage.

Load/Store Unit and Memory Consistency Model

To simulate an out-of-order execution of memory operations, **llvm-mca** utilizes a simulated load/store unit (LSUnit) to simulate the speculative execution of loads and stores.

Each load (or store) consumes an entry in the load (or store) queue. Users can specify flags `-lqueue` and `-squeue` to limit the number of entries in the load and store queues respectively. The queues are unbounded by default.

The LSUnit implements a relaxed consistency model for memory loads and stores. The rules are:

1. A younger load is allowed to pass an older load only if there are no intervening stores or barriers between the two loads.
2. A younger load is allowed to pass an older store provided that the load does not alias with the store.
3. A younger store is not allowed to pass an older store.
4. A younger store is not allowed to pass an older load.

By default, the LSUnit optimistically assumes that loads do not alias (*-noalias=true*) store operations. Under this assumption, younger loads are always allowed to pass older stores. Essentially, the LSUnit does not attempt to run any alias analysis to predict when loads and stores do not alias with each other.

Note that, in the case of write-combining memory, rule 3 could be relaxed to allow reordering of non-aliasing store operations. That being said, at the moment, there is no way to further relax the memory model (*-noalias* is the only option). Essentially, there is no option to specify a different memory type (e.g., write-back, write-combining, write-through; etc.) and consequently to weaken, or strengthen, the memory model.

Other limitations are:

- The LSUnit does not know when store-to-load forwarding may occur.
- The LSUnit does not know anything about cache hierarchy and memory types.
- The LSUnit does not know how to identify serializing operations and memory fences.

The LSUnit does not attempt to predict if a load or store hits or misses the L1 cache. It only knows if an instruction "MayLoad" and/or "MayStore." For loads, the scheduling model provides an "optimistic" load-to-use latency (which usually matches the load-to-use latency for when there is a hit in the L1D).

llvm-mca does not know about serializing operations or memory-barrier like instructions. The LSUnit conservatively assumes that an instruction which has both "MayLoad" and unmodeled side effects behaves like a "soft" load-barrier. That means, it serializes loads without forcing a flush of the load queue. Similarly, instructions that "MayStore" and have unmodeled side effects are treated like store barriers. A full memory barrier is a "MayLoad" and "MayStore" instruction with unmodeled side effects. This is inaccurate, but it is the best that we can do at the moment with the current information available in LLVM.

A load/store barrier consumes one entry of the load/store queue. A load/store barrier enforces ordering of loads/stores. A younger load cannot pass a load barrier. Also, a younger store cannot pass a store barrier. A younger load has to wait for the memory/load barrier to execute. A load/store barrier is "executed" when it becomes the oldest entry in the load/store queue(s). That also means, by construction, all of the older loads/stores have been executed.

In conclusion, the full set of load/store consistency rules are:

1. A store may not pass a previous store.
2. A store may not pass a previous load (regardless of *-noalias*).
3. A store has to wait until an older store barrier is fully executed.
4. A load may pass a previous load.
5. A load may not pass a previous store unless *-noalias* is set.
6. A load has to wait until an older load barrier is fully executed.

llvm-readobj - LLVM Object Reader

SYNOPSIS

```
llvm-readobj [options] [input...]
```

DESCRIPTION

The **llvm-readobj** tool displays low-level format-specific information about one or more object files.

If input is "-" or omitted, **llvm-readobj** reads from standard input. Otherwise, it will read from the specified filenames.

DIFFERENCES TO LLVM-READELF

llvm-readelf is an alias for the *llvm-readobj* tool with a slightly different command-line interface and output that is GNU compatible. Following is a list of differences between **llvm-readelf** and **llvm-readobj**:

- **llvm-readelf** uses *GNU* for the *--elf-output-style* option by default. **llvm-readobj** uses *LLVM*.
- **llvm-readelf** allows single-letter grouped flags (e.g. *llvm-readelf -SW* is the same as *llvm-readelf -S -W*). **llvm-readobj** does not allow grouping.
- **llvm-readelf** provides *-s* as an alias for *--symbols*, for GNU **readelf** compatibility, whereas it is an alias for *--section-headers* in **llvm-readobj**.
- **llvm-readobj** provides *-t* as an alias for *--symbols*. **llvm-readelf** does not.
- **llvm-readobj** provides *--sr*, *--sd*, *--st* and *--dt* as aliases for *--section-relocations*, *--section-data*, *--section-symbols* and *--dyn-symbols* respectively. **llvm-readelf** does not provide these aliases, to avoid conflicting with grouped flags.

GENERAL AND MULTI-FORMAT OPTIONS

These options are applicable to more than one file format, or are unrelated to file formats.

--all

Equivalent to specifying all the main display options relevant to the file format.

--addrsig

Display the address-significance table.

--color

Use colors in the output for warnings and errors.

--expand-relocs

When used with *--relocations*, display each relocation in an expanded multi-line format.

--file-headers, -h

Display file headers.

--headers, -e

Equivalent to setting: *--file-headers*, *--program-headers*, and *--sections*.

--help

Display a summary of command line options.

--help-list

Display an uncategorized summary of command line options.

--hex-dump=<section[, section, ...]>, -x

Display the specified section(s) as hexadecimal bytes. *section* may be a section index or section name.

--needed-libs

Display the needed libraries.

--relocations, --relocs, -r
 Display the relocation entries in the file.

--sections, --section-headers, -s, -S
 Display all sections.

--section-data, --sd
 When used with `--sections`, display section data for each section shown. This option has no effect for GNU style output.

--section-relocations, --sr
 When used with `--sections`, display relocations for each section shown. This option has no effect for GNU style output.

--section-symbols, --st
 When used with `--sections`, display symbols for each section shown. This option has no effect for GNU style output.

--stackmap
 Display contents of the stackmap section.

--string-dump=<section[, section, ...]>, -p
 Display the specified section(s) as a list of strings. `section` may be a section index or section name.

--symbols, --syms, -t
 Display the symbol table.

--unwind, -u
 Display unwind information.

--version
 Display the version of this program.

@<FILE>
 Read command-line options from response file `<FILE>`.

ELF SPECIFIC OPTIONS

The following options are implemented only for the ELF file format.

--arm-attributes
 Display the ARM attributes section. Only applicable for ARM architectures.

--demangle, -C
 Display demangled symbol names in the output.

--dyn-relocations
 Display the dynamic relocation entries.

--dyn-symbols, --dyn-syms, --dt
 Display the dynamic symbol table.

--dynamic-table, --dynamic, -d
 Display the dynamic table.

--elf-cg-profile
 Display the callgraph profile section.

--elf-hash-histogram, --histogram, -I
 Display a bucket list histogram for dynamic symbol hash tables.

--elf-linker-options

Display the linker options section.

--elf-output-style=<value>

Format ELF information in the specified style. Valid options are LLVM and GNU. LLVM output (the default) is an expanded and structured format, whilst GNU output mimics the equivalent GNU **readelf** output.

--elf-section-groups, --section-groups, -g

Display section groups.

--gnu-hash-table

Display the GNU hash table for dynamic symbols.

--hash-symbols

Display the expanded hash table with dynamic symbol data.

--hash-table

Display the hash table for dynamic symbols.

--notes, -n

Display all notes.

--program-headers, --segments, -l

Display the program headers.

--raw-relr

Do not decode relocations in RELR relocation sections when displaying them.

--section-mapping

Display the section to segment mapping.

--version-info, -V

Display version sections.

MACH-O SPECIFIC OPTIONS

The following options are implemented only for the Mach-O file format.

--macho-data-in-code

Display the Data in Code command.

--macho-dsymtab

Display the Dsymtab command.

--macho-indirect-symbols

Display indirect symbols.

--macho-linker-options

Display the Mach-O-specific linker options.

--macho-segment

Display the Segment command.

--macho-version-min

Display the version min command.

PE/COFF SPECIFIC OPTIONS

The following options are implemented only for the PE/COFF file format.

- codeview**
Display CodeView debug information.
- codeview-ghash**
Enable global hashing for CodeView type stream de-duplication.
- codeview-merged-types**
Display the merged CodeView type stream.
- codeview-subsection-bytes**
Dump raw contents of CodeView debug sections and records.
- coff-basereloc**
Display the .reloc section.
- coff-debug-directory**
Display the debug directory.
- coff-directives**
Display the .directve section.
- coff-exports**
Display the export table.
- coff-imports**
Display the import table.
- coff-load-config**
Display the load config.
- coff-resources**
Display the .rsrc section.

EXIT STATUS

llvm-readobj returns 0 under normal operation. It returns a non-zero exit code if there were any errors.

2.8.2 GNU binutils replacements

llvm-addr2line - a drop-in replacement for **addr2line**

SYNOPSIS

llvm-addr2line [*options*]

DESCRIPTION

llvm-addr2line is an alias for the **llvm-symbolizer** tool with different defaults. The goal is to make it a drop-in replacement for GNU's **addr2line**.

Here are some of those differences:

- Defaults not to print function names. Use *-f* to enable that.
- Defaults not to demangle function names. Use *-C* to switch the demangling on.
- Defaults not to print inlined frames. Use *-i* to show inlined frames for a source code location in an inlined function.
- Uses *--output-style=GNU* by default.

SEE ALSO

Refer to **llvm-symbolizer** for additional information.

llvm-ar - LLVM archiver

SYNOPSIS

llvm-ar [-]{dmpqrtx}[Rabfikou] [relpos] [count] <archive> [files...]

DESCRIPTION

The **llvm-ar** command is similar to the common Unix utility, **ar**. It archives several files together into a single file. The intent for this is to produce archive libraries by LLVM bitcode that can be linked into an LLVM program. However, the archive can contain any kind of file. By default, **llvm-ar** generates a symbol table that makes linking faster because only the symbol table needs to be consulted, not each individual file member of the archive.

The **llvm-ar** command can be used to *read* SVR4, GNU and BSD style archive files. However, right now it can only write in the GNU format. If an SVR4 or BSD style archive is used with the *r* (replace) or *q* (quick update) operations, the archive will be reconstructed in GNU format.

Here's where **llvm-ar** departs from previous **ar** implementations:

Symbol Table

Since **llvm-ar** supports bitcode files. The symbol table it creates is in GNU format and includes both native and bitcode files.

Long Paths

Currently **llvm-ar** can read GNU and BSD long file names, but only writes archives with the GNU format.

OPTIONS

The options to **llvm-ar** are compatible with other **ar** implementations. However, there are a few modifiers (*R*) that are not found in other **ar** implementations. The options to **llvm-ar** specify a single basic operation to perform on the archive, a variety of modifiers for that operation, the name of the archive file, and an optional list of file names. These options are used to determine how **llvm-ar** should process the archive file.

The Operations and Modifiers are explained in the sections below. The minimal set of options is at least one operator and the name of the archive. Typically archive files end with a `.a` suffix, but this is not required. Following the *archive-name* comes a list of *files* that indicate the specific members of the archive to operate on. If the *files* option is not specified, it generally means either "none" or "all" members, depending on the operation.

Operations

d

Delete files from the archive. No modifiers are applicable to this operation. The *files* options specify which members should be removed from the archive. It is not an error if a specified file does not appear in the archive. If no *files* are specified, the archive is not modified.

m[abi]

Move files from one location in the archive to another. The *a*, *b*, and *i* modifiers apply to this operation. The *files* will all be moved to the location given by the modifiers. If no modifiers are used, the files will be moved to the end of the archive. If no *files* are specified, the archive is not modified.

p

Print files to the standard output. This operation simply prints the *files* indicated to the standard output. If no *files* are specified, the entire archive is printed. Printing bitcode files is ill-advised as they might confuse your terminal settings. The *p* operation never modifies the archive.

q

Quickly append files to the end of the archive. This operation quickly adds the *files* to the archive without checking for duplicates that should be removed first. If no *files* are specified, the archive is not modified. Because of the way that **llvm-ar** constructs the archive file, its dubious whether the *q* operation is any faster than the *r* operation.

r[abu]

Replace or insert file members. The *a*, *b*, and *u* modifiers apply to this operation. This operation will replace existing *files* or insert them at the end of the archive if they do not exist. If no *files* are specified, the archive is not modified.

t[v]

Print the table of contents. Without any modifiers, this operation just prints the names of the members to the standard output. With the *v* modifier, **llvm-ar** also prints out the file type (B=bitcode, S=symbol table, blank=regular file), the permission mode, the owner and group, the size, and the date. If any *files* are specified, the listing is only for those files. If no *files* are specified, the table of contents for the whole archive is printed.

x[oP]

Extract archive members back to files. The *o* modifier applies to this operation. This operation retrieves the indicated *files* from the archive and writes them back to the operating system's file system. If no *files* are specified, the entire archive is extract.

Modifiers (operation specific)

The modifiers below are specific to certain operations. See the Operations section (above) to determine which modifiers are applicable to which operations.

[a]

When inserting or moving member files, this option specifies the destination of the new files as being after the *relopos* member. If *relopos* is not found, the files are placed at the end of the archive.

[b]

When inserting or moving member files, this option specifies the destination of the new files as being before the *relopos* member. If *relopos* is not found, the files are placed at the end of the archive. This modifier is identical to the *i* modifier.

[i]

A synonym for the *b* option.

[o]

When extracting files, this option will cause **llvm-ar** to preserve the original modification times of the files it writes.

[u]

When replacing existing files in the archive, only replace those files that have a time stamp than the time stamp of the member in the archive.

Modifiers (generic)

The modifiers below may be applied to any operation.

[c]

For all operations, **llvm-ar** will always create the archive if it doesn't exist. Normally, **llvm-ar** will print a warning message indicating that the archive is being created. Using this modifier turns off that warning.

[s]

This modifier requests that an archive index (or symbol table) be added to the archive. This is the default mode of operation. The symbol table will contain all the externally visible functions and global variables defined by all the bitcode files in the archive.

[S]

This modifier is the opposite of the *s* modifier. It instructs **llvm-ar** to not build the symbol table. If both *s* and *S* are used, the last modifier to occur in the options will prevail.

[v]

This modifier instructs **llvm-ar** to be verbose about what it is doing. Each editing operation taken against the archive will produce a line of output saying what is being done.

STANDARDS

The **llvm-ar** utility is intended to provide a superset of the IEEE Std 1003.2 (POSIX.2) functionality for **ar**. **llvm-ar** can read both SVR4 and BSD4.4 (or macOS) archives. If the **f** modifier is given to the **x** or **r** operations then **llvm-ar** will write SVR4 compatible archives. Without this modifier, **llvm-ar** will write BSD4.4 compatible archives that have long names immediately after the header and indicated using the "#1/ddd" notation for the name in the header.

FILE FORMAT

The file format for LLVM Archive files is similar to that of BSD 4.4 or macOS archive files. In fact, except for the symbol table, the **ar** commands on those operating systems should be able to read LLVM archive files. The details of the file format follow.

Each archive begins with the archive magic number which is the eight printable characters "**!<arch>n**" where **n** represents the newline character (0x0A). Following the magic number, the file is composed of even length members that begin with an archive header and end with a **n** padding character if necessary (to make the length even). Each file member is composed of a header (defined below), an optional newline-terminated "long file name" and the contents of the file.

The fields of the header are described in the items below. All fields of the header contain only ASCII characters, are left justified and are right padded with space characters.

name - char[16]

This field of the header provides the name of the archive member. If the name is longer than 15 characters or contains a slash (/) character, then this field contains #1/nnn where nnn provides the length of the name and the #1/ is literal. In this case, the actual name of the file is provided in the nnn bytes immediately following the header. If the name is 15 characters or less, it is contained directly in this field and terminated with a slash (/) character.

date - char[12]

This field provides the date of modification of the file in the form of a decimal encoded number that provides the number of seconds since the epoch (since 00:00:00 Jan 1, 1970) per Posix specifications.

uid - char[6]

This field provides the user id of the file encoded as a decimal ASCII string. This field might not make much sense on non-Unix systems. On Unix, it is the same value as the st_uid field of the stat structure returned by the stat(2) operating system call.

gid - char[6]

This field provides the group id of the file encoded as a decimal ASCII string. This field might not make much sense on non-Unix systems. On Unix, it is the same value as the st_gid field of the stat structure returned by the stat(2) operating system call.

mode - char[8]

This field provides the access mode of the file encoded as an octal ASCII string. This field might not make much sense on non-Unix systems. On Unix, it is the same value as the st_mode field of the stat structure returned by the stat(2) operating system call.

size - char[10]

This field provides the size of the file, in bytes, encoded as a decimal ASCII string.

fmag - char[2]

This field is the archive file member magic number. Its content is always the two characters back tick (0x60) and newline (0x0A). This provides some measure utility in identifying archive files that have been corrupted.

offset - vbr encoded 32-bit integer

The offset item provides the offset into the archive file where the bitcode member is stored that is associated with the symbol. The offset value is 0 based at the start of the first "normal" file member. To derive the actual file offset of the member, you must add the number of bytes occupied by the file signature (8 bytes) and the symbol tables. The value of this item is encoded using variable bit rate encoding to reduce the size of the symbol table. Variable bit rate encoding uses the high bit (0x80) of each byte to indicate if there are more bytes to follow. The remaining 7 bits in each byte carry bits from the value. The final byte does not have the high bit set.

length - vbr encoded 32-bit integer

The length item provides the length of the symbol that follows. Like this *offset* item, the length is variable bit rate encoded.

symbol - character array

The symbol item provides the text of the symbol that is associated with the *offset*. The symbol is not terminated by any character. Its length is provided by the *length* field. Note that is allowed (but unwise) to use non-printing characters (even 0x00) in the symbol. This allows for multiple encodings of symbol names.

EXIT STATUS

If **llvm-ar** succeeds, it will exit with 0. A usage error, results in an exit code of 1. A hard (file system typically) error results in an exit code of 2. Miscellaneous or unknown errors result in an exit code of 3.

llvm-cxxfilt - LLVM symbol name demangler

SYNOPSIS

```
llvm-cxxfilt [options] [mangled names...]
```

DESCRIPTION

llvm-cxxfilt is a symbol demangler that can be used as a replacement for the GNU **c++filt** tool. It takes a series of symbol names and prints their demangled form on the standard output stream. If a name cannot be demangled, it is simply printed as is.

If no names are specified on the command-line, names are read interactively from the standard input stream. When reading names from standard input, each input line is split on characters that are not part of valid Itanium name manglings, i.e. characters that are not alphanumeric, '.', '\$', or '_'. Separators between names are copied to the output as is.

EXAMPLE

```
$ llvm-cxxfilt _Z3foov _Z3bari not_mangled
foo()
bar(int)
not_mangled
$ cat input.txt
| _Z3foov *** _Z3bari *** not_mangled |
$ llvm-cxxfilt < input.txt
| foo() *** bar(int) *** not_mangled |
```

OPTIONS

--format=<value>, -s

Mangling scheme to assume. Valid values are `auto` (default, auto-detect the style) and `gnu` (assume GNU/Itanium style).

--help, -h

Print a summary of command line options.

--help-list

Print an uncategorized summary of command line options.

--strip-underscore, -_

Discard a single leading underscore, if present, from each input name before demangling.

--types, -t

Attempt to demangle names as type names as well as function names.

--version

Display the version of this program.

@<FILE>

Read command-line options from response file *<FILE>*.

EXIT STATUS

llvm-cxxfilt returns 0 unless it encounters a usage error, in which case a non-zero exit code is returned.

SEE ALSO

llvm-nm(1)

llvm-nm - list LLVM bitcode and object file's symbol table

SYNOPSIS

llvm-nm [*options*] [*filenames...*]

DESCRIPTION

The **llvm-nm** utility lists the names of symbols from LLVM bitcode files, object files, and archives. Each symbol is listed along with some simple information about its provenance. If no filename is specified, *a.out* is used as the input. If **-** is used as a filename, **llvm-nm** will read a file from its standard input stream.

llvm-nm's default output format is the traditional BSD **nm** output format. Each such output record consists of an (optional) 8-digit hexadecimal address, followed by a type code character, followed by a name, for each symbol. One record is printed per line; fields are separated by spaces. When the address is omitted, it is replaced by 8 spaces.

The supported type code characters are as follows. Where both lower and upper-case characters are listed for the same meaning, a lower-case character represents a local symbol, whilst an upper-case character represents a global (external) symbol:

a, A

Absolute symbol.

b, B

Uninitialized data (bss) object.

C

Common symbol. Multiple definitions link together into one definition.

d, D

Writable data object.

i, I

COFF: .idata symbol or symbol in a section with IMAGE_SCN_LNK_INFO set.

n

ELF: local symbol from non-alloc section.

COFF: debug symbol.

N

ELF: debug section symbol, or global symbol from non-alloc section.

s, S

COFF: section symbol.

Mach-O: absolute symbol or symbol from a section other than `__TEXT_EXEC __text`, `__TEXT __text`, `__DATA __data`, or `__DATA __bss`.

r, R

Read-only data object.

t, T

Code (text) object.

u

ELF: GNU unique symbol.

U

Named object is undefined in this file.

v

ELF: Undefined weak object. It is not a link failure if the object is not defined.

V

ELF: Defined weak object symbol. This definition will only be used if no regular definitions exist in a link. If multiple weak definitions and no regular definitions exist, one of the weak definitions will be used.

w

Undefined weak symbol other than an ELF object symbol. It is not a link failure if the symbol is not defined.

W

Defined weak symbol other than an ELF object symbol. This definition will only be used if no regular definitions exist in a link. If multiple weak definitions and no regular definitions exist, one of the weak definitions will be used.

-

Mach-O: N_STAB symbol.

?

Something unrecognizable.

Because LLVM bitcode files typically contain objects that are not considered to have addresses until they are linked into an executable image or dynamically compiled "just-in-time", **llvm-nm** does not print an address for any symbol in an LLVM bitcode file, even symbols which are defined in the bitcode file.

OPTIONS

-B

Use BSD output format. Alias for `--format=bsd`.

--debug-syms, -a

Show all symbols, even those usually suppressed.

--defined-only, -U

Print only symbols defined in this file.

--demangle, -C

Demangle symbol names.

--dynamic, -D

Display dynamic symbols instead of normal symbols.

--extern-only, -g

Print only symbols whose definitions are external; that is, accessible from other files.

--format=<format>, -f

Select an output format; *format* may be *sysv*, *posix*, *darwin*, or *bsd*. The default is *bsd*.

--help, -h

Print a summary of command-line options and their meanings.

--help-list

Print an uncategorized summary of command-line options and their meanings.

--just-symbol-name, -j

Print just the symbol names.

- m**
Use Darwin format. Alias for `--format=darwin`.
- no-demangle**
Don't demangle symbol names. This is the default.
- no-llvm-bc**
Disable the LLVM bitcode reader.
- no-sort, -p**
Show symbols in the order encountered.
- no-weak, -W**
Don't print weak symbols.
- numeric-sort, -n, -v**
Sort symbols by address.
- portability, -P**
Use POSIX.2 output format. Alias for `--format=posix`.
- print-armap, -M**
Print the archive symbol table, in addition to the symbols.
- print-file-name, -A, -o**
Precede each symbol with the file it came from.
- print-size, -S**
Show symbol size as well as address (not applicable for Mach-O).
- radix=<RADIX>, -t**
Specify the radix of the symbol address(es). Values accepted are *d* (decimal), *x* (hexadecimal) and *o* (octal).
- reverse-sort, -r**
Sort symbols in reverse order.
- size-sort**
Sort symbols by size.
- special-syms**
Ignored. For GNU compatibility only.
- undefined-only, -u**
Print only undefined symbols.
- version**
Display the version of this program. Does not stack with other commands.
- without-aliases**
Exclude aliases from the output.
- @<FILE>**
Read command-line options from response file *<FILE>*.

MACH-O SPECIFIC OPTIONS

--add-dyldinfo

Add symbols from the dyldinfo, if they are not already in the symbol table. This is the default.

--arch=<arch1[,arch2,...]>

Dump the symbols from the specified architecture(s).

--dyldinfo-only

Dump only symbols from the dyldinfo.

--no-dyldinfo

Do not add any symbols from the dyldinfo.

-s=<segment section>

Dump only symbols from this segment and section name.

-x

Print symbol entry in hex.

BUGS

- **llvm-nm** does not support the full set of arguments that GNU **nm** does.

EXIT STATUS

llvm-nm exits with an exit code of zero.

llvm-objcopy - object copying and editing tool

SYNOPSIS

llvm-objcopy [*options*] *input* [*output*]

DESCRIPTION

llvm-objcopy is a tool to copy and manipulate objects. In basic usage, it makes a semantic copy of the input to the output. If any options are specified, the output may be modified along the way, e.g. by removing sections.

If no output file is specified, the input file is modified in-place. If "-" is specified for the input file, the input is read from the program's standard input stream. If "-" is specified for the output file, the output is written to the standard output stream of the program.

If the input is an archive, any requested operations will be applied to each archive member individually.

The tool is still in active development, but in most scenarios it works as a drop-in replacement for GNU's **objcopy**.

GENERIC AND CROSS-PLATFORM OPTIONS

The following options are either agnostic of the file format, or apply to multiple file formats.

--add-gnu-debuglink <debug-file>

Add a .gnu_debuglink section for <debug-file> to the output.

--disable-deterministic-archives, -U

Use real values for UIDs, GIDs and timestamps when updating archive member headers.

--discard-all, -x

Remove most local symbols from the output. Different file formats may limit this to a subset of the local symbols. For example, file and section symbols in ELF objects will not be discarded.

--enable-deterministic-archives, -D

Enable deterministic mode when copying archives, i.e. use 0 for archive member header UIDs, GIDs and timestamp fields. On by default.

--help, -h

Print a summary of command line options.

--only-section <section>, **-j**

Remove all sections from the output, except for sections named <section>. Can be specified multiple times to keep multiple sections.

--regex

If specified, symbol and section names specified by other switches are treated as extended POSIX regular expression patterns.

--remove-section <section>, **-R**

Remove the specified section from the output. Can be specified multiple times to remove multiple sections simultaneously.

--strip-all-gnu

Remove all symbols, debug sections and relocations from the output. This option is equivalent to GNU **objcopy**'s **--strip-all** switch.

--strip-all, -S

For ELF objects, remove from the output all symbols and non-alloc sections not within segments, except for .gnu.warning, .ARM.attribute sections and the section name table.

For COFF objects, remove all symbols, debug sections, and relocations from the output.

--strip-debug, -g

Remove all debug sections from the output.

--strip-symbol <symbol>, **-N**

Remove all symbols named <symbol> from the output. Can be specified multiple times to remove multiple symbols.

--strip-symbols <filename>

Remove all symbols whose names appear in the file <filename>, from the output. In the file, each line represents a single symbol name, with leading and trailing whitespace ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.

--strip-unneeded-symbol <symbol>

Remove from the output all symbols named <symbol> that are local or undefined and are not required by any relocation.

--strip-unneeded-symbols <filename>

Remove all symbols whose names appear in the file <filename>, from the output, if they are local or undefined and are not required by any relocation. In the file, each line represents a single symbol name, with leading

and trailing whitespace ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.

--strip-unneeded

Remove from the output all local or undefined symbols that are not required by relocations.

--version, -V

Display the version of this program.

COFF-SPECIFIC OPTIONS

The following options are implemented only for COFF objects. If used with other objects, **llvm-objcopy** will either emit an error or silently ignore them.

--only-keep-debug

Remove the contents of non-debug sections from the output, but keep the section headers.

ELF-SPECIFIC OPTIONS

The following options are implemented only for ELF objects. If used with other objects, **llvm-objcopy** will either emit an error or silently ignore them.

--add-section <section=file>

Add a section named <section> with the contents of <file> to the output. The section will be of type *SHT_NOTE*, if the name starts with ".note". Otherwise, it will have type *SHT_PROGBITS*. Can be specified multiple times to add multiple sections.

--add-symbol <name>=[<section>:]<value>[,<flags>]

Add a new symbol called <name> to the output symbol table, in the section named <section>, with value <value>. If <section> is not specified, the symbol is added as an absolute symbol. The <flags> affect the symbol properties. Accepted values are:

- *global* = the symbol will have global binding.
- *local* = the symbol will have local binding.
- *weak* = the symbol will have weak binding.
- *default* = the symbol will have default visibility.
- *hidden* = the symbol will have hidden visibility.
- *file* = the symbol will be an *STT_FILE* symbol.
- *section* = the symbol will be an *STT_SECTION* symbol.
- *object* = the symbol will be an *STT_OBJECT* symbol.
- *function* = the symbol will be an *STT_FUNC* symbol.
- *indirect-function* = the symbol will be an *STT_GNU_IFUNC* symbol.

Additionally, the following flags are accepted but ignored: *debug*, *constructor*, *warning*, *indirect*, *synthetic*, *unique-object*, *before*.

Can be specified multiple times to add multiple symbols.

--allow-broken-links

Allow **llvm-objcopy** to remove sections even if it would leave invalid section references. Any invalid *sh_link* fields will be set to zero.

--binary-architecture <arch>, **-B**

Specify the architecture to use, when transforming an architecture-less format (e.g. binary) to another format. Valid options are:

- *aarch64*
- *arm*
- *i386*
- *i386:x86-64*
- *mips*
- *powerpc:common64*
- *riscv:rv32*
- *riscv:rv64*
- *sparc*
- *sparcel*
- *x86-64*

--build-id-link-dir <dir>

Set the directory used by *--build-id-link-input* and *--build-id-link-output*.

--build-id-link-input <suffix>

Hard-link the input to <dir>/xx/xxx<suffix>, where <dir> is the directory specified by *--build-id-link-dir*. The path used is derived from the hex build ID.

--build-id-link-output <suffix>

Hard-link the output to <dir>/xx/xxx<suffix>, where <dir> is the directory specified by *--build-id-link-dir*. The path used is derived from the hex build ID.

--change-start <incr>, **--adjust-start**

Add <incr> to the program's start address. Can be specified multiple times, in which case the values will be applied cumulatively.

--compress-debug-sections [<style>]

Compress DWARF debug sections in the output, using the specified style. Supported styles are *zlib-gnu* and *zlib*. Defaults to *zlib* if no style is specified.

--decompress-debug-sections

Decompress any compressed DWARF debug sections in the output.

--discard-locals, **-X**

Remove local symbols starting with ".L" from the output.

--dump-section <section>=<file>

Dump the contents of section <section> into the file <file>. Can be specified multiple times to dump multiple sections to different files. <file> is unrelated to the input and output files provided to **llvm-objcopy** and as such the normal copying and editing operations will still be performed. No operations are performed on the sections prior to dumping them.

--extract-dwo

Remove all sections that are not DWARF .dwo sections from the output.

--extract-main-partition

Extract the main partition from the output.

--extract-partition <name>

Extract the named partition from the output.

- globalize-symbol** <symbol>
Mark any defined symbols named <symbol> as global symbols in the output. Can be specified multiple times to mark multiple symbols.
- globalize-symbols** <filename>
Read a list of names from the file <filename> and mark defined symbols with those names as global in the output. In the file, each line represents a single symbol, with leading and trailing whitespace ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.
- input-target** <format>, **-I**
Read the input as the specified format. See *SUPPORTED FORMATS* for a list of valid <format> values. If unspecified, **llvm-objcopy** will attempt to determine the format automatically.
- keep-file-symbols**
Keep symbols of type *STT_FILE*, even if they would otherwise be stripped.
- keep-global-symbol** <symbol>
Make all symbols local in the output, except for symbols with the name <symbol>. Can be specified multiple times to ignore multiple symbols.
- keep-global-symbols** <filename>
Make all symbols local in the output, except for symbols named in the file <filename>. In the file, each line represents a single symbol, with leading and trailing whitespace ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.
- keep-section** <section>
When removing sections from the output, do not remove sections named <section>. Can be specified multiple times to keep multiple sections.
- keep-symbol** <symbol>, **-K**
When removing symbols from the output, do not remove symbols named <symbol>. Can be specified multiple times to keep multiple symbols.
- keep-symbols** <filename>
When removing symbols from the output do not remove symbols named in the file <filename>. In the file, each line represents a single symbol, with leading and trailing whitespace ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.
- localize-hidden**
Make all symbols with hidden or internal visibility local in the output.
- localize-symbol** <symbol>, **-L**
Mark any defined non-common symbol named <symbol> as a local symbol in the output. Can be specified multiple times to mark multiple symbols as local.
- localize-symbols** <filename>
Read a list of names from the file <filename> and mark defined non-common symbols with those names as local in the output. In the file, each line represents a single symbol, with leading and trailing whitespace ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.
- output-target** <format>, **-O**
Write the output as the specified format. See *SUPPORTED FORMATS* for a list of valid <format> values. If unspecified, the output format is assumed to be the same as the input file's format.
- prefix-alloc-sections** <prefix>
Add <prefix> to the front of the names of all allocatable sections in the output.
- prefix-symbols** <prefix>
Add <prefix> to the front of every symbol name in the output.

--preserve-dates, -p

Preserve access and modification timestamps in the output.

--redefine-sym <old>=<new>

Rename symbols called <old> to <new> in the output. Can be specified multiple times to rename multiple symbols.

--redefine-syms <filename>

Rename symbols in the output as described in the file <filename>. In the file, each line represents a single symbol to rename, with the old name and new name separated by an equals sign. Leading and trailing whitespace is ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.

--rename-section <old>=<new>[,<flag>,...]

Rename sections called <old> to <new> in the output, and apply any specified <flag> values. See [--set-section-flags](#) for a list of supported flags. Can be specified multiple times to rename multiple sections.

--set-section-flags <section>=<flag>[,<flag>,...]

Set section properties in the output of section <section> based on the specified <flag> values. Can be specified multiple times to update multiple sections.

Following is a list of supported flags and their effects:

- *alloc* = add the *SHF_ALLOC* flag.
- *load* = if the section has *SHT_NOBITS* type, mark it as a *SHT_PROGBITS* section.
- *readonly* = if this flag is not specified, add the *SHF_WRITE* flag.
- *code* = add the *SHF_EXECINSTR* flag.
- *merge* = add the *SHF_MERGE* flag.
- *strings* = add the *SHF_STRINGS* flag.
- *contents* = if the section has *SHT_NOBITS* type, mark it as a *SHT_PROGBITS* section.

The following flags are also accepted, but are ignored for GNU compatibility: *noload*, *debug*, *data*, *rom*, *share*.

--set-start-addr <addr>

Set the start address of the output to <addr>. Overrides any previously specified [--change-start](#) or [--adjust-start](#) options.

--split-dwo <dwo-file>

Equivalent to running **llvm-objcopy** with [--extract-dwo](#) and <dwo-file> as the output file and no other options, and then with [--strip-dwo](#) on the input file.

--strip-dwo

Remove all DWARF .dwo sections from the output.

--strip-non-alloc

Remove from the output all non-allocatable sections that are not within segments.

--strip-sections

Remove from the output all section headers and all section data not within segments. Note that many tools will not be able to use an object without section headers.

--target <format>, **-F**

Equivalent to [--input-target](#) and [--output-target](#) for the specified format. See [SUPPORTED FORMATS](#) for a list of valid <format> values.

--weaken-symbol <symbol>, **-W**

Mark any global symbol named <symbol> as a weak symbol in the output. Can be specified multiple times to mark multiple symbols as weak.

--weaken-symbols <filename>

Read a list of names from the file <filename> and mark global symbols with those names as weak in the output. In the file, each line represents a single symbol, with leading and trailing whitespace ignored, as is anything following a '#'. Can be specified multiple times to read names from multiple files.

--weaken

Mark all defined global symbols as weak in the output.

SUPPORTED FORMATS

The following values are currently supported by **llvm-objcopy** for the `--input-target`, `--output-target`, and `--target` options. For GNU **objcopy** compatibility, the values are all bfdnames.

- *binary*
- *ihex*
- *elf32-i386*
- *elf32-x86-64*
- *elf64-x86-64*
- *elf32-iamcu*
- *elf32-littlearm*
- *elf64-aarch64*
- *elf64-littleaarch64*
- *elf32-littleriscv*
- *elf64-littleriscv*
- *elf32-powerpc*
- *elf32-powerpcle*
- *elf64-powerpc*
- *elf64-powerpcle*
- *elf32-bigmips*
- *elf32-ntradbigmips*
- *elf32-ntradlittlemips*
- *elf32-tradbigmips*
- *elf32-tradlittlemips*
- *elf64-tradbigmips*
- *elf64-tradlittlemips*
- *elf32-sparc*
- *elf32-sparcel*

Additionally, all targets except *binary* and *ihex* can have *-freebsd* as a suffix.

BINARY INPUT AND OUTPUT

If *binary* is used as the value for `--input-target`, the input file will be embedded as a data section in an ELF relocatable object, with symbols `_binary_<file_name>_start`, `_binary_<file_name>_end`, and `_binary_<file_name>_size` representing the start, end and size of the data, where `<file_name>` is the path of the input file as specified on the command line with non-alphanumeric characters converted to `_`.

If *binary* is used as the value for `--output-target`, the output file will be a raw binary file, containing the memory image of the input file. Symbols and relocation information will be discarded. The image will start at the address of the first loadable section in the output.

EXIT STATUS

llvm-objcopy exits with a non-zero exit code if there is an error. Otherwise, it exits with code 0.

BUGS

To report bugs, please visit <http://llvm.org/bugs/>.

There is a known issue with `--input-target` and `--target` causing only `binary` and `ihex` formats to have any effect. Other values will be ignored and **llvm-objcopy** will attempt to guess the input format.

llvm-objdump - LLVM's object file dumper

SYNOPSIS

llvm-objdump [*commands*] [*options*] [*filenames...*]

DESCRIPTION

The **llvm-objdump** utility prints the contents of object files and final linked images named on the command line. If no file name is specified, **llvm-objdump** will attempt to read from *a.out*. If `-` is used as a file name, **llvm-objdump** will process a file on its standard input stream.

COMMANDS

At least one of the following commands are required, and some commands can be combined with other commands:

- a, --archive-headers**
Display the information contained within an archive's headers.
- d, --disassemble**
Disassemble all text sections found in the input files.
- D, --disassemble-all**
Disassemble all sections found in the input files.

--disassemble-functions=<symbol1[,symbol2,...]>
 Disassemble only the specified symbols. Takes demangled symbol names when *--demangle* is specified, otherwise takes mangled symbol names. Implies *--disassemble*.

--dwarf=<value>
 Dump the specified DWARF debug sections. The supported values are:
frames - .debug_frame

-f, --file-headers
 Display the contents of the overall file header.

--fault-map-section
 Display the content of the fault map section.

-h, --headers, --section-headers
 Display summaries of the headers for each section.

--help
 Display usage information and exit. Does not stack with other commands.

-p, --private-headers
 Display format-specific file headers.

-r, --reloc
 Display the relocation entries in the file.

-R, --dynamic-reloc
 Display the dynamic relocation entries in the file.

--raw-clang-ast
 Dump the raw binary contents of the clang AST section.

-s, --full-contents
 Display the contents of each section.

-t, --syms
 Display the symbol table.

-u, --unwind-info
 Display the unwind info of the input(s).

--version
 Display the version of this program. Does not stack with other commands.

-x, --all-headers
 Display all available header information. Equivalent to specifying *--archive-headers*, *--file-headers*, *--private-headers*, *--reloc*, *--section-headers*, and *--syms*.

OPTIONS

llvm-objdump supports the following options:

--adjust-vma=<offset>
 Increase the displayed address in disassembly or section header printing by the specified offset.

--arch-name=<string>
 Specify the target architecture when disassembling. Use *--version* for a list of available targets.

-C, --demangle
 Demangle symbol names in the output.

- j, --section=<section1[,section2,...]>**
Perform commands on the specified sections only. For Mach-O use *segment,section* to specify the section name.
- l, --line-numbers**
When disassembling, display source line numbers. Implies *--disassemble*.
- M, --disassembler-options=<opt1[,opt2,...]>**
Pass target-specific disassembler options. Currently supported for ARM targets only. Available options are *reg-names-std* and *reg-names-raw*.
- mcpu=<cpu-name>**
Target a specific CPU type for disassembly. Specify *--mcpu=help* to display available CPUs.
- mattr=<a1,+a2,-a3,...>**
Enable/disable target-specific attributes. Specify *--mcpu=help* to display the available attributes.
- no-leading-addr**
When disassembling, do not print leading addresses.
- no-show-raw-insn**
When disassembling, do not print the raw bytes of each instruction.
- print-imm-hex**
Use hex format when printing immediate values in disassembly output.
- S, --source**
When disassembling, display source interleaved with the disassembly. Implies *--disassemble*.
- show-lma**
Display the LMA column when dumping ELF section headers. Defaults to off unless any section has different VMA and LMAs.
- start-address=<address>**
When disassembling, only disassemble from the specified address.

When printing relocations, only print the relocations patching offsets from at least address.

When printing symbols, only print symbols with a value of at least address.
- stop-address=<address>**
When disassembling, only disassemble up to, but not including the specified address.

When printing relocations, only print the relocations patching offsets up to address.

When printing symbols, only print symbols with a value up to address.
- triple=<string>**
Target triple to disassemble for, see *--version* for available targets.
- w, --wide**
Ignored for compatibility with GNU objdump.
- x86-asm-syntax=<style>**
When used with *--disassemble*, choose style of code to emit from X86 backend. Supported values are:
- att**
AT&T-style assembly
 - intel**
Intel-style assembly
- The default disassembly style is **att**.
- z, --disassemble-zeroes**
Do not skip blocks of zeroes when disassembling.

@<FILE>

Read command-line options and commands from response file <FILE>.

MACH-O ONLY OPTIONS AND COMMANDS

--arch=<architecture>

Specify the architecture to disassemble. see `--version` for available architectures.

--archive-member-offsets

Print the offset to each archive member for Mach-O archives (requires `--archive-headers`).

--bind

Display binding info

--cfg

Create a CFG for every symbol in the object file and write it to a graphviz file.

--data-in-code

Display the data in code table.

--dis-symname=<name>

Disassemble just the specified symbol's instructions.

--dylibs-used

Display the shared libraries used for linked files.

--dsym=<string>

Use .dSYM file for debug info.

--dylib-id

Display the shared library's ID for dylib files.

--exports-trie

Display exported symbols.

-g

Print line information from debug info if available.

--full-leading-addr

Print the full leading address when disassembling.

--indirect-symbols

Display the indirect symbol table.

--info-plist

Display the info plist section as strings.

--lazy-bind

Display lazy binding info.

--link-opt-hints

Display the linker optimization hints.

-m, --macho

Use Mach-O specific object file parser. Commands and other options may behave differently when used with `--macho`.

--no-leading-headers

Do not print any leading headers.

--no-symbolic-operands

Do not print symbolic operands when disassembling.

--non-verbose

Display the information for Mach-O objects in non-verbose or numeric form.

--objc-meta-data

Display the Objective-C runtime meta data.

--private-header

Display only the first format specific file header.

--rebase

Display rebasing information.

--universal-headers

Display universal headers.

--weak-bind

Display weak binding information.

BUGS

llvm-ranlib - generates an archive index

SYNOPSIS

llvm-ranlib [*options*]

DESCRIPTION

llvm-ranlib is an alias for the [llvm-ar](#) tool that generates an index for an archive. It can be used as a replacement for GNU's **ranlib** tool.

Running **llvm-ranlib** is equivalent to running **llvm-ar s**.

SEE ALSO

Refer to [llvm-ar](#) for additional information.

llvm-readelf - GNU-style LLVM Object Reader

SYNOPSIS

llvm-readelf [*options*] [*input...*]

DESCRIPTION

The **llvm-readelf** tool displays low-level format-specific information about one or more object files.

If *input* is "-" or omitted, **llvm-readelf** reads from standard input. Otherwise, it will read from the specified filenames.

OPTIONS

--all

Equivalent to specifying all the main display options.

--addrsig

Display the address-significance table.

--arm-attributes

Display the ARM attributes section. Only applicable for ARM architectures.

--color

Use colors in the output for warnings and errors.

--demangle, -C

Display demangled symbol names in the output.

--dyn-relocations

Display the dynamic relocation entries.

--dyn-symbols, --dyn-syms

Display the dynamic symbol table.

--dynamic-table, --dynamic, -d

Display the dynamic table.

--elf-cg-profile

Display the callgraph profile section.

--elf-hash-histogram, --histogram, -I

Display a bucket list histogram for dynamic symbol hash tables.

--elf-linker-options

Display the linker options section.

--elf-output-style=<value>

Format ELF information in the specified style. Valid options are LLVM and GNU. LLVM output is an expanded and structured format, whilst GNU (the default) output mimics the equivalent GNU **readelf** output.

--elf-section-groups, --section-groups, -g

Display section groups.

--expand-relocs

When used with **--relocations**, display each relocation in an expanded multi-line format.

- file-headers, -h**
Display file headers.
- gnu-hash-table**
Display the GNU hash table for dynamic symbols.
- hash-symbols**
Display the expanded hash table with dynamic symbol data.
- hash-table**
Display the hash table for dynamic symbols.
- headers, -e**
Equivalent to setting: *--file-headers*, *--program-headers*, and *--sections*.
- help**
Display a summary of command line options.
- help-list**
Display an uncategorized summary of command line options.
- hex-dump=<section[,section,...]>, -x**
Display the specified section(s) as hexadecimal bytes. *section* may be a section index or section name.
- needed-libs**
Display the needed libraries.
- notes, -n**
Display all notes.
- program-headers, --segments, -l**
Display the program headers.
- raw-relr**
Do not decode relocations in RELR relocation sections when displaying them.
- relocations, --relocs, -r**
Display the relocation entries in the file.
- sections, --section-headers, -S**
Display all sections.
- section-data**
When used with *--sections*, display section data for each section shown. This option has no effect for GNU style output.
- section-mapping**
Display the section to segment mapping.
- section-relocations**
When used with *--sections*, display relocations for each section shown. This option has no effect for GNU style output.
- section-symbols**
When used with *--sections*, display symbols for each section shown. This option has no effect for GNU style output.
- stackmap**
Display contents of the stackmap section.
- string-dump=<section[,section,...]>, -p**
Display the specified section(s) as a list of strings. *section* may be a section index or section name.

--symbols, --syms, -s
Display the symbol table.

--unwind, -u
Display unwind information.

--version
Display the version of this program.

--version-info, -V
Display version sections.

@<FILE>
Read command-line options from response file <FILE>.

EXIT STATUS

llvm-readelf returns 0 under normal operation. It returns a non-zero exit code if there were any errors.

llvm-nm(1), llvm-objdump(1), llvm-readobj(1)

llvm-size - print segment sizes

SYNOPSIS

llvm-size [*options*]

DESCRIPTION

llvm-size is a tool that prints segment sizes in object files. The goal is to make it a drop-in replacement for GNU's **size**.

llvm-strings - print strings

SYNOPSIS

llvm-strings [*options*]

DESCRIPTION

llvm-strings is a tool that prints strings in object files. The goal is to make it a drop-in replacement for GNU's **size**.

llvm-strip - object stripping tool

SYNOPSIS

llvm-strip [*options*]

DESCRIPTION

llvm-strip is a tool to strip sections and symbols from object files.

The tool is still in active development, but in most scenarios it works as a drop-in replacement for GNU's **strip**.

[llvm-objcopy](#)

2.8.3 Debugging Tools

bugpoint - automatic test case reduction tool

SYNOPSIS

bugpoint [*options*] [*input LLVM ll/bc files*] [*LLVM passes*] **--args** *program arguments*

DESCRIPTION

bugpoint narrows down the source of problems in LLVM tools and passes. It can be used to debug three types of failures: optimizer crashes, miscompilations by optimizers, or bad native code generation (including problems in the static and JIT compilers). It aims to reduce large test cases to small, useful ones. For more information on the design and inner workings of **bugpoint**, as well as advice for using bugpoint, see [LLVM bugpoint tool: design and usage](#) in the LLVM distribution.

OPTIONS

--additional-so *library*

Load the dynamic shared object *library* into the test program whenever it is run. This is useful if you are debugging programs which depend on non-LLVM libraries (such as the X or curses libraries) to run.

--append-exit-code={*true,false*}

Append the test programs exit code to the output file so that a change in exit code is considered a test failure. Defaults to false.

--args *program args*

Pass all arguments specified after **--args** to the test program whenever it runs. Note that if any of the *program args* start with a "-", you should use:

```
bugpoint [bugpoint args] --args -- [program args]
```

The "--" right after the **--args** option tells **bugpoint** to consider any options starting with "-" to be part of the **--args** option, not as options to **bugpoint** itself.

--tool-args *tool args*

Pass all arguments specified after **--tool-args** to the LLVM tool under test (**llc**, **lli**, etc.) whenever it runs. You should use this option in the following way:

```
bugpoint [bugpoint args] --tool-args -- [tool args]
```

The "--" right after the **--tool-args** option tells **bugpoint** to consider any options starting with "-" to be part of the **--tool-args** option, not as options to **bugpoint** itself. (See **--args**, above.)

--safe-tool-args *tool args*

Pass all arguments specified after **--safe-tool-args** to the "safe" execution tool.

--gcc-tool-args *gcc tool args*

Pass all arguments specified after **--gcc-tool-args** to the invocation of **gcc**.

--opt-args *opt args*

Pass all arguments specified after **--opt-args** to the invocation of **opt**.

--disable-{dce,simplifcfg}

Do not run the specified passes to clean up and reduce the size of the test program. By default, **bugpoint** uses these passes internally when attempting to reduce test programs. If you're trying to find a bug in one of these passes, **bugpoint** may crash.

--enable-valgrind

Use valgrind to find faults in the optimization phase. This will allow bugpoint to find otherwise asymptomatic problems caused by memory mis-management.

-find-bugs

Continually randomize the specified passes and run them on the test program until a bug is found or the user kills **bugpoint**.

-help

Print a summary of command line options.

--input *filename*

Open *filename* and redirect the standard input of the test program, whenever it runs, to come from that file.

--load *plugin*

Load the dynamic object *plugin* into **bugpoint** itself. This object should register new optimization passes. Once loaded, the object will add new command line options to enable various optimizations. To see the new complete list of optimizations, use the **-help** and **--load** options together; for example:

```
bugpoint --load myNewPass.so -help
```

--mlimit *megabytes*

Specifies an upper limit on memory usage of the optimization and codegen. Set to zero to disable the limit.

--output *filename*

Whenever the test program produces output on its standard output stream, it should match the contents of *filename* (the "reference output"). If you do not use this option, **bugpoint** will attempt to generate a reference output by compiling the program with the "safe" backend and running it.

--run-{int,jit,llc,custom}

Whenever the test program is compiled, **bugpoint** should generate code for it using the specified code generator. These options allow you to choose the interpreter, the JIT compiler, the static native code compiler, or a custom command (see **--exec-command**) respectively.

--safe-{llc,custom}

When debugging a code generator, **bugpoint** should use the specified code generator as the "safe" code generator. This is a known-good code generator used to generate the "reference output" if it has not been provided, and to compile portions of the program that as they are excluded from the testcase. These options allow you to choose the static native code compiler, or a custom command, (see **--exec-command**) respectively. The interpreter and the JIT backends cannot currently be used as the "safe" backends.

--exec-command *command*

This option defines the command to use with the **--run-custom** and **--safe-custom** options to execute the bitcode testcase. This can be useful for cross-compilation.

--compile-command *command*

This option defines the command to use with the **--compile-custom** option to compile the bitcode testcase. The command should exit with a failure exit code if the file is "interesting" and should exit with a success exit code (i.e. 0) otherwise (this is the same as if it crashed on "interesting" inputs).

This can be useful for testing compiler output without running any link or execute stages. To generate a reduced unit test, you may add CHECK directives to the testcase and pass the name of an executable compile-command script in this form:

```
#!/bin/sh
llc "$@"
not FileCheck [bugpoint input file].ll < bugpoint-test-program.s
```

This script will "fail" as long as FileCheck passes. So the result will be the minimum bitcode that passes FileCheck.

--safe-path *path*

This option defines the path to the command to execute with the **--safe-{int,jit,llc,custom}** option.

--verbose-errors={true,false}

The default behavior of bugpoint is to print "<crash>" when it finds a reduced test that crashes compilation. This flag prints the output of the crashing program to stderr. This is useful to make sure it is the same error being tracked down and not a different error that happens to crash the compiler as well. Defaults to false.

EXIT STATUS

If **bugpoint** succeeds in finding a problem, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

SEE ALSO

opt (1)

llvm-extract - extract a function from an LLVM module

SYNOPSIS

llvm-extract [*options*] **--func** *function-name* [*filename*]

DESCRIPTION

The **llvm-extract** command takes the name of a function and extracts it from the specified LLVM bitcode file. It is primarily used as a debugging tool to reduce test cases from larger programs that are triggering a bug.

In addition to extracting the bitcode of the specified function, **llvm-extract** will also remove unreachable global variables, prototypes, and unused types.

The **llvm-extract** command reads its input from standard input if filename is omitted or if filename is `-`. The output is always written to standard output, unless the **-o** option is specified (see below).

OPTIONS

-f

Enable binary output on terminals. Normally, **llvm-extract** will refuse to write raw bitcode output if the output stream is a terminal. With this option, **llvm-extract** will write raw bitcode regardless of the output device.

--func *function-name*

Extract the function named *function-name* from the LLVM bitcode. May be specified multiple times to extract multiple functions at once.

--rfunc *function-regular-expr*

Extract the function(s) matching *function-regular-expr* from the LLVM bitcode. All functions matching the regular expression will be extracted. May be specified multiple times.

--glob *global-name*

Extract the global variable named *global-name* from the LLVM bitcode. May be specified multiple times to extract multiple global variables at once.

--rglob *glob-regular-expr*

Extract the global variable(s) matching *global-regular-expr* from the LLVM bitcode. All global variables matching the regular expression will be extracted. May be specified multiple times.

-help

Print a summary of command line options.

-o *filename*

Specify the output filename. If filename is "-" (the default), then **llvm-extract** sends its output to standard output.

-S

Write output in LLVM intermediate language (instead of bitcode).

EXIT STATUS

If **llvm-extract** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

llvm-bcanalyzer - LLVM bitcode analyzer

SYNOPSIS

llvm-bcanalyzer [*options*] [*filename*]

DESCRIPTION

The **llvm-bcanalyzer** command is a small utility for analyzing bitcode files. The tool reads a bitcode file (such as generated with the **llvm-as** tool) and produces a statistical report on the contents of the bitcode file. The tool can also dump a low level but human readable version of the bitcode file. This tool is probably not of much interest or utility except for those working directly with the bitcode file format. Most LLVM users can just ignore this tool.

If *filename* is omitted or is -, then **llvm-bcanalyzer** reads its input from standard input. This is useful for combining the tool into a pipeline. Output is written to the standard output.

OPTIONS

-nodetails

Causes **llvm-bcanalyzer** to abbreviate its output by writing out only a module level summary. The details for individual functions are not displayed.

-dump

Causes **llvm-bcanalyzer** to dump the bitcode in a human readable format. This format is significantly different from LLVM assembly and provides details about the encoding of the bitcode file.

-verify

Causes **llvm-bcanalyzer** to verify the module produced by reading the bitcode. This ensures that the statistics generated are based on a consistent module.

-help

Print a summary of command line options.

EXIT STATUS

If **llvm-bcanalyzer** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value, usually 1.

SUMMARY OUTPUT DEFINITIONS

The following items are always printed by **llvm-bcanalyzer**. They comprise the summary output.

Bitcode Analysis Of Module

This just provides the name of the module for which bitcode analysis is being generated.

Bitcode Version Number

The bitcode version (not LLVM version) of the file read by the analyzer.

File Size

The size, in bytes, of the entire bitcode file.

Module Bytes

The size, in bytes, of the module block. Percentage is relative to File Size.

Function Bytes

The size, in bytes, of all the function blocks. Percentage is relative to File Size.

Global Types Bytes

The size, in bytes, of the Global Types Pool. Percentage is relative to File Size. This is the size of the definitions of all types in the bitcode file.

Constant Pool Bytes

The size, in bytes, of the Constant Pool Blocks Percentage is relative to File Size.

Module Globals Bytes

This size, in bytes, of the Global Variable Definitions and their initializers. Percentage is relative to File Size.

Instruction List Bytes

The size, in bytes, of all the instruction lists in all the functions. Percentage is relative to File Size. Note that this value is also included in the Function Bytes.

Compaction Table Bytes

The size, in bytes, of all the compaction tables in all the functions. Percentage is relative to File Size. Note that this value is also included in the Function Bytes.

Symbol Table Bytes

The size, in bytes, of all the symbol tables in all the functions. Percentage is relative to File Size. Note that this value is also included in the Function Bytes.

Dependent Libraries Bytes

The size, in bytes, of the list of dependent libraries in the module. Percentage is relative to File Size. Note that this value is also included in the Module Global Bytes.

Number Of Bitcode Blocks

The total number of blocks of any kind in the bitcode file.

Number Of Functions

The total number of function definitions in the bitcode file.

Number Of Types

The total number of types defined in the Global Types Pool.

Number Of Constants

The total number of constants (of any type) defined in the Constant Pool.

Number Of Basic Blocks

The total number of basic blocks defined in all functions in the bitcode file.

Number Of Instructions

The total number of instructions defined in all functions in the bitcode file.

Number Of Long Instructions

The total number of long instructions defined in all functions in the bitcode file. Long instructions are those taking greater than 4 bytes. Typically long instructions are `GetElementPtr` with several indices, `PHI` nodes, and calls to functions with large numbers of arguments.

Number Of Operands

The total number of operands used in all instructions in the bitcode file.

Number Of Compaction Tables

The total number of compaction tables in all functions in the bitcode file.

Number Of Symbol Tables

The total number of symbol tables in all functions in the bitcode file.

Number Of Dependent Libs

The total number of dependent libraries found in the bitcode file.

Total Instruction Size

The total size of the instructions in all functions in the bitcode file.

Average Instruction Size

The average number of bytes per instruction across all functions in the bitcode file. This value is computed by dividing Total Instruction Size by Number Of Instructions.

Maximum Type Slot Number

The maximum value used for a type's slot number. Larger slot number values take more bytes to encode.

Maximum Value Slot Number

The maximum value used for a value's slot number. Larger slot number values take more bytes to encode.

Bytes Per Value

The average size of a Value definition (of any type). This is computed by dividing File Size by the total number of values of any type.

Bytes Per Global

The average size of a global definition (constants and global variables).

Bytes Per Function

The average number of bytes per function definition. This is computed by dividing Function Bytes by Number Of Functions.

of VBR 32-bit Integers

The total number of 32-bit integers encoded using the Variable Bit Rate encoding scheme.

of VBR 64-bit Integers

The total number of 64-bit integers encoded using the Variable Bit Rate encoding scheme.

of VBR Compressed Bytes

The total number of bytes consumed by the 32-bit and 64-bit integers that use the Variable Bit Rate encoding scheme.

of VBR Expanded Bytes

The total number of bytes that would have been consumed by the 32-bit and 64-bit integers had they not been compressed with the Variable Bit Rate encoding scheme.

Bytes Saved With VBR

The total number of bytes saved by using the Variable Bit Rate encoding scheme. The percentage is relative to # of VBR Expanded Bytes.

DETAILED OUTPUT DEFINITIONS

The following definitions occur only if the -nodetails option was not given. The detailed output provides additional information on a per-function basis.

Type

The type signature of the function.

Byte Size

The total number of bytes in the function's block.

Basic Blocks

The number of basic blocks defined by the function.

Instructions

The number of instructions defined by the function.

Long Instructions

The number of instructions using the long instruction format in the function.

Operands

The number of operands used by all instructions in the function.

Instruction Size

The number of bytes consumed by instructions in the function.

Average Instruction Size

The average number of bytes consumed by the instructions in the function. This value is computed by dividing Instruction Size by Instructions.

Bytes Per Instruction

The average number of bytes used by the function per instruction. This value is computed by dividing Byte Size by Instructions. Note that this is not the same as Average Instruction Size. It computes a number relative to the total function size not just the size of the instruction list.

Number of VBR 32-bit Integers

The total number of 32-bit integers found in this function (for any use).

Number of VBR 64-bit Integers

The total number of 64-bit integers found in this function (for any use).

Number of VBR Compressed Bytes

The total number of bytes in this function consumed by the 32-bit and 64-bit integers that use the Variable Bit Rate encoding scheme.

Number of VBR Expanded Bytes

The total number of bytes in this function that would have been consumed by the 32-bit and 64-bit integers had they not been compressed with the Variable Bit Rate encoding scheme.

Bytes Saved With VBR

The total number of bytes saved in this function by using the Variable Bit Rate encoding scheme. The percentage is relative to # of VBR Expanded Bytes.

FileCheck - Flexible pattern matching file verifier**SYNOPSIS**

FileCheck *match-filename* [*--check-prefix=XXX*] [*--strict-whitespace*]

DESCRIPTION

FileCheck reads two files (one from standard input, and one specified on the command line) and uses one to verify the other. This behavior is particularly useful for the testsuite, which wants to verify that the output of some tool (e.g. **l1c**) contains the expected information (for example, a `movsd` from `esp` or whatever is interesting). This is similar to using **grep**, but it is optimized for matching multiple different inputs in one file in a specific order.

The `match-filename` file specifies the file that contains the patterns to match. The file to verify is read from standard input unless the `--input-file` option is used.

OPTIONS

Options are parsed from the environment variable `FILECHECK_OPTS` and from the command line.

-help

Print a summary of command line options.

--check-prefix *prefix*

FileCheck searches the contents of *match-filename* for patterns to match. By default, these patterns are prefixed with "CHECK:". If you'd like to use a different prefix (e.g. because the same input file is checking multiple different tool or options), the `--check-prefix` argument allows you to specify one or more prefixes to match. Multiple prefixes are useful for tests which might change for different run options, but most lines remain the same.

--check-prefixes *prefix1, prefix2, ...*

An alias of `--check-prefix` that allows multiple prefixes to be specified as a comma separated list.

--input-file *filename*

File to check (defaults to stdin).

--match-full-lines

By default, FileCheck allows matches of anywhere on a line. This option will require all positive matches to cover an entire line. Leading and trailing whitespace is ignored, unless `--strict-whitespace` is also specified. (Note: negative matches from CHECK-NOT are not affected by this option!)

Passing this option is equivalent to inserting `{{^ *}}` or `{{^}}` before, and `{{ *$}}` or `{{ $}}` after every positive check pattern.

--strict-whitespace

By default, FileCheck canonicalizes input horizontal whitespace (spaces and tabs) which causes it to ignore these differences (a space will match a tab). The `--strict-whitespace` argument disables this behavior. End-of-line sequences are canonicalized to UNIX-style `\n` in all modes.

--implicit-check-not *check-pattern*

Adds implicit negative checks for the specified patterns between positive checks. The option allows writing stricter tests without stuffing them with CHECK-NOTs.

For example, `--implicit-check-not warning:` can be useful when testing diagnostic messages from tools that don't have an option similar to `clang -verify`. With this option FileCheck will verify that input does not contain warnings not covered by any CHECK: patterns.

--dump-input *<mode>*

Dump input to stderr, adding annotations representing currently enabled diagnostics. Do this either 'always', on 'fail', or 'never'. Specify 'help' to explain the dump format and quit.

--dump-input-on-failure

When the check fails, dump all of the original input. This option is deprecated in favor of `--dump-input=fail`.

--enable-var-scope

Enables scope for regex variables.

Variables with names that start with `$` are considered global and remain set throughout the file.

All other variables get undefined after each encountered CHECK-LABEL.

-D<VAR=VALUE>

Sets a filecheck pattern variable VAR with value VALUE that can be used in CHECK: lines.

-D#<NUMVAR>=<VALUE EXPRESSION>

Sets a filecheck numeric variable NUMVAR to the result of evaluating <VALUE EXPRESSION> that can be used in CHECK: lines. See section FileCheck Numeric Variables and Expressions for details on the format and meaning of <VALUE EXPRESSION>.

-version

Show the version number of this program.

-v

Print good directive pattern matches. However, if `-input-dump=fail` or `-input-dump=always`, add those matches as input annotations instead.

-vv

Print information helpful in diagnosing internal FileCheck issues, such as discarded overlapping `CHECK-DAG :` matches, implicit EOF pattern matches, and `CHECK-NOT :` patterns that do not have matches. Implies `-v`. However, if `-input-dump=fail` or `-input-dump=always`, just add that information as input annotations instead.

--allow-deprecated-dag-overlap

Enable overlapping among matches in a group of consecutive `CHECK-DAG :` directives. This option is deprecated and is only provided for convenience as old tests are migrated to the new non-overlapping `CHECK-DAG :` implementation.

--color

Use colors in output (autodetected by default).

EXIT STATUS

If **FileCheck** verifies that the file matches the expected contents, it exits with 0. Otherwise, if not, or if an error occurs, it will exit with a non-zero value.

TUTORIAL

FileCheck is typically used from LLVM regression tests, being invoked on the RUN line of the test. A simple example of using FileCheck from a RUN line looks like this:

```
; RUN: llvm-as < %s | llc -march=x86-64 | FileCheck %s
```

This syntax says to pipe the current file ("`%s`") into `llvm-as`, pipe that into `llc`, then pipe the output of `llc` into `FileCheck`. This means that `FileCheck` will be verifying its standard input (the `llc` output) against the filename argument specified (the original `.ll` file specified by "`%s`"). To see how this works, let's look at the rest of the `.ll` file (after the RUN line):

```
define void @sub1(i32* %p, i32 %v) {
entry:
; CHECK: sub1:
; CHECK: sub1
    %0 = tail call i32 @llvm.atomic.load.sub.i32.p0i32(i32* %p, i32 %v)
    ret void
}

define void @inc4(i64* %p) {
entry:
; CHECK: inc4:
; CHECK: incq
    %0 = tail call i64 @llvm.atomic.load.add.i64.p0i64(i64* %p, i64 1)
    ret void
}
```

Here you can see some "CHECK:" lines specified in comments. Now you can see how the file is piped into `llvm-as`, then `llc`, and the machine code output is what we are verifying. FileCheck checks the machine code output to verify that it matches what the "CHECK:" lines specify.

The syntax of the "CHECK:" lines is very simple: they are fixed strings that must occur in order. FileCheck defaults to ignoring horizontal whitespace differences (e.g. a space is allowed to match a tab) but otherwise, the contents of the "CHECK:" line is required to match some thing in the test file exactly.

One nice thing about FileCheck (compared to `grep`) is that it allows merging test cases together into logical groups. For example, because the test above is checking for the "sub1:" and "inc4:" labels, it will not match unless there is a "sub1" in between those labels. If it existed somewhere else in the file, that would not count: "`grep sub1`" matches if "sub1" exists anywhere in the file.

The FileCheck -check-prefix option

The FileCheck `-check-prefix` option allows multiple test configurations to be driven from one `.ll` file. This is useful in many circumstances, for example, testing different architectural variants with `llc`. Here's a simple example:

```
; RUN: llvm-as < %s | llc -mtriple=i686-apple-darwin9 -mattr=sse41 \
; RUN:          | FileCheck %s -check-prefix=X32
; RUN: llvm-as < %s | llc -mtriple=x86_64-apple-darwin9 -mattr=sse41 \
; RUN:          | FileCheck %s -check-prefix=X64

define <4 x i32> @pinsrd_1(i32 %s, <4 x i32> %tmp) nounwind {
    %tmp1 = insertelement <4 x i32>; %tmp, i32 %s, i32 1
    ret <4 x i32> %tmp1
; X32: pinsrd_1:
; X32:    pinsrd $1, 4(%esp), %xmm0

; X64: pinsrd_1:
; X64:    pinsrd $1, %edi, %xmm0
}
```

In this case, we're testing that we get the expected code generation with both 32-bit and 64-bit code generation.

The "CHECK-NEXT:" directive

Sometimes you want to match lines and would like to verify that matches happen on exactly consecutive lines with no other lines in between them. In this case, you can use "CHECK:" and "CHECK-NEXT:" directives to specify this. If you specified a custom check prefix, just use "<PREFIX>-NEXT:". For example, something like this works as you'd expect:

```
define void @t2(<2 x double>* %r, <2 x double>* %A, double %B) {
    %tmp3 = load <2 x double>* %A, align 16
    %tmp7 = insertelement <2 x double> undef, double %B, i32 0
    %tmp9 = shufflevector <2 x double> %tmp3,
                        <2 x double> %tmp7,
                        <2 x i32> < i32 0, i32 2 >
    store <2 x double> %tmp9, <2 x double>* %r, align 16
    ret void

; CHECK:          t2:
; CHECK:          movl    8(%esp), %eax
; CHECK-NEXT:     movapd  (%eax), %xmm0
; CHECK-NEXT:     movhpd 12(%esp), %xmm0
```

(continues on next page)

(continued from previous page)

```

; CHECK-NEXT:      movl    4(%esp), %eax
; CHECK-NEXT:      movapd  %xmm0, (%eax)
; CHECK-NEXT:      ret
}

```

"CHECK-NEXT:" directives reject the input unless there is exactly one newline between it and the previous directive. A "CHECK-NEXT:" cannot be the first directive in a file.

The "CHECK-SAME:" directive

Sometimes you want to match lines and would like to verify that matches happen on the same line as the previous match. In this case, you can use "CHECK:" and "CHECK-SAME:" directives to specify this. If you specified a custom check prefix, just use "<PREFIX>-SAME:".

"CHECK-SAME:" is particularly powerful in conjunction with "CHECK-NOT:" (described below).

For example, the following works like you'd expect:

```

!0 = !DILocation(line: 5, scope: !1, inlinedAt: !2)

; CHECK:      !DILocation(line: 5,
; CHECK-NOT:      column:
; CHECK-SAME:      scope: ![[SCOPE:[0-9]+]]

```

"CHECK-SAME:" directives reject the input if there are any newlines between it and the previous directive. A "CHECK-SAME:" cannot be the first directive in a file.

The "CHECK-EMPTY:" directive

If you need to check that the next line has nothing on it, not even whitespace, you can use the "CHECK-EMPTY:" directive.

```

declare void @foo()

declare void @bar()
; CHECK: foo
; CHECK-EMPTY:
; CHECK-NEXT: bar

```

Just like "CHECK-NEXT:" the directive will fail if there is more than one newline before it finds the next blank line, and it cannot be the first directive in a file.

The "CHECK-NOT:" directive

The "CHECK-NOT:" directive is used to verify that a string doesn't occur between two matches (or before the first match, or after the last match). For example, to verify that a load is removed by a transformation, a test like this can be used:

```

define i8 @coerce_offset0(i32 %V, i32* %P) {
    store i32 %V, i32* %P

    %P2 = bitcast i32* %P to i8*

```

(continues on next page)

(continued from previous page)

```

%P3 = getelementptr i8* %P2, i32 2

%A = load i8* %P3
ret i8 %A
; CHECK: @coerce_offset0
; CHECK-NOT: load
; CHECK: ret i8
}

```

The "CHECK-COUNT:" directive

If you need to match multiple lines with the same pattern over and over again you can repeat a plain `CHECK:` as many times as needed. If that looks too boring you can instead use a counted check `"CHECK-COUNT-<num>:"`, where `<num>` is a positive decimal number. It will match the pattern exactly `<num>` times, no more and no less. If you specified a custom check prefix, just use `"<PREFIX>-COUNT-<num>:"` for the same effect. Here is a simple example:

```

Loop at depth 1
Loop at depth 1
Loop at depth 1
Loop at depth 1
  Loop at depth 2
    Loop at depth 3

; CHECK-COUNT-6: Loop at depth {[0-9]+}
; CHECK-NOT:      Loop at depth {[0-9]+}

```

The "CHECK-DAG:" directive

If it's necessary to match strings that don't occur in a strictly sequential order, `"CHECK-DAG:"` could be used to verify them between two matches (or before the first match, or after the last match). For example, clang emits vtable globals in reverse order. Using `CHECK-DAG:`, we can keep the checks in the natural order:

```

// RUN: %clang_cc1 %s -emit-llvm -o - | FileCheck %s

struct Foo { virtual void method(); };
Foo f; // emit vtable
// CHECK-DAG: @_ZTV3Foo =

struct Bar { virtual void method(); };
Bar b;
// CHECK-DAG: @_ZTV3Bar =

```

`CHECK-NOT:` directives could be mixed with `CHECK-DAG:` directives to exclude strings between the surrounding `CHECK-DAG:` directives. As a result, the surrounding `CHECK-DAG:` directives cannot be reordered, i.e. all occurrences matching `CHECK-DAG:` before `CHECK-NOT:` must not fall behind occurrences matching `CHECK-DAG:` after `CHECK-NOT:`. For example,

```

; CHECK-DAG: BEFORE
; CHECK-NOT: NOT
; CHECK-DAG: AFTER

```

This case will reject input strings where `BEFORE` occurs after `AFTER`.

With captured variables, `CHECK-DAG:` is able to match valid topological orderings of a DAG with edges from the definition of a variable to its use. It's useful, e.g., when your test cases need to match different output sequences from the instruction scheduler. For example,

```
; CHECK-DAG: add [[REG1:r[0-9]+]], r1, r2
; CHECK-DAG: add [[REG2:r[0-9]+]], r3, r4
; CHECK:      mul r5, [[REG1]], [[REG2]]
```

In this case, any order of that two `add` instructions will be allowed.

If you are defining *and* using variables in the same `CHECK-DAG:` block, be aware that the definition rule can match *after* its use.

So, for instance, the code below will pass:

```
; CHECK-DAG: vmov.32 [[REG2:d[0-9]+]] [0]
; CHECK-DAG: vmov.32 [[REG2]] [1]
vmov.32 d0 [1]
vmov.32 d0 [0]
```

While this other code, will not:

```
; CHECK-DAG: vmov.32 [[REG2:d[0-9]+]] [0]
; CHECK-DAG: vmov.32 [[REG2]] [1]
vmov.32 d1 [1]
vmov.32 d0 [0]
```

While this can be very useful, it's also dangerous, because in the case of register sequence, you must have a strong order (read before write, copy before use, etc). If the definition your test is looking for doesn't match (because of a bug in the compiler), it may match further away from the use, and mask real bugs away.

In those cases, to enforce the order, use a non-DAG directive between DAG-blocks.

A `CHECK-DAG:` directive skips matches that overlap the matches of any preceding `CHECK-DAG:` directives in the same `CHECK-DAG:` block. Not only is this non-overlapping behavior consistent with other directives, but it's also necessary to handle sets of non-unique strings or patterns. For example, the following directives look for unordered log entries for two tasks in a parallel program, such as the OpenMP runtime:

```
// CHECK-DAG: [[THREAD_ID:[0-9]+]]: task_begin
// CHECK-DAG: [[THREAD_ID]]: task_end
//
// CHECK-DAG: [[THREAD_ID:[0-9]+]]: task_begin
// CHECK-DAG: [[THREAD_ID]]: task_end
```

The second pair of directives is guaranteed not to match the same log entries as the first pair even though the patterns are identical and even if the text of the log entries is identical because the thread ID manages to be reused.

The "CHECK-LABEL:" directive

Sometimes in a file containing multiple tests divided into logical blocks, one or more `CHECK:` directives may inadvertently succeed by matching lines in a later block. While an error will usually eventually be generated, the check flagged as causing the error may not actually bear any relationship to the actual source of the problem.

In order to produce better error messages in these cases, the "CHECK-LABEL:" directive can be used. It is treated identically to a normal `CHECK` directive except that FileCheck makes an additional assumption that a line matched by the directive cannot also be matched by any other check present in `match-filename`; this is intended to be used for lines containing labels or other unique identifiers. Conceptually, the presence of `CHECK-LABEL` divides the input stream into separate blocks, each of which is processed independently, preventing a `CHECK:` directive in one

block matching a line in another block. If `--enable-var-scope` is in effect, all local variables are cleared at the beginning of the block.

For example,

```
define %struct.C* @C_ctor_base(%struct.C* %this, i32 %x) {
entry:
; CHECK-LABEL: C_ctor_base:
; CHECK: mov [[SAVETHIS:r[0-9]+]], r0
; CHECK: bl A_ctor_base
; CHECK: mov r0, [[SAVETHIS]]
%0 = bitcast %struct.C* %this to %struct.A*
%call = tail call %struct.A* @A_ctor_base(%struct.A* %0)
%1 = bitcast %struct.C* %this to %struct.B*
%call2 = tail call %struct.B* @B_ctor_base(%struct.B* %1, i32 %x)
ret %struct.C* %this
}

define %struct.D* @D_ctor_base(%struct.D* %this, i32 %x) {
entry:
; CHECK-LABEL: D_ctor_base:
```

The use of `CHECK-LABEL:` directives in this case ensures that the three `CHECK:` directives only accept lines corresponding to the body of the `@C_ctor_base` function, even if the patterns match lines found later in the file. Furthermore, if one of these three `CHECK:` directives fail, `FileCheck` will recover by continuing to the next block, allowing multiple test failures to be detected in a single invocation.

There is no requirement that `CHECK-LABEL:` directives contain strings that correspond to actual syntactic labels in a source or output language: they must simply uniquely match a single line in the file being verified.

`CHECK-LABEL:` directives cannot contain variable definitions or uses.

FileCheck Regex Matching Syntax

All `FileCheck` directives take a pattern to match. For most uses of `FileCheck`, fixed string matching is perfectly sufficient. For some things, a more flexible form of matching is desired. To support this, `FileCheck` allows you to specify regular expressions in matching strings, surrounded by double braces: `{{yourregex}}`. `FileCheck` implements a POSIX regular expression matcher; it supports Extended POSIX regular expressions (ERE). Because we want to use fixed string matching for a majority of what we do, `FileCheck` has been designed to support mixing and matching fixed string matching with regular expressions. This allows you to write things like this:

```
; CHECK: movhpd      {{{[0-9]+}}}(%esp), {{{xmm[0-7]}}}
```

In this case, any offset from the ESP register will be allowed, and any xmm register will be allowed.

Because regular expressions are enclosed with double braces, they are visually distinct, and you don't need to use escape characters within the double braces like you would in C. In the rare case that you want to match double braces explicitly from the input, you can use something ugly like `{{[{}][{}]}}` as your pattern.

FileCheck String Substitution Blocks

It is often useful to match a pattern and then verify that it occurs again later in the file. For codegen tests, this can be useful to allow any register, but verify that that register is used consistently later. To do this, **FileCheck** supports string substitution blocks that allow string variables to be defined and substituted into patterns. Here is a simple example:

```
; CHECK: test5:
; CHECK:      notw      [[REGISTER:%[a-z]+]]
; CHECK:      andw      {{.*}} [[REGISTER]]
```

The first check line matches a regex `%[a-z]+` and captures it into the string variable `REGISTER`. The second line verifies that whatever is in `REGISTER` occurs later in the file after an `"andw"`. **FileCheck** string substitution blocks are always contained in `[[]]` pairs, and string variable names can be formed with the regex `[a-zA-Z_][a-zA-Z0-9_]*`. If a colon follows the name, then it is a definition of the variable; otherwise, it is a substitution.

FileCheck variables can be defined multiple times, and substitutions always get the latest value. Variables can also be substituted later on the same line they were defined on. For example:

```
; CHECK: op [[REG:r[0-9]+]], [[REG]]
```

Can be useful if you want the operands of `op` to be the same register, and don't care exactly which register it is.

If `--enable-var-scope` is in effect, variables with names that start with `$` are considered to be global. All others variables are local. All local variables get undefined at the beginning of each `CHECK-LABEL` block. Global variables are not affected by `CHECK-LABEL`. This makes it easier to ensure that individual tests are not affected by variables set in preceding tests.

FileCheck Numeric Substitution Blocks

FileCheck also supports numeric substitution blocks that allow defining numeric variables and checking for numeric values that satisfy a numeric expression constraint based on those variables via a numeric substitution. This allows `CHECK:` directives to verify a numeric relation between two numbers, such as the need for consecutive registers to be used.

The syntax to define a numeric variable is `[[#<NUMVAR>:]]` where `<NUMVAR>` is the name of the numeric variable to define to the matching value.

For example:

```
; CHECK: mov r[[#REG:]], 42
```

would match `mov r5, 42` and set `REG` to the value 5.

The syntax of a numeric substitution is `[[#<expr>]]` where `<expr>` is an expression. An expression is recursively defined as:

- a numeric operand, or
- an expression followed by an operator and a numeric operand.

A numeric operand is a previously defined numeric variable, or an integer literal. The supported operators are `+` and `-`. Spaces are accepted before, after and between any of these elements.

For example:

```
; CHECK: load r[[#REG:]], [r0]
; CHECK: load r[[#REG+1]], [r1]
```

The above example would match the text:

```
load r5, [r0]
load r6, [r1]
```

but would not match the text:

```
load r5, [r0]
load r7, [r1]
```

due to 7 being unequal to $5 + 1$.

The `--enable-var-scope` option has the same effect on numeric variables as on string variables.

Important note: In its current implementation, an expression cannot use a numeric variable defined on the same line.

FileCheck Pseudo Numeric Variables

Sometimes there's a need to verify output that contains line numbers of the match file, e.g. when testing compiler diagnostics. This introduces a certain fragility of the match file structure, as "CHECK:" lines contain absolute line numbers in the same file, which have to be updated whenever line numbers change due to text addition or deletion.

To support this case, FileCheck expressions understand the `@LINE` pseudo numeric variable which evaluates to the line number of the CHECK pattern where it is found.

This way match patterns can be put near the relevant test lines and include relative line number references, for example:

```
// CHECK: test.cpp:[[# @LINE + 4]]:6: error: expected ';' after top level declarator
// CHECK-NEXT: {{^int a}}
// CHECK-NEXT: {{^    \^}}
// CHECK-NEXT: {{^    ;}}
int a
```

To support legacy uses of `@LINE` as a special string variable, **FileCheck** also accepts the following uses of `@LINE` with string substitution block syntax: `[@@LINE]`, `[@@LINE+<offset>]` and `[@@LINE-<offset>]` without any spaces inside the brackets and where `offset` is an integer.

Matching Newline Characters

To match newline characters in regular expressions the character class `[[:space:]]` can be used. For example, the following pattern:

```
// CHECK: DW_AT_location [DW_FORM_sec_offset] ([DLOC:0x[0-9a-f]+]){{[[:space:]].*}}
↪ "intd"
```

matches output of the form (from `llvm-dwarfdump`):

```
DW_AT_location [DW_FORM_sec_offset]    (0x00000233)
DW_AT_name [DW_FORM_strp]    ( .debug_str[0x000000c9] = "intd")
```

letting us set the **FileCheck** variable `DLOC` to the desired value `0x00000233`, extracted from the line immediately preceding "intd".

tblgen - Target Description To C++ Code Generator

SYNOPSIS

tblgen [*options*] [*filename*]

DESCRIPTION

tblgen translates from target description (`.td`) files into C++ code that can be included in the definition of an LLVM target library. Most users of LLVM will not need to use this program. It is only for assisting with writing an LLVM target backend.

The input and output of **tblgen** is beyond the scope of this short introduction; please see the [introduction to TableGen](#).

The *filename* argument specifies the name of a Target Description (`.td`) file to read as input.

OPTIONS

-help

Print a summary of command line options.

-o *filename*

Specify the output file name. If *filename* is `-`, then **tblgen** sends its output to standard output.

-I *directory*

Specify where to find other target description files for inclusion. The *directory* value should be a full or partial path to a directory that contains target description files.

-asmparsernum *N*

Make -gen-asm-parser emit assembly writer number *N*.

-asmwriternum *N*

Make -gen-asm-writer emit assembly writer number *N*.

-class *className*

Print the enumeration list for this class.

-print-records

Print all records to standard output (default).

-dump-json

Print a JSON representation of all records, suitable for further automated processing.

-print-enums

Print enumeration values for a class.

-print-sets

Print expanded sets for testing DAG exprs.

-gen-emitter

Generate machine code emitter.

-gen-register-info

Generate registers and register classes info.

-gen-instr-info

Generate instruction descriptions.

-gen-asm-writer
Generate the assembly writer.

-gen-disassembler
Generate disassembler.

-gen-pseudo-lowering
Generate pseudo instruction lowering.

-gen-dag-isel
Generate a DAG (Directed Acycle Graph) instruction selector.

-gen-asm-matcher
Generate assembly instruction matcher.

-gen-dfa-packetizer
Generate DFA Packetizer for VLIW targets.

-gen-fast-isel
Generate a "fast" instruction selector.

-gen-subtarget
Generate subtarget enumerations.

-gen-intrinsic-enums
Generate intrinsic enums.

-gen-intrinsic-impl
Generate intrinsic implementation.

-gen-tgt-intrinsic
Generate target intrinsic information.

-gen-enhanced-disassembly-info
Generate enhanced disassembly info.

-gen-exegesis
Generate llvm-exegesis tables.

-version
Show the version number of this program.

EXIT STATUS

If **tblgen** succeeds, it will exit with 0. Otherwise, if an error occurs, it will exit with a non-zero value.

lit - LLVM Integrated Tester

SYNOPSIS

lit [*options*] [*tests*]

DESCRIPTION

lit is a portable tool for executing LLVM and Clang style test suites, summarizing their results, and providing indication of failures. **lit** is designed to be a lightweight testing tool with as simple a user interface as possible.

lit should be run with one or more *tests* to run specified on the command line. Tests can be either individual test files or directories to search for tests (see [TEST DISCOVERY](#)).

Each specified test will be executed (potentially in parallel) and once all tests have been run **lit** will print summary information on the number of tests which passed or failed (see [TEST STATUS RESULTS](#)). The **lit** program will execute with a non-zero exit code if any tests fail.

By default **lit** will use a succinct progress display and will only print summary information for test failures. See [OUTPUT OPTIONS](#) for options controlling the **lit** progress display and output.

lit also includes a number of options for controlling how tests are executed (specific features may depend on the particular test format). See [EXECUTION OPTIONS](#) for more information.

Finally, **lit** also supports additional options for only running a subset of the options specified on the command line, see [SELECTION OPTIONS](#) for more information.

lit parses options from the environment variable `LIT_OPTS` after parsing options from the command line. `LIT_OPTS` is primarily useful for supplementing or overriding the command-line options supplied to **lit** by check targets defined by a project's build system.

Users interested in the **lit** architecture or designing a **lit** testing implementation should see [LIT INFRASTRUCTURE](#).

GENERAL OPTIONS

-h, --help

Show the **lit** help message.

-j N, --threads=N

Run *N* tests in parallel. By default, this is automatically chosen to match the number of detected available CPUs.

--config-prefix=NAME

Search for *NAME.cfg* and *NAME.site.cfg* when searching for test suites, instead of *lit.cfg* and *lit.site.cfg*.

-D NAME[=VALUE], --param NAME[=VALUE]

Add a user defined parameter *NAME* with the given *VALUE* (or the empty string if not given). The meaning and use of these parameters is test suite dependent.

OUTPUT OPTIONS

-q, --quiet

Suppress any output except for test failures.

-s, --succinct

Show less output, for example don't show information on tests that pass.

-v, --verbose

Show more information on test failures, for example the entire test output instead of just the test result.

-vv, --echo-all-commands

Echo all commands to stdout, as they are being executed. This can be valuable for debugging test failures, as the last echoed command will be the one which has failed. **lit** normally inserts a no-op command (`:` in the

case of `bash`) with argument `'RUN: at line N'` before each command pipeline, and this option also causes those no-op commands to be echoed to `stdout` to help you locate the source line of the failed command. This option implies `--verbose`.

-a, --show-all

Show more information about all tests, for example the entire test commandline and output.

--no-progress-bar

Do not use curses based progress bar.

--show-unsupported

Show the names of unsupported tests.

--show-xfail

Show the names of tests that were expected to fail.

EXECUTION OPTIONS

--path=PATH

Specify an additional `PATH` to use when searching for executables in tests.

--vg

Run individual tests under `valgrind` (using the `memcheck` tool). The `--error-exitcode` argument for `valgrind` is used so that `valgrind` failures will cause the program to exit with a non-zero status.

When this option is enabled, `lit` will also automatically provide a "valgrind" feature that can be used to conditionally disable (or expect failure in) certain tests.

--vg-arg=ARG

When `--vg` is used, specify an additional argument to pass to `valgrind` itself.

--vg-leak

When `--vg` is used, enable memory leak checks. When this option is enabled, `lit` will also automatically provide a "vg_leak" feature that can be used to conditionally disable (or expect failure in) certain tests.

--time-tests

Track the wall time individual tests take to execute and includes the results in the summary output. This is useful for determining which tests in a test suite take the most time to execute. Note that this option is most useful with `-j 1`.

SELECTION OPTIONS

--max-tests=N

Run at most `N` tests and then terminate.

--max-time=N

Spend at most `N` seconds (approximately) running tests and then terminate.

--shuffle

Run the tests in a random order.

--num-shards=M

Divide the set of selected tests into `M` equal-sized subsets or "shards", and run only one of them. Must be used with the `--run-shard=N` option, which selects the shard to run. The environment variable `LIT_NUM_SHARDS` can also be used in place of this option. These two options provide a coarse mechanism for partitioning large test suites, for parallel execution on separate machines (say in a large testing farm).

--run-shard=N

Select which shard to run, assuming the `--num-shards=M` option was provided. The two options must be used together, and the value of `N` must be in the range `1..M`. The environment variable `LIT_RUN_SHARD` can also be used in place of this option.

--filter=REGEXP

Run only those tests whose name matches the regular expression specified in `REGEXP`. The environment variable `LIT_FILTER` can be also used in place of this option, which is especially useful in environments where the call to `lit` is issued indirectly.

ADDITIONAL OPTIONS

--debug

Run `lit` in debug mode, for debugging configuration issues and `lit` itself.

--show-suites

List the discovered test suites and exit.

--show-tests

List all of the discovered tests and exit.

EXIT STATUS

`lit` will exit with an exit code of 1 if there are any FAIL or XPASS results. Otherwise, it will exit with the status 0. Other exit codes are used for non-test related failures (for example a user error or an internal program error).

TEST DISCOVERY

The inputs passed to `lit` can be either individual tests, or entire directories or hierarchies of tests to run. When `lit` starts up, the first thing it does is convert the inputs into a complete list of tests to run as part of *test discovery*.

In the `lit` model, every test must exist inside some *test suite*. `lit` resolves the inputs specified on the command line to test suites by searching upwards from the input path until it finds a `lit.cfg` or `lit.site.cfg` file. These files serve as both a marker of test suites and as configuration files which `lit` loads in order to understand how to find and run the tests inside the test suite.

Once `lit` has mapped the inputs into test suites it traverses the list of inputs adding tests for individual files and recursively searching for tests in directories.

This behavior makes it easy to specify a subset of tests to run, while still allowing the test suite configuration to control exactly how tests are interpreted. In addition, `lit` always identifies tests by the test suite they are in, and their relative path inside the test suite. For appropriately configured projects, this allows `lit` to provide convenient and flexible support for out-of-tree builds.

TEST STATUS RESULTS

Each test ultimately produces one of the following six results:

PASS

The test succeeded.

XFAIL

The test failed, but that is expected. This is used for test formats which allow specifying that a test does not currently work, but wish to leave it in the test suite.

XPASS

The test succeeded, but it was expected to fail. This is used for tests which were specified as expected to fail, but are now succeeding (generally because the feature they test was broken and has been fixed).

FAIL

The test failed.

UNRESOLVED

The test result could not be determined. For example, this occurs when the test could not be run, the test itself is invalid, or the test was interrupted.

UNSUPPORTED

The test is not supported in this environment. This is used by test formats which can report unsupported tests.

Depending on the test format tests may produce additional information about their status (generally only for failures). See the *OUTPUT OPTIONS* section for more information.

LIT INFRASTRUCTURE

This section describes the **lit** testing architecture for users interested in creating a new **lit** testing implementation, or extending an existing one.

lit proper is primarily an infrastructure for discovering and running arbitrary tests, and to expose a single convenient interface to these tests. **lit** itself doesn't know how to run tests, rather this logic is defined by *test suites*.

TEST SUITES

As described in *TEST DISCOVERY*, tests are always located inside a *test suite*. Test suites serve to define the format of the tests they contain, the logic for finding those tests, and any additional information to run the tests.

lit identifies test suites as directories containing `lit.cfg` or `lit.site.cfg` files (see also *--config-prefix*). Test suites are initially discovered by recursively searching up the directory hierarchy for all the input files passed on the command line. You can use *--show-suites* to display the discovered test suites at startup.

Once a test suite is discovered, its config file is loaded. Config files themselves are Python modules which will be executed. When the config file is executed, two important global variables are predefined:

lit_config

The global **lit** configuration object (a *LitConfig* instance), which defines the builtin test formats, global configuration parameters, and other helper routines for implementing test configurations.

config

This is the config object (a *TestingConfig* instance) for the test suite, which the config file is expected to populate. The following variables are also available on the *config* object, some of which must be set by the config and others are optional or predefined:

name [*required*] The name of the test suite, for use in reports and diagnostics.

test_format [*required*] The test format object which will be used to discover and run tests in the test suite. Generally this will be a builtin test format available from the *lit.formats* module.

test_source_root The filesystem path to the test suite root. For out-of-dir builds this is the directory that will be scanned for tests.

test_exec_root For out-of-dir builds, the path to the test suite root inside the object directory. This is where tests will be run and temporary output files placed.

environment A dictionary representing the environment to use when executing tests in the suite.

suffixes For **lit** test formats which scan directories for tests, this variable is a list of suffixes to identify test files. Used by: *ShTest*.

substitutions For **lit** test formats which substitute variables into a test script, the list of substitutions to perform. Used by: *ShTest*.

unsupported Mark an unsupported directory, all tests within it will be reported as unsupported. Used by: *ShTest*.

parent The parent configuration, this is the config object for the directory containing the test suite, or None.

root The root configuration. This is the top-most **lit** configuration in the project.

pipefail Normally a test using a shell pipe fails if any of the commands on the pipe fail. If this is not desired, setting this variable to false makes the test fail only if the last command in the pipe fails.

available_features A set of features that can be used in *XFAIL*, *REQUIRES*, and *UNSUPPORTED* directives.

TEST DISCOVERY

Once test suites are located, **lit** recursively traverses the source directory (following *test_source_root*) looking for tests. When **lit** enters a sub-directory, it first checks to see if a nested test suite is defined in that directory. If so, it loads that test suite recursively, otherwise it instantiates a local test config for the directory (see [LOCAL CONFIGURATION FILES](#)).

Tests are identified by the test suite they are contained within, and the relative path inside that suite. Note that the relative path may not refer to an actual file on disk; some test formats (such as *GoogleTest*) define "virtual tests" which have a path that contains both the path to the actual test file and a subpath to identify the virtual test.

LOCAL CONFIGURATION FILES

When **lit** loads a subdirectory in a test suite, it instantiates a local test configuration by cloning the configuration for the parent directory --- the root of this configuration chain will always be a test suite. Once the test configuration is cloned **lit** checks for a *lit.local.cfg* file in the subdirectory. If present, this file will be loaded and can be used to specialize the configuration for each individual directory. This facility can be used to define subdirectories of optional tests, or to change other configuration parameters --- for example, to change the test format, or the suffixes which identify test files.

PRE-DEFINED SUBSTITUTIONS

lit provides various patterns that can be used with the RUN command. These are defined in TestRunner.py. The base set of substitutions are:

Macro	Substitution
%s	source path (path to the file currently being run)
%S	source dir (directory of the file currently being run)
%p	same as %S
{%pathsep}	path separator
%t	temporary file name unique to the test
%T	parent directory of %t (not unique, deprecated, do not use)
%%	%

Other substitutions are provided that are variations on this base set and further substitution patterns can be defined by each test module. See the modules [LOCAL CONFIGURATION FILES](#).

More detailed information on substitutions can be found in the *LLVM Testing Infrastructure Guide*.

TEST RUN OUTPUT FORMAT

The **lit** output for a test run conforms to the following schema, in both short and verbose modes (although in short mode no PASS lines will be shown). This schema has been chosen to be relatively easy to reliably parse by a machine (for example in buildbot log scraping), and for other tools to generate.

Each test result is expected to appear on a line that matches:

```
<result code>: <test name> (<progress info>)
```

where `<result-code>` is a standard test result such as PASS, FAIL, XFAIL, XPASS, UNRESOLVED, or UNSUPPORTED. The performance result codes of IMPROVED and REGRESSED are also allowed.

The `<test name>` field can consist of an arbitrary string containing no newline.

The `<progress info>` field can be used to report progress information such as (1/300) or can be empty, but even when empty the parentheses are required.

Each test result may include additional (multiline) log information in the following format:

```
<log delineator> TEST '(<test name>)' <trailing delineator>
... log message ...
<log delineator>
```

where `<test name>` should be the name of a preceding reported test, `<log delineator>` is a string of `"*"` characters *at least* four characters long (the recommended length is 20), and `<trailing delineator>` is an arbitrary (unparsed) string.

The following is an example of a test run output which consists of four tests A, B, C, and D, and a log message for the failing test C:

```
PASS: A (1 of 4)
PASS: B (2 of 4)
FAIL: C (3 of 4)
***** TEST 'C' FAILED *****
Test 'C' failed as a result of exit code 1.
*****
PASS: D (4 of 4)
```

LIT EXAMPLE TESTS

The `lit` distribution contains several example implementations of test suites in the *ExampleTests* directory.

llvm-build - LLVM Project Build Utility

SYNOPSIS

llvm-build [*options*]

DESCRIPTION

llvm-build is a tool for working with LLVM projects that use the LLVMBuild system for describing their components.

At heart, **llvm-build** is responsible for loading, verifying, and manipulating the project's component data. The tool is primarily designed for use in implementing build systems and tools which need access to the project structure information.

OPTIONS

-h, --help

Print the builtin program help.

--source-root=PATH

If given, load the project at the given source root path. If this option is not given, the location of the project sources will be inferred from the location of the **llvm-build** script itself.

--print-tree

Print the component tree for the project.

--write-library-table

Write out the C++ fragment which defines the components, library names, and required libraries. This C++ fragment is built into `llvm-config` in order to provide clients with the list of required libraries for arbitrary component combinations.

--write-llvmbuild

Write out new *LLVMBuild.txt* files based on the loaded components. This is useful for auto-upgrading the schema of the files. **llvm-build** will try to a limited extent to preserve the comments which were written in the original source file, although at this time it only preserves block comments that precede the section names in the *LLVMBuild* files.

--write-cmake-fragment

Write out the LLVMBuild in the form of a CMake fragment, so it can easily be consumed by the CMake based build system. The exact contents and format of this file are closely tied to how LLVMBuild is integrated with CMake, see LLVM's top-level CMakeLists.txt.

--write-make-fragment

Write out the LLVMBuild in the form of a Makefile fragment, so it can easily be consumed by a Make based build system. The exact contents and format of this file are closely tied to how LLVMBuild is integrated with the Makefiles, see LLVM's Makefile.rules.

--llvmbuild-source-root=PATH

If given, expect the *LLVMBuild* files for the project to be rooted at the given path, instead of inside the source tree itself. This option is primarily designed for use in conjunction with **--write-llvmbuild** to test changes to *LLVMBuild* schema.

EXIT STATUS

llvm-build exits with 0 if operation was successful. Otherwise, it will exist with a non-zero value.

llvm-exegesis - LLVM Machine Instruction Benchmark

SYNOPSIS

llvm-exegesis [*options*]

DESCRIPTION

llvm-exegesis is a benchmarking tool that uses information available in LLVM to measure host machine instruction characteristics like latency, throughput, or port decomposition.

Given an LLVM opcode name and a benchmarking mode, **llvm-exegesis** generates a code snippet that makes execution as serial (resp. as parallel) as possible so that we can measure the latency (resp. inverse throughput/uop decomposition) of the instruction. The code snippet is jitted and executed on the host subtarget. The time taken (resp. resource usage) is measured using hardware performance counters. The result is printed out as YAML to the standard output.

The main goal of this tool is to automatically (in)validate the LLVM's TableDef scheduling models. To that end, we also provide analysis of the results.

llvm-exegesis can also benchmark arbitrary user-provided code snippets.

EXAMPLE 1: benchmarking instructions

Assume you have an X86-64 machine. To measure the latency of a single instruction, run:

```
$ llvm-exegesis -mode=latency -opcode-name=ADD64rr
```

Measuring the uop decomposition or inverse throughput of an instruction works similarly:

```
$ llvm-exegesis -mode=uops -opcode-name=ADD64rr
$ llvm-exegesis -mode=inverse_throughput -opcode-name=ADD64rr
```

The output is a YAML document (the default is to write to stdout, but you can redirect the output to a file using *-benchmarks-file*):

```
---
key:
  opcode_name:      ADD64rr
  mode:             latency
  config:           ''
cpu_name:          haswell
llvm_triple:       x86_64-unknown-linux-gnu
num_repetitions:   10000
measurements:
  - { key: latency, value: 1.0058, debug_string: '' }
error:             ''
info:              'explicit self cycles, selecting one aliasing configuration.
Snippet:
ADD64rr R8, R8, R10
'
...
```

To measure the latency of all instructions for the host architecture, run:

```
#!/bin/bash
readonly INSTRUCTIONS=$((($(grep INSTRUCTION_LIST_END build/lib/Target/X86/
↪X86GenInstrInfo.inc | cut -f2 -d=) - 1))
for INSTRUCTION in $(seq 1 ${INSTRUCTIONS});
do
  ./build/bin/llvm-exegesis -mode=latency -opcode-index=${INSTRUCTION} | sed -n '/---/
↪,$p'
done
```

FIXME: Provide an **llvm-exegesis** option to test all instructions.

EXAMPLE 2: benchmarking a custom code snippet

To measure the latency/uops of a custom piece of code, you can specify the *snippets-file* option (- reads from standard input).

```
$ echo "vzeroupper" | llvm-exegesis -mode=uops -snippets-file=-
```

Real-life code snippets typically depend on registers or memory. **llvm-exegesis** checks the liveness of registers (i.e. any register use has a corresponding def or is a "live in"). If your code depends on the value of some registers, you have two options:

- Mark the register as requiring a definition. **llvm-exegesis** will automatically assign a value to the register. This can be done using the directive *LLVM-EXEGESIS-DEFREG* *<reg name>* *<hex_value>*, where

<hex_value> is a bit pattern used to fill <reg_name>. If <hex_value> is smaller than the register width, it will be sign-extended.

- Mark the register as a "live in". **llvm-exegesis** will benchmark using whatever value was in this registers on entry. This can be done using the directive *LLVM-EXEGESIS-LIVEIN* <reg name>.

For example, the following code snippet depends on the values of XMM1 (which will be set by the tool) and the memory buffer passed in RDI (live in).

```
# LLVM-EXEGESIS-LIVEIN RDI
# LLVM-EXEGESIS-DEFREG XMM1 42
vmulps      (%rdi), %xmm1, %xmm2
vhaddps     %xmm2, %xmm2, %xmm3
addq $0x10, %rdi
```

EXAMPLE 3: analysis

Assuming you have a set of benchmarked instructions (either latency or uops) as YAML in file */tmp/benchmarks.yaml*, you can analyze the results using the following command:

```
$ llvm-exegesis -mode=analysis \
-benchmarks-file=/tmp/benchmarks.yaml \
-analysis-clusters-output-file=/tmp/clusters.csv \
-analysis-inconsistencies-output-file=/tmp/inconsistencies.html
```

This will group the instructions into clusters with the same performance characteristics. The clusters will be written out to */tmp/clusters.csv* in the following format:

```
cluster_id,opcode_name,config,sched_class
...
2,ADD32ri8_DB,,WriteALU,1.00
2,ADD32ri_DB,,WriteALU,1.01
2,ADD32rr,,WriteALU,1.01
2,ADD32rr_DB,,WriteALU,1.00
2,ADD32rr_REV,,WriteALU,1.00
2,ADD64i32,,WriteALU,1.01
2,ADD64ri32,,WriteALU,1.01
2,MOV64rr32,,BSWAP32r_BSWAP64r_MOV64rr32,1.00
2,VPADDQYrr,,VPADDBYrr_VPADDDYrr_VPADQYrr_VPADWYrr_VPSUBBYrr_VPSBDYrr_VPSUBQYrr_
↳VPSUBWYrr,1.02
2,VPSUBQYrr,,VPADDBYrr_VPADDDYrr_VPADQYrr_VPADWYrr_VPSUBBYrr_VPSBDYrr_VPSUBQYrr_
↳VPSUBWYrr,1.01
2,ADD64ri8,,WriteALU,1.00
2,SETBr,,WriteSETCC,1.01
...
```

llvm-exegesis will also analyze the clusters to point out inconsistencies in the scheduling information. The output is an html file. For example, */tmp/inconsistencies.html* will contain messages like the following :

Sched Class `EXTRACTPSrr_VEXTRACTPSrr` contains instructions with distinct performance characteristics, falling into 2 clusters:

ClusterId	Opcode/Config	latency
3	VEXTRACTPSrr	2.01
4	EXTRACTPSrr	3.00

llvm data:

Valid	Variant	uOps	Latency	WriteProcRes
✓	×	2	2	BWPort0: 1 BWPort5: 1

Note that the scheduling class names will be resolved only when `llvm-exegesis` is compiled in debug mode, else only the class id will be shown. This does not invalidate any of the analysis results though.

OPTIONS

-help

Print a summary of command line options.

-opcode-index=<LLVM opcode index>

Specify the opcode to measure, by index. See example 1 for details. Either *opcode-index*, *opcode-name* or *snippets-file* must be set.

-opcode-name=<opcode name 1>,<opcode name 2>,...

Specify the opcode to measure, by name. Several opcodes can be specified as a comma-separated list. See example 1 for details. Either *opcode-index*, *opcode-name* or *snippets-file* must be set.

-snippets-file=<filename>

Specify the custom code snippet to measure. See example 2 for details. Either *opcode-index*, *opcode-name* or *snippets-file* must be set.

-mode=[latency|uops|inverse_throughput|analysis]

Specify the run mode. Note that if you pick *analysis* mode, you also need to specify at least one of the *-analysis-clusters-output-file=* and *-analysis-inconsistencies-output-file=*.

-num-repetitions=<Number of repetition>

Specify the number of repetitions of the asm snippet. Higher values lead to more accurate measurements but lengthen the benchmark.

-benchmarks-file=</path/to/file>

File to read (*analysis* mode) or write (*latency/uops/inverse_throughput* modes) benchmark results. "-" uses stdin/stdout.

-analysis-clusters-output-file=</path/to/file>

If provided, write the analysis clusters as CSV to this file. "-" prints to stdout. By default, this analysis is not run.

-analysis-inconsistencies-output-file=</path/to/file>

If non-empty, write inconsistencies found during analysis to this file. - prints to stdout. By default, this analysis is not run.

-analysis-clustering=[dbscan,naive]

Specify the clustering algorithm to use. By default DBSCAN will be used. Naive clustering algorithm is better for doing further work on the *-analysis-inconsistencies-output-file=* output, it will create one cluster per opcode, and check that the cluster is stable (all points are neighbours).

- analysis-numpoints**=<dbscan numPoints parameter>
Specify the numPoints parameters to be used for DBSCAN clustering (*analysis* mode, DBSCAN only).
- analysis-clustering-epsilon**=<dbscan epsilon parameter>
Specify the epsilon parameter used for clustering of benchmark points (*analysis* mode).
- analysis-inconsistency-epsilon**=<epsilon>
Specify the epsilon parameter used for detection of when the cluster is different from the LLVM schedule profile values (*analysis* mode).
- analysis-display-unstable-clusters**
If there is more than one benchmark for an opcode, said benchmarks may end up not being clustered into the same cluster if the measured performance characteristics are different. by default all such opcodes are filtered out. This flag will instead show only such unstable opcodes.
- ignore-invalid-sched-class**=false
If set, ignore instructions that do not have a sched class (class idx = 0).
- mcpu**=<cpu name>
If set, measure the cpu characteristics using the counters for this CPU. This is useful when creating new sched models (the host CPU is unknown to LLVM).
- dump-object-to-disk**=true
By default, llvm-exegesis will dump the generated code to a temporary file to enable code inspection. You may disable it to speed up the execution and save disk space.

EXIT STATUS

llvm-exegesis returns 0 on success. Otherwise, an error message is printed to standard error, and the tool returns a non 0 value.

Synopsis

llvm-pdbutil [*subcommand*] [*options*]

Description

Display types, symbols, CodeView records, and other information from a PDB file, as well as manipulate and create PDB files. **llvm-pdbutil** is normally used by FileCheck-based tests to test LLVM's PDB reading and writing functionality, but can also be used for general PDB file investigation and forensics, or as a replacement for cvdump.

Subcommands

llvm-pdbutil is separated into several subcommands each tailored to a different purpose. A brief summary of each command follows, with more detail in the sections that follow.

- *pretty* - Dump symbol and type information in a format that tries to look as much like the original source code as possible.
- *dump* - Dump low level types and structures from the PDB file, including CodeView records, hash tables, PDB streams, etc.
- *bytes* - Dump data from the PDB file's streams, records, types, symbols, etc as raw bytes.
- *yaml2pdb* - Given a yaml description of a PDB file, produce a valid PDB file that matches that description.
- *pdb2yaml* - For a given PDB file, produce a YAML description of some or all of the file in a way that the PDB can be reconstructed.
- *merge* - Given two PDBs, produce a third PDB that is the result of merging the two input PDBs.

pretty

Important: The **pretty** subcommand is built on the Windows DIA SDK, and as such is not supported on non-Windows platforms.

USAGE: **llvm-pdbutil** pretty [*options*] <input PDB file>

Summary

The *pretty* subcommand displays a very high level representation of your program's debug info. Since it is built on the Windows DIA SDK which is the standard API that Windows tools and debuggers query debug information, it presents a more authoritative view of how a debugger is going to interpret your debug information than a mode which displays low-level CodeView records.

Options

Filtering and Sorting Options

Note: *exclude* filters take priority over *include* filters. So if a filter matches both an include and an exclude rule, then it is excluded.

-exclude-compilands=<string>

When dumping compilands, compiland source-file contributions, or per-compiland symbols, this option instructs **llvm-pdbutil** to omit any compilands that match the specified regular expression.

-exclude-symbols=<string>

When dumping global, public, or per-compiland symbols, this option instructs **llvm-pdbutil** to omit any symbols that match the specified regular expression.

-exclude-types=<string>

When dumping types, this option instructs `llvm-pdbutil` to omit any types that match the specified regular expression.

-include-compilands=<string>

When dumping compilands, compiland source-file contributions, or per-compiland symbols, limit the initial search to only those compilands that match the specified regular expression.

-include-symbols=<string>

When dumping global, public, or per-compiland symbols, limit the initial search to only those symbols that match the specified regular expression.

-include-types=<string>

When dumping types, limit the initial search to only those types that match the specified regular expression.

-min-class-padding=<uint>

Only display types that have at least the specified amount of alignment padding, accounting for padding in base classes and aggregate field members.

-min-class-padding-imm=<uint>

Only display types that have at least the specified amount of alignment padding, ignoring padding in base classes and aggregate field members.

-min-type-size=<uint>

Only display types T where `sizeof(T)` is greater than or equal to the specified amount.

-no-compiler-generated

Don't show compiler generated types and symbols

-no-enum-definitions

When dumping an enum, don't show the full enum (e.g. the individual enumerator values).

-no-system-libs

Don't show symbols from system libraries

Symbol Type Options

-all

Implies all other options in this category.

-class-definitions=<format>

Displays class definitions in the specified format.

```
=all      - Display all class members including data, constants, typedefs, ↵  
↪functions, etc (default)  
=layout  - Only display members that contribute to class size.  
=none    - Don't display class definitions (e.g. only display the name and base ↵  
↪list)
```

-class-order

Displays classes in the specified order.

```
=none      - Undefined / no particular sort order (default)  
=name     - Sort classes by name  
=size     - Sort classes by size  
=padding  - Sort classes by amount of padding  
=padding-pct - Sort classes by percentage of space consumed by padding  
=padding-imm - Sort classes by amount of immediate padding  
=padding-pct-imm - Sort classes by percentage of space consumed by immediate ↵  
↪padding
```

(continues on next page)

(continued from previous page)

-class-recurse-depth=<uint>

When dumping class definitions, stop after recursing the specified number of times. The default is 0, which is no limit.

-classes

Display classes

-compilands

Display compilands (e.g. object files)

-enums

Display enums

-externals

Dump external (e.g. exported) symbols

-globals

Dump global symbols

-lines

Dump the mappings between source lines and code addresses.

-module-syms

Display symbols (variables, functions, etc) for each compiland

-sym-types=<types>

Type of symbols to dump when -globals, -externals, or -module-syms is specified. (default all)

```
=thunks - Display thunk symbols
=data   - Display data symbols
=funcs  - Display function symbols
=all    - Display all symbols (default)
```

-symbol-order=<order>

For symbols dumped via the -module-syms, -globals, or -externals options, sort the results in specified order.

```
=none - Undefined / no particular sort order
=name - Sort symbols by name
=size - Sort symbols by size
```

-typedefs

Display typedef types

-types

Display all types (implies -classes, -enums, -typedefs)

Other Options**-color-output**

Force color output on or off. By default, color if used if outputting to a terminal.

-load-address=<uint>

When displaying relative virtual addresses, assume the process is loaded at the given address and display what would be the absolute address.

dump

USAGE: `llvm-pdbutil dump [options] <input PDB file>`

Summary

The **dump** subcommand displays low level information about the structure of a PDB file. It is used heavily by LLVM's testing infrastructure, but can also be used for PDB forensics. It serves a role similar to that of Microsoft's *cvdump* tool.

Note: The **dump** subcommand exposes internal details of the file format. As such, the reader should be familiar with *The PDB File Format* before using this command.

Options

MSF Container Options

-streams

dump a summary of all of the streams in the PDB file.

-stream-blocks

In conjunction with *-streams*, add information to the output about what blocks the specified stream occupies.

-summary

Dump MSF and PDB header information.

Module & File Options

-modi=<uint>

For all options that dump information from each module/compiland, limit to the specified module.

-files

Dump the source files that contribute to each displayed module.

-il

Dump inlinee line information (DEBUG_S_INLINEELINES CodeView subsection)

-l

Dump line information (DEBUG_S_LINES CodeView subsection)

-modules

Dump compiland information

-xme

Dump cross module exports (DEBUG_S_CROSSSCOPEEXPORTS CodeView subsection)

-xmi

Dump cross module imports (DEBUG_S_CROSSSCOPEIMPORTS CodeView subsection)

Symbol Options

- globals**
dump global symbol records
- global-extras**
dump additional information about the globals, such as hash buckets and hash values.
- publics**
dump public symbol records
- public-extras**
dump additional information about the publics, such as hash buckets and hash values.
- symbols**
dump symbols (functions, variables, etc) for each module dumped.
- sym-data**
For each symbol record dumped as a result of the *-symbols* option, display the full bytes of the record in binary as well.

Type Record Options

- types**
Dump CodeView type records from TPI stream
- type-extras**
Dump additional information from the TPI stream, such as hashes and the type index offsets array.
- type-data**
For each type record dumped, display the full bytes of the record in binary as well.
- type-index=<uint>**
Only dump types with the specified type index.
- ids**
Dump CodeView type records from IPI stream.
- id-extras**
Dump additional information from the IPI stream, such as hashes and the type index offsets array.
- id-data**
For each ID record dumped, display the full bytes of the record in binary as well.
- id-index=<uint>**
only dump ID records with the specified hexadecimal type index.
- dependents**
When used in conjunction with *-type-index* or *-id-index*, dumps the entire dependency graph for the specified index instead of just the single record with the specified index. For example, if type index 0x4000 is a function whose return type has index 0x3000, and you specify *-dependents=0x4000*, then this would dump both records (as well as any other dependents in the tree).

Miscellaneous Options

- all**
Implies most other options.
- section-contribs**
Dump section contributions.
- section-headers**
Dump image section headers.
- section-map**
Dump section map.
- string-table**
Dump PDB string table.

bytes

USAGE: **llvm-pdbutil** bytes [*options*] <input PDB file>

Summary

Like the **dump** subcommand, the **bytes** subcommand displays low level information about the structure of a PDB file, but it is used for even deeper forensics. The **bytes** subcommand finds various structures in a PDB file based on the command line options specified, and dumps them in hex. Someone working on support for emitting PDBs would use this heavily, for example, to compare one PDB against another PDB to ensure byte-for-byte compatibility. It is not enough to simply compare the bytes of an entire file, or an entire stream because it's perfectly fine for the same structure to exist at different locations in two different PDBs, and "finding" the structure is half the battle.

Options

MSF File Options

- block-range**=<start [-end]>
Dump binary data from specified range of MSF file blocks.
- byte-range**=<start [-end]>
Dump binary data from specified range of bytes in the file.
- fpm**
Dump the MSF free page map.
- stream-data**=<string>
Dump binary data from the specified streams. Format is SN[:Start][@Size]. For example, *-stream-data=7:3@12* dumps 12 bytes from stream 7, starting at offset 3 in the stream.

PDB Stream Options

-name-map
Dump bytes of PDB Name Map

DBI Stream Options

-ec
Dump the edit and continue map substream of the DBI stream.

-files
Dump the file info substream of the DBI stream.

-modi
Dump the modi substream of the DBI stream.

-sc
Dump section contributions substream of the DBI stream.

-sm
Dump the section map from the DBI stream.

-type-server
Dump the type server map from the DBI stream.

Module Options

-mod=<uint>
Limit all options in this category to the specified module index. By default, options in this category will dump bytes from all modules.

-chunks
Dump the bytes of each module's C13 debug subsection.

-split-chunks
When specified with *-chunks*, split the C13 debug subsection into a separate chunk for each subsection type, and dump them separately.

-syms
Dump the symbol record substream from each module.

Type Record Options

-id=<uint>
Dump the record from the IPI stream with the given type index.

-type=<uint>
Dump the record from the TPI stream with the given type index.

pdb2yaml

USAGE: `llvm-pdbutil` pdb2yaml [*options*] <input PDB file>

Summary

Options

yaml2pdb

USAGE: `llvm-pdbutil` yaml2pdb [*options*] <input YAML file>

Summary

Generate a PDB file from a YAML description. The YAML syntax is not described here. Instead, use *llvm-pdbutil* *pdb2yaml* and examine the output for an example starting point.

Options

`-pdb=<file-name>`

Write the resulting PDB to the specified file.

merge

USAGE: `llvm-pdbutil` merge [*options*] <input PDB file 1> <input PDB file 2>

Summary

Merge two PDB files into a single file.

Options

`-pdb=<file-name>`

Write the resulting PDB to the specified file.

2.9.1 Overview

Welcome to the LLVM project! In order to get started, you first need to know some basic information.

First, the LLVM project has multiple components. The core of the project is itself called "LLVM". This contains all of the tools, libraries, and header files needed to process an intermediate representation and convert it into object files. It contains an assembler, disassembler, bitcode analyzer and bitcode optimizer. It also contains basic regression tests.

Another piece is the [Clang](#) front end. This component compiles C, C++, Objective C, and Objective C++ code into LLVM bitcode -- and from there into object files, using LLVM.

There are other components as well: the [libc++ C++ standard library](#), the [LLD linker](#), and more.

2.9.2 Getting Started Quickly (A Summary)

The LLVM Getting Started documentation may be out of date. So, the [Clang Getting Started](#) page might also be a good place to start.

Here's the short story for getting up and running quickly with LLVM:

1. Read the documentation.
2. Read the documentation.
3. Remember that you were warned twice about reading the documentation.
4. Checkout LLVM (including related subprojects like Clang):
 - `git clone https://github.com/llvm/llvm-project.git`
 - Or, on windows, `git clone --config core.autocrlf=false https://github.com/llvm/llvm-project.git`
5. Configure and build LLVM and Clang:.
 - `cd llvm-project`
 - `mkdir build`
 - `cd build`
 - `cmake -G <generator> [options] ../llvm`

Some common generators are:

- Ninja --- for generating [Ninja](#) build files. Most llvm developers use Ninja.
- Unix Makefiles --- for generating make-compatible parallel makefiles.
- Visual Studio --- for generating Visual Studio projects and solutions.
- Xcode --- for generating Xcode projects.

Some Common options:

- `-DLLVM_ENABLE_PROJECTS='...'` --- semicolon-separated list of the LLVM subprojects you'd like to additionally build. Can include any of: clang, clang-tools-extra, libcxx, libcxxabi, libunwind, lldb, compiler-rt, lld, polly, or debuginfo-tests.

For example, to build LLVM, Clang, libcxx, and libcxxabi, use `-DLLVM_ENABLE_PROJECTS="clang;libcxx;libcxxabi"`.

- `-DCMAKE_INSTALL_PREFIX=directory` --- Specify for *directory* the full pathname of where you want the LLVM tools and libraries to be installed (default `/usr/local`).

- `-DCMAKE_BUILD_TYPE=type` --- Valid options for *type* are Debug, Release, RelWithDebInfo, and MinSizeRel. Default is Debug.
- `-DLLVM_ENABLE_ASSERTIONS=On` --- Compile with assertion checks enabled (default is Yes for Debug builds, No for all other build types).
- Run your build tool of choice!
 - The default target (i.e. `ninja` or `make`) will build all of LLVM.
 - The `check-all` target (i.e. `ninja check-all`) will run the regression tests to ensure everything is in working order.
 - CMake will generate build targets for each tool and library, and most LLVM sub-projects generate their own `check-<project>` target.
 - Running a serial build will be *slow*. Make sure you run a parallel build. That's already done by default in Ninja; for make, use `make -j NNN` (with an appropriate value of NNN, e.g. number of CPUs you have.)
- For more information see [CMake](#)
- If you get an "internal compiler error (ICE)" or test failures, see [below](#).

Consult the [Getting Started with LLVM](#) section for detailed information on configuring and compiling LLVM. Go to [Directory Layout](#) to learn about the layout of the source code tree.

2.9.3 Requirements

Before you begin to use the LLVM system, review the requirements given below. This may save you some trouble by knowing ahead of time what hardware and software you will need.

Hardware

LLVM is known to work on the following host platforms:

OS	Arch	Compilers
Linux	x86 ¹	GCC, Clang
Linux	amd64	GCC, Clang
Linux	ARM	GCC, Clang
Linux	PowerPC	GCC, Clang
Solaris	V9 (Ultrasparc)	GCC
FreeBSD	x86 ¹	GCC, Clang
FreeBSD	amd64	GCC, Clang
NetBSD	x86 ¹	GCC, Clang
NetBSD	amd64	GCC, Clang
macOS ²	PowerPC	GCC
macOS	x86	GCC, Clang
Cygwin/Win32	x86 ^{1, 3}	GCC
Windows	x86 ¹	Visual Studio
Windows x64	x86-64	Visual Studio

Note:

1. Code generation supported for Pentium processors and up

2. Code generation supported for 32-bit ABI only
 3. To use LLVM modules on Win32-based system, you may configure LLVM with `-DBUILD_SHARED_LIBS=On`.
-

Note that Debug builds require a lot of time and disk space. An LLVM-only build will need about 1-3 GB of space. A full build of LLVM and Clang will need around 15-20 GB of disk space. The exact space requirements will vary by system. (It is so large because of all the debugging information and the fact that the libraries are statically linked into multiple tools).

If you are space-constrained, you can build only selected tools or only selected targets. The Release build requires considerably less space.

The LLVM suite *may* compile on other platforms, but it is not guaranteed to do so. If compilation is successful, the LLVM utilities should be able to assemble, disassemble, analyze, and optimize LLVM bitcode. Code generation should work as well, although the generated native code may not work on your platform.

Software

Compiling LLVM requires that you have several software packages installed. The table below lists those required packages. The Package column is the usual name for the software package that LLVM depends on. The Version column provides "known to work" versions of the package. The Notes column describes how LLVM uses the package and provides other details.

Package	Version	Notes
GNU Make	3.79, 3.79.1	Makefile/build processor
GCC	$\geq 5.1.0$	C/C++ compiler ¹
python	≥ 2.7	Automated test suite ²
zlib	$\geq 1.2.3.4$	Compression library ³

Note:

1. Only the C and C++ languages are needed so there's no need to build the other languages for LLVM's purposes. See *below* for specific version info.
 2. Only needed if you want to run the automated test suite in the `llvm/test` directory.
 3. Optional, adds compression / uncompression capabilities to selected LLVM tools.
-

Additionally, your compilation host is expected to have the usual plethora of Unix utilities. Specifically:

- **ar** --- archive library builder
- **bzip2** --- bzip2 command for distribution generation
- **bunzip2** --- bunzip2 command for distribution checking
- **chmod** --- change permissions on a file
- **cat** --- output concatenation utility
- **cp** --- copy files
- **date** --- print the current date/time
- **echo** --- print to standard output
- **egrep** --- extended regular expression search utility

- **find** --- find files/dirs in a file system
- **grep** --- regular expression search utility
- **gzip** --- gzip command for distribution generation
- **gunzip** --- gunzip command for distribution checking
- **install** --- install directories/files
- **mkdir** --- create a directory
- **mv** --- move (rename) files
- **ranlib** --- symbol table builder for archive libraries
- **rm** --- remove (delete) files and directories
- **sed** --- stream editor for transforming output
- **sh** --- Bourne shell for make build scripts
- **tar** --- tape archive for distribution generation
- **test** --- test things in file system
- **unzip** --- unzip command for distribution checking
- **zip** --- zip command for distribution generation

Host C++ Toolchain, both Compiler and Standard Library

LLVM is very demanding of the host C++ compiler, and as such tends to expose bugs in the compiler. We also attempt to follow improvements and developments in the C++ language and library reasonably closely. As such, we require a modern host C++ toolchain, both compiler and standard library, in order to build LLVM.

LLVM is written using the subset of C++ documented in *coding standards*. To enforce this language version, we check the most popular host toolchains for specific minimum versions in our build systems:

- Clang 3.5
- Apple Clang 6.0
- GCC 5.1
- Visual Studio 2017

The below versions currently soft-error as we transition to the new compiler versions listed above. The LLVM code-base is currently known to compile correctly with the following compilers, though this will change in the near future:

- Clang 3.1
- Apple Clang 3.1
- GCC 4.8
- Visual Studio 2017

Anything older than these toolchains *may* work, but will require forcing the build system with a special option and is not really a supported host platform. Also note that older versions of these compilers have often crashed or miscompiled LLVM.

For less widely used host toolchains such as ICC or xIC, be aware that a very recent version may be required to support all of the C++ features used in LLVM.

We track certain versions of software that are *known* to fail when used as part of the host toolchain. These even include linkers at times.

GNU ld 2.16.X. Some 2.16.X versions of the ld linker will produce very long warning messages complaining that some `".gnu.linkonce.t.*"` symbol was defined in a discarded section. You can safely ignore these messages as they are erroneous and the linkage is correct. These messages disappear using ld 2.17.

GNU binutils 2.17: Binutils 2.17 contains a [bug](#) which causes huge link times (minutes instead of seconds) when building LLVM. We recommend upgrading to a newer version (2.17.50.0.4 or later).

GNU Binutils 2.19.1 Gold: This version of Gold contained a [bug](#) which causes intermittent failures when building LLVM with position independent code. The symptom is an error about cyclic dependencies. We recommend upgrading to a newer version of Gold.

Getting a Modern Host C++ Toolchain

This section mostly applies to Linux and older BSDs. On macOS, you should have a sufficiently modern Xcode, or you will likely need to upgrade until you do. Windows does not have a "system compiler", so you must install either Visual Studio 2017 or a recent version of mingw64. FreeBSD 10.0 and newer have a modern Clang as the system compiler.

However, some Linux distributions and some other or older BSDs sometimes have extremely old versions of GCC. These steps attempt to help you upgrade your compiler even on such a system. However, if at all possible, we encourage you to use a recent version of a distribution with a modern system compiler that meets these requirements. Note that it is tempting to install a prior version of Clang and libc++ to be the host compiler, however libc++ was not well tested or set up to build on Linux until relatively recently. As a consequence, this guide suggests just using libstdc++ and a modern GCC as the initial host in a bootstrap, and then using Clang (and potentially libc++).

The first step is to get a recent GCC toolchain installed. The most common distribution on which users have struggled with the version requirements is Ubuntu Precise, 12.04 LTS. For this distribution, one easy option is to install the [toolchain testing PPA](#) and use it to install a modern GCC. There is a really nice discussions of this on the [ask ubuntu stack exchange](#) and a [github gist](#) with updated commands. However, not all users can use PPAs and there are many other distributions, so it may be necessary (or just useful, if you're here you *are* doing compiler development after all) to build and install GCC from source. It is also quite easy to do these days.

Easy steps for installing GCC 5.1.0:

```
% gcc_version=5.1.0
% wget https://ftp.gnu.org/gnu/gcc/gcc- $\{gcc\_version\}$ /gcc- $\{gcc\_version\}$ .tar.bz2
% wget https://ftp.gnu.org/gnu/gcc/gcc- $\{gcc\_version\}$ /gcc- $\{gcc\_version\}$ .tar.bz2.sig
% wget https://ftp.gnu.org/gnu/gnu-keyring.gpg
% signature_invalid=`gpg --verify --no-default-keyring --keyring ./gnu-keyring.gpg gcc-
↪ $\{gcc\_version\}$ .tar.bz2.sig`
% if [ $signature_invalid ]; then echo "Invalid signature" ; exit 1 ; fi
% tar -xvzf gcc- $\{gcc\_version\}$ .tar.bz2
% cd gcc- $\{gcc\_version\}$ 
% ./contrib/download_prerequisites
% cd ..
% mkdir gcc- $\{gcc\_version\}$ -build
% cd gcc- $\{gcc\_version\}$ -build
% $PWD/../../gcc- $\{gcc\_version\}$ /configure --prefix=$HOME/toolchains --enable-languages=c,
↪c++
% make -j$(nproc)
% make install
```

For more details, check out the excellent [GCC wiki entry](#), where I got most of this information from.

Once you have a GCC toolchain, configure your build of LLVM to use the new toolchain for your host compiler and C++ standard library. Because the new version of libstdc++ is not on the system library search path, you need to pass extra linker flags so that it can be found at link time (`-L`) and at runtime (`-rpath`). If you are using CMake, this invocation should produce working binaries:

```
% mkdir build
% cd build
% CC=$HOME/toolchains/bin/gcc CXX=$HOME/toolchains/bin/g++ \
  cmake .. -DCMAKE_CXX_LINK_FLAGS="-Wl,-rpath,$HOME/toolchains/lib64 -L$HOME/
↳toolchains/lib64"
```

If you fail to set `rpath`, most LLVM binaries will fail on startup with a message from the loader similar to `libstdc++.so.6: version 'GLIBCXX_3.4.20' not found`. This means you need to tweak the `-rpath` linker flag.

When you build Clang, you will need to give *it* access to modern C++ standard library in order to use it as your new host in part of a bootstrap. There are two easy ways to do this, either build (and install) `libc++` along with Clang and then use it with the `-stdlib=libc++` compile and link flag, or install Clang into the same prefix (`$HOME/toolchains` above) as GCC. Clang will look within its own prefix for `libstdc++` and use it if found. You can also add an explicit prefix for Clang to look in for a GCC toolchain with the `--gcc-toolchain=/opt/my/gcc/prefix` flag, passing it to both compile and link commands when using your just-built-Clang to bootstrap.

2.9.4 Getting Started with LLVM

The remainder of this guide is meant to get you up and running with LLVM and to give you some basic information about the LLVM environment.

The later sections of this guide describe the *general layout* of the LLVM source tree, a *simple example* using the LLVM tool chain, and *links* to find more information about LLVM or to get help via e-mail.

Terminology and Notation

Throughout this manual, the following names are used to denote paths specific to the local system and working environment. *These are not environment variables you need to set but just strings used in the rest of this document below*. In any of the examples below, simply replace each of these names with the appropriate pathname on your local system. All these paths are absolute:

`SRC_ROOT`

This is the top level directory of the LLVM source tree.

`OBJ_ROOT`

This is the top level directory of the LLVM object tree (i.e. the tree where object files and compiled programs will be placed. It can be the same as `SRC_ROOT`).

Unpacking the LLVM Archives

If you have the LLVM distribution, you will need to unpack it before you can begin to compile it. LLVM is distributed as a number of different subprojects. Each one has its own download which is a TAR archive that is compressed with the `gzip` program.

The files are as follows, with `x.y` marking the version number:

`llvm-x.y.tar.gz`

Source release for the LLVM libraries and tools.

`cfe-x.y.tar.gz`

Source release for the Clang frontend.

Checkout LLVM from Git

You can also checkout the source code for LLVM from Git. While the LLVM project's official source-code repository is Subversion, we are in the process of migrating to git. We currently recommend that all developers use Git for day-to-day development.

Note: Passing `--config core.autocrlf=false` should not be required in the future after we adjust the `.gitattribute` settings correctly, but is required for Windows users at the time of this writing.

Simply run:

```
% git clone https://github.com/llvm/llvm-project.git
```

or on Windows,

```
% git clone --config core.autocrlf=false https://github.com/llvm/llvm-project.git
```

This will create an 'llvm-project' directory in the current directory and fully populate it with all of the source code, test directories, and local copies of documentation files for LLVM and all the related subprojects. Note that unlike the tarballs, which contain each subproject in a separate file, the git repository contains all of the projects together.

If you want to get a specific release (as opposed to the most recent revision), you can check out a tag after cloning the repository. E.g., `git checkout llvmorg-6.0.1` inside the `llvm-project` directory created by the above command. Use `git tag -l` to list all of them.

Sending patches

Please read [Developer Policy](#), too.

We don't currently accept github pull requests, so you'll need to send patches either via emailing to `llvm-commits`, or, preferably, via [Phabricator](#).

You'll generally want to make sure your branch has a single commit, corresponding to the review you wish to send, up-to-date with the upstream `origin/master` branch, and doesn't contain merges. Once you have that, you can use `git show` or `git format-patch` to output the diff, and attach it to a Phabricator review (or to an email message).

However, using the "Arcanist" tool is often easier. After [installing arcanist](#), you can upload the latest commit using:

```
% arc diff HEAD~1
```

Additionally, before sending a patch for review, please also try to ensure it's formatted properly. We use `clang-format` for this, which has git integration through the `git-clang-format` script. On some systems, it may already be installed (or be installable via your package manager). If so, you can simply run it -- the following command will format only the code changed in the most recent commit:

```
% git clang-format HEAD~1
```

Note that this modifies the files, but doesn't commit them -- you'll likely want to run

```
% git commit --amend -a
```

in order to update the last commit with all pending changes.

Note: If you don't already have `clang-format` or `git clang-format` installed on your system, the `clang-format` binary will be built alongside `clang`, and the `git` integration can be run from `clang/tools/clang-format/git-clang-format`.

For developers to commit changes from Git

A helper script is provided in `llvm/utils/git-svn/git-llvm`. After you add it to your path, you can push committed changes upstream with `git llvm push`. While this creates a Subversion checkout and patches it under the hood, it does not require you to have interaction with it.

```
% export PATH=$PATH:$TOP_LEVEL_DIR/llvm-project/llvm/utils/git-svn/
% git llvm push
```

Within a couple minutes after pushing to subversion, the `svn` commit will have been converted back to a `Git` commit, and made its way into the official `Git` repository. At that point, `git pull` should get back the changes as they were committed.

You'll likely want to `git pull --rebase` to get the official `git` commit downloaded back to your repository. The `SVN` revision numbers of each commit can be found at the end of the commit message, e.g. `llvm-svn: 350914`.

You may also find the `-n` flag useful, like `git llvm push -n`. This runs through all the steps of committing `_without_` actually doing the commit, and tell you what it would have done. That can be useful if you're unsure whether the right thing will happen.

Reverting a change when using Git

If you're using `Git` and need to revert a patch, `Git` needs to be supplied a commit hash, not an `svn` revision. To make things easier, you can use `git llvm revert` to revert with either an `SVN` revision or a `Git` hash instead.

Additionally, you can first run with `git llvm revert -n` to print which `Git` commands will run, without doing anything.

Running `git llvm revert` will only revert things in your local repository. To push the revert upstream, you still need to run `git llvm push` as described earlier.

```
% git llvm revert rNNNNNNN      # Revert by SVN id
% git llvm revert abcdef123456  # Revert by Git commit hash
% git llvm revert -n rNNNNNNN   # Print the commands without doing anything
```

Checkout via SVN (deprecated)

Until we have fully migrated to `Git`, you may also get a fresh copy of the code from the official Subversion repository.

- `cd where-you-want-llvm-to-live`
- Read-Only: `svn co http://llvm.org/svn/llvm-project/llvm/trunk llvm`
- Read-Write: `svn co https://user@llvm.org/svn/llvm-project/llvm/trunk llvm`

This will create an `'llvm'` directory in the current directory and fully populate it with the `LLVM` source code, `Makefiles`, test directories, and local copies of documentation files.

If you want to get a specific release (as opposed to the most recent revision), you can check it out from the 'tags' directory (instead of 'trunk'). The following releases are located in the following subdirectories of the 'tags' directory:

- Release 3.5.0 and later: **RELEASE_350/final** and so on
- Release 2.9 through 3.4: **RELEASE_29/final** and so on
- Release 1.1 through 2.8: **RELEASE_11** and so on
- Release 1.0: **RELEASE_1**

Local LLVM Configuration

Once checked out repository, the LLVM suite source code must be configured before being built. This process uses CMake. Unlike the normal `configure` script, CMake generates the build files in whatever format you request as well as various `*.inc` files, and `llvm/include/Config/config.h`.

Variables are passed to `cmake` on the command line using the format `-D<variable name>=<value>`. The following variables are some common options used by people developing LLVM.

Variable	Purpose
<code>CMAKE_C_COMPILER</code>	Which C compiler to use. By default, this will be <code>/usr/bin/cc</code> .
<code>CMAKE_CXX_COMPILER</code>	Which C++ compiler to use. By default, this will be <code>/usr/bin/c++</code> .
<code>CMAKE_BUILD_TYPE</code>	What type of build you are trying to generate files for. Valid options are <code>Debug</code> , <code>Release</code> , <code>RelWithDebInfo</code> , and <code>MinSizeRel</code> . Default is <code>Debug</code> .
<code>CMAKE_INSTALL_PREFIX</code>	Install directory to target when running the install action of the build files.
<code>PYTHON_EXECUTABLE</code>	Use a specific Python version by passing a path to a Python interpreter. By default the Python version of the interpreter in your <code>PATH</code> is used.
<code>LLVM_TARGETS_TO_BUILD</code>	Unlimited list controlling which targets will be built and linked into <code>llvm</code> . The default list is defined as <code>LLVM_ALL_TARGETS</code> , and can be set to include out-of-tree targets. The default value includes: <code>AArch64</code> , <code>AMDGPU</code> , <code>ARM</code> , <code>BPF</code> , <code>Hexagon</code> , <code>Mips</code> , <code>MSP430</code> , <code>NVPTX</code> , <code>PowerPC</code> , <code>Sparc</code> , <code>SystemZ</code> , <code>X86</code> , <code>XCore</code> .
<code>LLVM_ENABLE_DOXYGEN</code>	Use Doxygen-based documentation from the source code. This is disabled by default because it is slow and generates a lot of output.
<code>LLVM_ENABLE_PROJECTS</code>	Unlimited list selecting which of the other LLVM subprojects to additionally build. (Only effective when using a side-by-side project layout e.g. via <code>git</code>). The default list is empty. Can include: <code>clang</code> , <code>libcxx</code> , <code>libcxxabi</code> , <code>libunwind</code> , <code>lldb</code> , <code>compiler-rt</code> , <code>lld</code> , <code>polly</code> , or <code>debuginfo-tests</code> .
<code>LLVM_ENABLE_SPHINX</code>	Use Sphinx-based documentation from the source code. This is disabled by default because it is slow and generates a lot of output. Sphinx version 1.5 or later recommended.
<code>LLVM_BUILD_LIBRARY</code>	Default LLVM library. This library contains a default set of LLVM components that can be overridden with <code>LLVM_DYLIB_COMPONENTS</code> . The default contains most of LLVM and is defined in <code>tools/llvm-shlib/CMakeLists.txt</code> .
<code>LLVM_OPTIMIZED_TABLEGEN</code>	Use <code>tblgen</code> that gets used during the LLVM build. This can dramatically speed up debug builds.

To configure LLVM, follow these steps:

1. Change directory into the object root directory:

```
% cd OBJ_ROOT
```

2. Run the `cmake`:

```
% cmake -G "Unix Makefiles" -DCMAKE_INSTALL_PREFIX=/install/path
[other options] SRC_ROOT
```

Compiling the LLVM Suite Source Code

Unlike with autotools, with CMake your build type is defined at configuration. If you want to change your build type, you can re-run cmake with the following invocation:

```
% cmake -G "Unix Makefiles" -DCMAKE_BUILD_TYPE=type SRC_ROOT
```

Between runs, CMake preserves the values set for all options. CMake has the following build types defined:

Debug

These builds are the default. The build system will compile the tools and libraries unoptimized, with debugging information, and asserts enabled.

Release

For these builds, the build system will compile the tools and libraries with optimizations enabled and not generate debug info. CMake's default optimization level is -O3. This can be configured by setting the CMAKE_CXX_FLAGS_RELEASE variable on the CMake command line.

RelWithDebInfo

These builds are useful when debugging. They generate optimized binaries with debug information. CMake's default optimization level is -O2. This can be configured by setting the CMAKE_CXX_FLAGS_RELWITHDEBINFO variable on the CMake command line.

Once you have LLVM configured, you can build it by entering the *OBJ_ROOT* directory and issuing the following command:

```
% make
```

If the build fails, please [check here](#) to see if you are using a version of GCC that is known not to compile LLVM.

If you have multiple processors in your machine, you may wish to use some of the parallel build options provided by GNU Make. For example, you could use the command:

```
% make -j2
```

There are several special targets which are useful when working with the LLVM source code:

`make clean`

Removes all files generated by the build. This includes object files, generated C/C++ files, libraries, and executables.

`make install`

Installs LLVM header files, libraries, tools, and documentation in a hierarchy under \$PREFIX, specified with CMAKE_INSTALL_PREFIX, which defaults to /usr/local.

`make docs-llvm-html`

If configured with -DLLVM_ENABLE_SPHINX=On, this will generate a directory at OBJ_ROOT/docs/html which contains the HTML formatted documentation.

Cross-Compiling LLVM

It is possible to cross-compile LLVM itself. That is, you can create LLVM executables and libraries to be hosted on a platform different from the platform where they are built (a Canadian Cross build). To generate build files for cross-compiling CMake provides a variable `CMAKE_TOOLCHAIN_FILE` which can define compiler flags and variables used during the CMake test operations.

The result of such a build is executables that are not runnable on the build host but can be executed on the target. As an example the following CMake invocation can generate build files targeting iOS. This will work on macOS with the latest Xcode:

```
% cmake -G "Ninja" -DCMAKE_OSX_ARCHITECTURES="armv7;armv7s;arm64"
-D CMAKE_TOOLCHAIN_FILE=<PATH_TO_LLVM>/cmake/platforms/iOS.cmake
-D CMAKE_BUILD_TYPE=Release -DLLVM_BUILD_RUNTIME=Off -DLLVM_INCLUDE_TESTS=Off
-D LLVM_INCLUDE_EXAMPLES=Off -DLLVM_ENABLE_BACKTRACES=Off [options]
<PATH_TO_LLVM>
```

Note: There are some additional flags that need to be passed when building for iOS due to limitations in the iOS SDK.

Check [How To Cross-Compile Clang/LLVM using Clang/LLVM](#) and [Clang docs on how to cross-compile in general](#) for more information about cross-compiling.

The Location of LLVM Object Files

The LLVM build system is capable of sharing a single LLVM source tree among several LLVM builds. Hence, it is possible to build LLVM for several different platforms or configurations using the same source tree.

- Change directory to where the LLVM object files should live:

```
% cd OBJ_ROOT
```

- Run cmake:

```
% cmake -G "Unix Makefiles" SRC_ROOT
```

The LLVM build will create a structure underneath `OBJ_ROOT` that matches the LLVM source tree. At each level where source files are present in the source tree there will be a corresponding `CMakeFiles` directory in the `OBJ_ROOT`. Underneath that directory there is another directory with a name ending in `.dir` under which you'll find object files for each source.

For example:

```
% cd llvm_build_dir
% find lib/Support/ -name APFloat*
lib/Support/CMakeFiles/LLVMSupport.dir/APFloat.cpp.o
```

Optional Configuration Items

If you're running on a Linux system that supports the `binfmt_misc` module, and you have root access on the system, you can set your system up to execute LLVM bitcode files directly. To do this, use commands like this (the first command may not be required if you are already using the module):

```
% mount -t binfmt_misc none /proc/sys/fs/binfmt_misc
% echo ':llvm:M::BC::/path/to/lli:' > /proc/sys/fs/binfmt_misc/register
% chmod u+x hello.bc      (if needed)
% ./hello.bc
```

This allows you to execute LLVM bitcode files directly. On Debian, you can also use this command instead of the 'echo' command above:

```
% sudo update-binfmts --install llvm /path/to/lli --magic 'BC'
```

2.9.5 Directory Layout

One useful source of information about the LLVM source base is the LLVM [doxygen](http://llvm.org/doxygen/) documentation available at <http://llvm.org/doxygen/>. The following is a brief introduction to code layout:

llvm/examples

Simple examples using the LLVM IR and JIT.

llvm/include

Public header files exported from the LLVM library. The three main subdirectories:

llvm/include/llvm

All LLVM-specific header files, and subdirectories for different portions of LLVM: Analysis, CodeGen, Target, Transforms, etc...

llvm/include/llvm/Support

Generic support libraries provided with LLVM but not necessarily specific to LLVM. For example, some C++ STL utilities and a Command Line option processing library store header files here.

llvm/include/llvm/Config

Header files configured by `cmake`. They wrap "standard" UNIX and C header files. Source code can include these header files which automatically take care of the conditional `#includes` that `cmake` generates.

llvm/lib

Most source files are here. By putting code in libraries, LLVM makes it easy to share code among the *tools*.

llvm/lib/IR/

Core LLVM source files that implement core classes like Instruction and BasicBlock.

llvm/lib/AsmParser/

Source code for the LLVM assembly language parser library.

llvm/lib/Bitcode/

Code for reading and writing bitcode.

llvm/lib/Analysis/

A variety of program analyses, such as Call Graphs, Induction Variables, Natural Loop Identification, etc.

llvm/lib/Transforms/

IR-to-IR program transformations, such as Aggressive Dead Code Elimination, Sparse Conditional Constant Propagation, Inlining, Loop Invariant Code Motion, Dead Global Elimination, and many others.

llvm/lib/Target/

Files describing target architectures for code generation. For example, `llvm/lib/Target/X86` holds the X86 machine description.

`llvm/lib/CodeGen/`

The major parts of the code generator: Instruction Selector, Instruction Scheduling, and Register Allocation.

`llvm/lib/MC/`

(FIXME: T.B.D.)?

`llvm/lib/ExecutionEngine/`

Libraries for directly executing bitcode at runtime in interpreted and JIT-compiled scenarios.

`llvm/lib/Support/`

Source code that corresponding to the header files in `llvm/include/ADT/` and `llvm/include/Support/`.

llvm/projects

Projects not strictly part of LLVM but shipped with LLVM. This is also the directory for creating your own LLVM-based projects which leverage the LLVM build system.

llvm/test

Feature and regression tests and other sanity checks on LLVM infrastructure. These are intended to run quickly and cover a lot of territory without being exhaustive.

test-suite

A comprehensive correctness, performance, and benchmarking test suite for LLVM. This comes in a separate git repository <<https://github.com/llvm/llvm-test-suite>>, because it contains a large amount of third-party code under a variety of licenses. For details see the *Testing Guide* document.

llvm/tools

Executables built out of the libraries above, which form the main part of the user interface. You can always get help for a tool by typing `tool_name -help`. The following is a brief introduction to the most important tools. More detailed information is in the *Command Guide*.

`bugpoint`

`bugpoint` is used to debug optimization passes or code generation backends by narrowing down the given test case to the minimum number of passes and/or instructions that still cause a problem, whether it is a crash or miscompilation. See [HowToSubmitABug.html](#) for more information on using `bugpoint`.

`llvm-ar`

The archiver produces an archive containing the given LLVM bitcode files, optionally with an index for faster lookup.

`llvm-as`

The assembler transforms the human readable LLVM assembly to LLVM bitcode.

`llvm-dis`

The disassembler transforms the LLVM bitcode to human readable LLVM assembly.

`llvm-link`

`llvm-link`, not surprisingly, links multiple LLVM modules into a single program.

`lli`

`lli` is the LLVM interpreter, which can directly execute LLVM bitcode (although very slowly...). For architectures that support it (currently x86, Sparc, and PowerPC), by default, `lli` will function as a Just-In-Time compiler (if the functionality was compiled in), and will execute the code *much* faster than the interpreter.

`llc`

`llc` is the LLVM backend compiler, which translates LLVM bitcode to a native code assembly file.

`opt`

`opt` reads LLVM bitcode, applies a series of LLVM to LLVM transformations (which are specified on the command line), and outputs the resultant bitcode. '`opt -help`' is a good way to get a list of the program transformations available in LLVM.

`opt` can also run a specific analysis on an input LLVM bitcode file and print the results. Primarily useful for debugging analyses, or familiarizing yourself with what an analysis does.

llvm/utils

Utilities for working with LLVM source code; some are part of the build process because they are code generators for parts of the infrastructure.

`codegen-diff`

`codegen-diff` finds differences between code that LLC generates and code that LLI generates. This is useful if you are debugging one of them, assuming that the other generates correct output. For the full user manual, run '`perldoc codegen-diff`'.

`emacs/`

Emacs and XEmacs syntax highlighting for LLVM assembly files and TableGen description files. See the README for information on using them.

`getsrsrcs.sh`

Finds and outputs all non-generated source files, useful if one wishes to do a lot of development across directories and does not want to find each file. One way to use it is to run, for example: `xemacs `utils/getsources.sh`` from the top of the LLVM source tree.

`llvmgrep`

Performs an `egrep -H -n` on each source file in LLVM and passes to it a regular expression provided on `llvmgrep`'s command line. This is an efficient way of searching the source base for a particular regular expression.

`TableGen/`

Contains the tool used to generate register descriptions, instruction set descriptions, and even assemblers from common TableGen description files.

`vim/`

`vim` syntax-highlighting for LLVM assembly files and TableGen description files. See the README for how to use them.

2.9.6 An Example Using the LLVM Tool Chain

This section gives an example of using LLVM with the Clang front end.

Example with clang

1. First, create a simple C file, name it 'hello.c':

```
#include <stdio.h>

int main() {
    printf("hello world\n");
    return 0;
}
```

2. Next, compile the C file into a native executable:

```
% clang hello.c -o hello
```

Note: Clang works just like GCC by default. The standard `-S` and `-c` arguments work as usual (producing a native `.s` or `.o` file, respectively).

3. Next, compile the C file into an LLVM bitcode file:

```
% clang -O3 -emit-llvm hello.c -c -o hello.bc
```

The `-emit-llvm` option can be used with the `-S` or `-c` options to emit an LLVM `.ll` or `.bc` file (respectively) for the code. This allows you to use the [standard LLVM tools](#) on the bitcode file.

4. Run the program in both forms. To run the program, use:

```
% ./hello
```

and

```
% lli hello.bc
```

The second examples shows how to invoke the LLVM JIT, *lli*.

5. Use the `llvm-dis` utility to take a look at the LLVM assembly code:

```
% llvm-dis < hello.bc | less
```

6. Compile the program to native assembly using the LLC code generator:

```
% llc hello.bc -o hello.s
```

7. Assemble the native assembly language file into a program:

```
% /opt/SUNWspro/bin/cc -xarch=v9 hello.s -o hello.native # On Solaris
% gcc hello.s -o hello.native # On others
```

8. Execute the native code program:

```
% ./hello.native
```

Note that using clang to compile directly to native code (i.e. when the `-emit-llvm` option is not present) does steps 6/7/8 for you.

2.9.7 Common Problems

If you are having problems building or using LLVM, or if you have any other general questions about LLVM, please consult the [Frequently Asked Questions](#) page.

2.9.8 Links

This document is just an **introduction** on how to use LLVM to do some simple things... there are many more interesting and complicated things that you can do that aren't documented here (but we'll gladly accept a patch if you want to write something up!). For more information about LLVM, check out:

- [LLVM Homepage](#)
- [LLVM Doxygen Tree](#)
- [Starting a Project that Uses LLVM](#)

2.10 Getting Started with the LLVM System using Microsoft Visual Studio

- *Overview*
- *Requirements*
 - *Hardware*
 - *Software*
- *Getting Started*
- *An Example Using the LLVM Tool Chain*
- *Common Problems*
- *Links*

2.10.1 Overview

Welcome to LLVM on Windows! This document only covers LLVM on Windows using Visual Studio, not mingw or cygwin. In order to get started, you first need to know some basic information.

There are many different projects that compose LLVM. The first piece is the LLVM suite. This contains all of the tools, libraries, and header files needed to use LLVM. It contains an assembler, disassembler, bitcode analyzer and bitcode optimizer. It also contains basic regression tests that can be used to test the LLVM tools and the Clang front end.

The second piece is the [Clang](#) front end. This component compiles C, C++, Objective C, and Objective C++ code into LLVM bitcode. Clang typically uses LLVM libraries to optimize the bitcode and emit machine code. LLVM fully supports the COFF object file format, which is compatible with all other existing Windows toolchains.

The last major part of LLVM, the execution Test Suite, does not run on Windows, and this document does not discuss it.

Additional information about the LLVM directory structure and tool chain can be found on the main [Getting Started with the LLVM System](#) page.

2.10.2 Requirements

Before you begin to use the LLVM system, review the requirements given below. This may save you some trouble by knowing ahead of time what hardware and software you will need.

Hardware

Any system that can adequately run Visual Studio 2017 is fine. The LLVM source tree and object files, libraries and executables will consume approximately 3GB.

Software

You will need Visual Studio 2017 or higher, with the latest Update installed.

You will also need the [CMake](#) build system since it generates the project files you will use to build with.

If you would like to run the LLVM tests you will need [Python](#). Version 2.7 and newer are known to work. You will need [GnuWin32](#) tools, too.

Do not install the LLVM directory tree into a path containing spaces (e.g. `C:\Documents and Settings\...`) as the configure step will fail.

2.10.3 Getting Started

Here's the short story for getting up and running quickly with LLVM:

1. Read the documentation.
2. Seriously, read the documentation.
3. Remember that you were warned twice about reading the documentation.
4. Get the Source Code

- With the distributed files:

1. `cd <where-you-want-llvm-to-live>`
2. `gunzip --stdout llvm-VERSION.tar.gz | tar -xvf -` (*or use WinZip*)
3. `cd llvm`

- With anonymous Subversion access:

Note: some regression tests require Unix-style line ending (`\n`). To pass all regression tests, please add two lines `enable-auto-props = yes` and `* = svn:mime-type=application/octet-stream` to `C:\Users\<username>\AppData\Roaming\Subversion\config`.

1. `cd <where-you-want-llvm-to-live>`

2. `svn co http://llvm.org/svn/llvm-project/llvm/trunk llvm`
3. `cd llvm`

5. Use CMake to generate up-to-date project files:

- Once CMake is installed then the simplest way is to just start the CMake GUI, select the directory where you have LLVM extracted to, and the default options should all be fine. One option you may really want to change, regardless of anything else, might be the `CMAKE_INSTALL_PREFIX` setting to select a directory to INSTALL to once compiling is complete, although installation is not mandatory for using LLVM. Another important option is `LLVM_TARGETS_TO_BUILD`, which controls the LLVM target architectures that are included on the build.
- If CMake complains that it cannot find the compiler, make sure that you have the Visual Studio C++ Tools installed, not just Visual Studio itself (trying to create a C++ project in Visual Studio will generally download the C++ tools if they haven't already been).
- See the *LLVM CMake guide* for detailed information about how to configure the LLVM build.
- CMake generates project files for all build types. To select a specific build type, use the Configuration manager from the VS IDE or the `/property:Configuration` command line option when using MSBuild.
- By default, the Visual Studio project files generated by CMake use the 32-bit toolset. If you are developing on a 64-bit version of Windows and want to use the 64-bit toolset, pass the `-Thost=x64` flag when generating the Visual Studio solution. This requires CMake 3.8.0 or later.

6. Start Visual Studio

- In the directory you created the project files will have an `llvm.sln` file, just double-click on that to open Visual Studio.

7. Build the LLVM Suite:

- The projects may still be built individually, but to build them all do not just select all of them in batch build (as some are meant as configuration projects), but rather select and build just the `ALL_BUILD` project to build everything, or the `INSTALL` project, which first builds the `ALL_BUILD` project, then installs the LLVM headers, libs, and other useful things to the directory set by the `CMAKE_INSTALL_PREFIX` setting when you first configured CMake.
- The Fibonacci project is a sample program that uses the JIT. Modify the project's debugging properties to provide a numeric command line argument or run it from the command line. The program will print the corresponding fibonacci value.

8. Test LLVM in Visual Studio:

- If `%PATH%` does not contain GnuWin32, you may specify `LLVM_LIT_TOOLS_DIR` on CMake for the path to GnuWin32.
- You can run LLVM tests by merely building the project "check". The test results will be shown in the VS output window.

9. Test LLVM on the command line:

- The LLVM tests can be run by changing directory to the `llvm` source directory and running:

```
C:\..\llvm> python ..\build\bin\llvm-lit --param build_config=Win32 --param_
↪build_mode=Debug --param llvm_site_config=../build/test/lit.site.cfg test
```

This example assumes that Python is in your PATH variable, you have built a Win32 Debug version of `llvm` with a standard out of line build. You should not see any unexpected failures, but will see many unsupported tests and expected failures.

A specific test or test directory can be run with:

```
C:\..\llvm> python ..\build\bin\llvm-lit --param build_config=Win32 --param_
↳ build_mode=Debug --param llvm_site_config=../build/test/lit.site.cfg test/
↳ path/to/test
```

2.10.4 An Example Using the LLVM Tool Chain

1. First, create a simple C file, name it 'hello.c':

```
#include <stdio.h>
int main() {
    printf("hello world\n");
    return 0;
}
```

2. Next, compile the C file into an LLVM bytecode file:

```
C:\..\> clang -c hello.c -emit-llvm -o hello.bc
```

This will create the result file `hello.bc` which is the LLVM bytecode that corresponds the compiled program and the library facilities that it required. You can execute this file directly using `lli` tool, compile it to native assembly with the `llc`, optimize or analyze it further with the `opt` tool, etc.

Alternatively you can directly output an executable with clang with:

```
C:\..\> clang hello.c -o hello.exe
```

The `-o hello.exe` is required because clang currently outputs a `.out` when neither `-o` nor `-c` are given.

3. Run the program using the just-in-time compiler:

```
C:\..\> lli hello.bc
```

4. Use the `llvm-dis` utility to take a look at the LLVM assembly code:

```
C:\..\> llvm-dis < hello.bc | more
```

5. Compile the program to object code using the LLVM code generator:

```
C:\..\> llc -filetype=obj hello.bc
```

6. Link to binary using Microsoft link:

```
C:\..\> link hello.obj -defaultlib:libcmt
```

7. Execute the native code program:

```
C:\..\> hello.exe
```

2.10.5 Common Problems

If you are having problems building or using LLVM, or if you have any other general questions about LLVM, please consult the *Frequently Asked Questions* page.

2.10.6 Links

This document is just an **introduction** to how to use LLVM to do some simple things... there are many more interesting and complicated things that you can do that aren't documented here (but we'll gladly accept a patch if you want to write something up!). For more information about LLVM, check out:

- [LLVM homepage](#)
- [LLVM doxygen tree](#)

2.11.1 License

Does the University of Illinois Open Source License really qualify as an "open source" license?

Yes, the license is [certified](#) by the Open Source Initiative (OSI).

Can I modify LLVM source code and redistribute the modified source?

Yes. The modified source distribution must retain the copyright notice and follow the three bulleted conditions listed in the [LLVM license](#).

Can I modify the LLVM source code and redistribute binaries or other tools based on it, without redistributing the source?

Yes. This is why we distribute LLVM under a less restrictive license than GPL, as explained in the first question above.

2.11.2 Source Code

In what language is LLVM written?

All of the LLVM tools and libraries are written in C++ with extensive use of the STL.

How portable is the LLVM source code?

The LLVM source code should be portable to most modern Unix-like operating systems. Most of the code is written in standard C++ with operating system services abstracted to a support library. The tools required to build and test LLVM have been ported to a plethora of platforms.

What API do I use to store a value to one of the virtual registers in LLVM IR's SSA representation?

In short: you can't. It's actually kind of a silly question once you grok what's going on. Basically, in code like:

```
%result = add i32 %foo, %bar
```

, `%result` is just a name given to the `Value` of the `add` instruction. In other words, `%result` is the `add` instruction. The "assignment" doesn't explicitly "store" anything to any "virtual register"; the "=" is more like the mathematical sense of equality.

Longer explanation: In order to generate a textual representation of the IR, some kind of name has to be given to each instruction so that other instructions can textually reference it. However, the isomorphic in-memory representation that you manipulate from C++ has no such restriction since instructions can simply keep pointers to any other `Value`'s that they reference. In fact, the names of dummy numbered temporaries like `%1` are not explicitly represented in the in-memory representation at all (see `Value::getName()`).

2.11.3 Source Languages

What source languages are supported?

LLVM currently has full support for C and C++ source languages through [Clang](#). Many other language frontends have been written using LLVM, and an incomplete list is available at [projects with LLVM](#).

I'd like to write a self-hosting LLVM compiler. How should I interface with the LLVM middle-end optimizers and back-end code generators?

Your compiler front-end will communicate with LLVM by creating a module in the LLVM intermediate representation (IR) format. Assuming you want to write your language's compiler in the language itself (rather than C++), there are 3 major ways to tackle generating LLVM IR from a front-end:

1. **Call into the LLVM libraries code using your language's FFI (foreign function interface).**
 - *for*: best tracks changes to the LLVM IR, .ll syntax, and .bc format
 - *for*: enables running LLVM optimization passes without a emit/parse overhead
 - *for*: adapts well to a JIT context
 - *against*: lots of ugly glue code to write
2. **Emit LLVM assembly from your compiler's native language.**
 - *for*: very straightforward to get started
 - *against*: the .ll parser is slower than the bitcode reader when interfacing to the middle end
 - *against*: it may be harder to track changes to the IR
3. **Emit LLVM bitcode from your compiler's native language.**
 - *for*: can use the more-efficient bitcode reader when interfacing to the middle end
 - *against*: you'll have to re-engineer the LLVM IR object model and bitcode writer in your language
 - *against*: it may be harder to track changes to the IR

If you go with the first option, the C bindings in `include/llvm-c` should help a lot, since most languages have strong support for interfacing with C. The most common hurdle with calling C from managed code is interfacing with the garbage collector. The C interface was designed to require very little memory management, and so is straightforward in this regard.

What support is there for a higher level source language constructs for building a compiler?

Currently, there isn't much. LLVM supports an intermediate representation which is useful for code representation but will not support the high level (abstract syntax tree) representation needed by most compilers. There are no facilities for lexical nor semantic analysis.

I don't understand the `GetElementPtr` instruction. Help!

See [The Often Misunderstood GEP Instruction](#).

2.11.4 Using the C and C++ Front Ends

Can I compile C or C++ code to platform-independent LLVM bytecode?

No. C and C++ are inherently platform-dependent languages. The most obvious example of this is the preprocessor. A very common way that C code is made portable is by using the preprocessor to include platform-specific code. In practice, information about other platforms is lost after preprocessing, so the result is inherently dependent on the platform that the preprocessing was targeting.

Another example is `sizeof`. It's common for `sizeof(long)` to vary between platforms. In most C front-ends, `sizeof` is expanded to a constant immediately, thus hard-wiring a platform-specific detail.

Also, since many platforms define their ABIs in terms of C, and since LLVM is lower-level than C, front-ends currently must emit platform-specific IR in order to have the result conform to the platform ABI.

2.11.5 Questions about code generated by the demo page

What is this `llvm.global_ctors` and `_GLOBAL__I_a...` stuff that happens when I `#include <iostream>`?

If you `#include` the `<iostream>` header into a C++ translation unit, the file will probably use the `std::cin/std::cout/...` global objects. However, C++ does not guarantee an order of initialization between static objects in different translation units, so if a static ctor/dtor in your `.cpp` file used `std::cout`, for example, the object would not necessarily be automatically initialized before your use.

To make `std::cout` and friends work correctly in these scenarios, the STL that we use declares a static object that gets created in every translation unit that includes `<iostream>`. This object has a static constructor and destructor that initializes and destroys the global `iostream` objects before they could possibly be used in the file. The code that you see in the `.ll` file corresponds to the constructor and destructor registration code.

If you would like to make it easier to *understand* the LLVM code generated by the compiler in the demo page, consider using `printf()` instead of `iostreams` to print values.

Where did all of my code go??

If you are using the LLVM demo page, you may often wonder what happened to all of the code that you typed in. Remember that the demo script is running the code through the LLVM optimizers, so if your code doesn't actually do anything useful, it might all be deleted.

To prevent this, make sure that the code is actually needed. For example, if you are computing some expression, return the value from the function instead of leaving it in a local variable. If you really want to constrain the optimizer, you can read from and assign to `volatile` global variables.

What is this "undef" thing that shows up in my code?

undef is the LLVM way of representing a value that is not defined. You can get these if you do not initialize a variable before you use it. For example, the C function:

```
int X() { int i; return i; }
```

Is compiled to "ret i32 undef" because "i" never has a value specified for it.

Why does instcombine + simplifycfg turn a call to a function with a mismatched calling convention into "unreachable"? Why not make the verifier reject it?

This is a common problem run into by authors of front-ends that are using custom calling conventions: you need to make sure to set the right calling convention on both the function and on each call to the function. For example, this code:

```
define fastcc void @foo() {
    ret void
}
define void @bar() {
    call void @foo()
    ret void
}
```

Is optimized to:

```
define fastcc void @foo() {
    ret void
}
define void @bar() {
    unreachable
}
```

... with "opt -instcombine -simplifycfg". This often bites people because "all their code disappears". Setting the calling convention on the caller and callee is required for indirect calls to work, so people often ask why not make the verifier reject this sort of thing.

The answer is that this code has undefined behavior, but it is not illegal. If we made it illegal, then every transformation that could potentially create this would have to ensure that it doesn't, and there is valid code that can create this sort of construct (in dead code). The sorts of things that can cause this to happen are fairly contrived, but we still need to accept them. Here's an example:

```
define fastcc void @foo() {
    ret void
}
define internal void @bar(void()* %FP, i1 %cond) {
    br i1 %cond, label %T, label %F
T:
    call void %FP()
    ret void
F:
    call fastcc void %FP()
    ret void
}
define void @test() {
    %X = or i1 false, false
```

(continues on next page)

(continued from previous page)

```

    call void @bar(void()* @foo, i1 %X)
    ret void
}

```

In this example, "test" always passes @foo/false into bar, which ensures that it is dynamically called with the right calling conv (thus, the code is perfectly well defined). If you run this through the inliner, you get this (the explicit "or" is there so that the inliner doesn't dead code eliminate a bunch of stuff):

```

define fastcc void @foo() {
    ret void
}
define void @test() {
    %X = or i1 false, false
    br i1 %X, label %T.i, label %F.i
T.i:
    call void @foo()
    br label %bar.exit
F.i:
    call fastcc void @foo()
    br label %bar.exit
bar.exit:
    ret void
}

```

Here you can see that the inlining pass made an undefined call to @foo with the wrong calling convention. We really don't want to make the inliner have to know about this sort of thing, so it needs to be valid code. In this case, dead code elimination can trivially remove the undefined code. However, if %X was an input argument to @test, the inliner would produce this:

```

define fastcc void @foo() {
    ret void
}

define void @test(i1 %X) {
    br i1 %X, label %T.i, label %F.i
T.i:
    call void @foo()
    br label %bar.exit
F.i:
    call fastcc void @foo()
    br label %bar.exit
bar.exit:
    ret void
}

```

The interesting thing about this is that %X *must* be false for the code to be well-defined, but no amount of dead code elimination will be able to delete the broken call as unreachable. However, since instcombine/simplifycfg turns the undefined call into unreachable, we end up with a branch on a condition that goes to unreachable: a branch to unreachable can never happen, so "-inline -instcombine -simplifycfg" is able to produce:

```

define fastcc void @foo() {
    ret void
}
define void @test(i1 %X) {
F.i:
    call fastcc void @foo()
}

```

(continues on next page)

(continued from previous page)

```
ret void  
}
```

2.12 The LLVM Lexicon

Note: This document is a work in progress!

2.12.1 Definitions

A

ADCE Aggressive Dead Code Elimination

AST Abstract Syntax Tree.

Due to Clang's influence (mostly the fact that parsing and semantic analysis are so intertwined for C and especially C++), the typical working definition of AST in the LLVM community is roughly "the compiler's first complete symbolic (as opposed to textual) representation of an input program". As such, an "AST" might be a more general graph instead of a "tree" (consider the symbolic representation for the type of a typical "linked list node"). This working definition is closer to what some authors call an "annotated abstract syntax tree".

Consult your favorite compiler book or search engine for more details.

B

BB Vectorization Basic-Block Vectorization

BDCE Bit-tracking dead code elimination. Some bit-wise instructions (shifts, ands, ors, etc.) "kill" some of their input bits -- that is, they make it such that those bits can be either zero or one without affecting control or data flow of a program. The BDCE pass removes instructions that only compute these dead bits.

BURS Bottom Up Rewriting System --- A method of instruction selection for code generation. An example is the [BURG](#) tool.

C

CFI Call Frame Information. Used in DWARF debug info and in C++ unwind info to show how the function prolog lays out the stack frame.

CIE Common Information Entry. A kind of CFI used to reduce the size of FDEs. The compiler creates a CIE which contains the information common across all the FDEs. Each FDE then points to its CIE.

CSE Common Subexpression Elimination. An optimization that removes common subexpression computation. For example $(a+b) * (a+b)$ has two subexpressions that are the same: $(a+b)$. This optimization would perform the addition only once and then perform the multiply (but only if it's computationally correct/safe).

D

DAG Directed Acyclic Graph

Derived Pointer A pointer to the interior of an object, such that a garbage collector is unable to use the pointer for reachability analysis. While a derived pointer is live, the corresponding object pointer must be kept in a root, otherwise the collector might free the referenced object. With copying collectors, derived pointers pose an additional hazard that they may be invalidated at any *safe point*. This term is used in opposition to *object pointer*.

DSA Data Structure Analysis

DSE Dead Store Elimination

F

FCA First Class Aggregate

FDE Frame Description Entry. A kind of CFI used to describe the stack frame of one function.

G

GC Garbage Collection. The practice of using reachability analysis instead of explicit memory management to reclaim unused memory.

GEP `GetElementPtr`. An LLVM IR instruction that is used to get the address of a subelement of an aggregate data structure. It is documented in detail [here](#).

GVN Global Value Numbering. GVN is a pass that partitions values computed by a function into congruence classes. Values ending up in the same congruence class are guaranteed to be the same for every execution of the program. In that respect, congruency is a compile-time approximation of equivalence of values at runtime.

H

Heap In garbage collection, the region of memory which is managed using reachability analysis.

I

ICE Internal Compiler Error. This abbreviation is used to describe errors that occur in LLVM or Clang as they are compiling source code. For example, if a valid C++ source program were to trigger an assert in Clang when compiled, that could be referred to as an "ICE".

IPA Inter-Procedural Analysis. Refers to any variety of code analysis that occurs between procedures, functions or compilation units (modules).

IPO Inter-Procedural Optimization. Refers to any variety of code optimization that occurs between procedures, functions or compilation units (modules).

ISel Instruction Selection

L

LCSSA Loop-Closed Static Single Assignment Form

LGTM "Looks Good To Me". In a review thread, this indicates that the reviewer thinks that the patch is okay to commit.

LICM Loop Invariant Code Motion

LSDA Language Specific Data Area. C++ "zero cost" unwinding is built on top a generic unwinding mechanism. As the unwinder walks each frame, it calls a "personality" function to do language specific analysis. Each function's FDE points to an optional LSDA which is passed to the personality function. For C++, the LSDA contain info about the type and location of catch statements in that function.

Load-VN Load Value Numbering

LTO Link-Time Optimization

M

MC Machine Code

N

NFC "No functional change". Used in a commit message to indicate that a patch is a pure refactoring/cleanup. Usually used in the first line, so it is visible without opening the actual commit email.

O

Object Pointer A pointer to an object such that the garbage collector is able to trace references contained within the object. This term is used in opposition to *derived pointer*.

P

PR Problem report. A bug filed on [the LLVM Bug Tracking System](#).

PRE Partial Redundancy Elimination

R

RAUW

Replace All Uses With. The functions `User::replaceUsesOfWith()`, `Value::replaceAllUsesWith()`, and `Constant::replaceUsesOfWithOnConstant()` implement the replacement of one Value with another by iterating over its def/use chain and fixing up all of the pointers to point to the new value. See also [def/use chains](#).

Reassociation Rearranging associative expressions to promote better redundancy elimination and other optimization. For example, changing $(A+B-A)$ into $(B+A-A)$, permitting it to be optimized into $(B+0)$ then (B) .

Root In garbage collection, a pointer variable lying outside of the *heap* from which the collector begins its reachability analysis. In the context of code generation, "root" almost always refers to a "stack root" --- a local or temporary variable within an executing function.

RPO Reverse postorder

S

Safe Point In garbage collection, it is necessary to identify *stack roots* so that reachability analysis may proceed. It may be infeasible to provide this information for every instruction, so instead the information may be calculated only at designated safe points. With a copying collector, *derived pointers* must not be retained across safe points and *object pointers* must be reloaded from stack roots.

SDISel Selection DAG Instruction Selection.

SCC Strongly Connected Component

SCCP Sparse Conditional Constant Propagation

SLP Superword-Level Parallelism, same as *Basic-Block Vectorization*.

Splat Splat refers to a vector of identical scalar elements.

The term is based on the PowerPC AltiVec instructions that provided this functionality in hardware. For example, "vsplth" and the corresponding software intrinsic "vec_splat()". Examples of other hardware names for this action include "duplicate" (ARM) and "broadcast" (x86).

SRoA Scalar Replacement of Aggregates

SSA Static Single Assignment

Stack Map In garbage collection, metadata emitted by the code generator which identifies *roots* within the stack frame of an executing function.

T

TBAA Type-Based Alias Analysis

2.13 How To Add Your Build Configuration To LLVM Buildbot Infrastructure

2.13.1 Introduction

This document contains information about adding a build configuration and builds slave to private slave builder to LLVM Buildbot Infrastructure.

2.13.2 Buildmasters

There are two buildmasters running.

- The main buildmaster at <http://lab.llvm.org:8011>. All builders attached to this machine will notify commit authors every time they break the build.
- The staging buildbot at <http://lab.llvm.org:8014>. All builders attached to this machine will be completely silent by default when the build is broken. Builders for experimental backends should generally be attached to this buildmaster.

2.13.3 Steps To Add Builder To LLVM Buildbot

Volunteers can provide their build machines to work as build slaves to public LLVM Buildbot.

Here are the steps you can follow to do so:

1. Check the existing build configurations to make sure the one you are interested in is not covered yet or gets built on your computer much faster than on the existing one. We prefer faster builds so developers will get feedback sooner after changes get committed.
2. The computer you will be registering with the LLVM buildbot infrastructure should have all dependencies installed and you can actually build your configuration successfully. Please check what degree of parallelism (-j param) would give the fastest build. You can build multiple configurations on one computer.
3. Install builds slave (currently we are using buildbot version 0.8.5). Depending on the platform, builds slave could be available to download and install with your package manager, or you can download it directly from <http://trac.buildbot.net> and install it manually.
4. Create a designated user account, your builds slave will be running under, and set appropriate permissions.
5. Choose the builds slave root directory (all builds will be placed under it), builds slave access name and password the build master will be using to authenticate your builds slave.
6. Create a builds slave in context of that builds slave account. Point it to the **lab.llvm.org** port **9990** (see [Buildbot documentation](#), [Creating a slave](#) for more details) by running the following command:

```
$ builds slave create-slave <builds slave-root-directory> \
    lab.llvm.org:9990 \
    <builds slave-access-name> <builds slave-access-password>
```

To point a slave to silent master please use lab.llvm.org:9994 instead of lab.llvm.org:9990.

7. Fill the builds slave description and admin name/e-mail. Here is an example of the builds slave description:

```
Windows 7 x64
Core i7 (2.66GHz), 16GB of RAM

g++.exe (TDM-1 mingw32) 4.4.0
GNU Binutils 2.19.1
cmake version 2.8.4
Microsoft(R) 32-bit C/C++ Optimizing Compiler Version 16.00.40219.01 for 80x86
```

8. Make sure you can actually start the builds slave successfully. Then set up your builds slave to start automatically at the start up time. See the buildbot documentation for help. You may want to restart your computer to see if it works.
9. Send a patch which adds your build slave and your builder to zorg.
 - slaves are added to buildbot/osuosl/master/config/slaves.py
 - builders are added to buildbot/osuosl/master/config/builders.py

Please make sure your builder name and its builddir are unique through the file.

It is possible to whitelist email addresses to unconditionally receive notifications on build failure; for this you'll need to add an InformativeMailNotifier to buildbot/osuosl/master/config/status.py. This is particularly useful for the staging buildmaster which is silent otherwise.

10. Send the builds slave access name and the access password directly to [Galina Kistanova](#), and wait till she will let you know that your changes are applied and buildmaster is reconfigured.

11. Check the status of your builds slave on the [Waterfall Display](#) to make sure it is connected, and `http://lab.llvm.org:8011/buildslaves/<your-buildslave-name>` to see if administrator contact and slave information are correct.
12. Wait for the first build to succeed and enjoy.

2.14 yaml2obj

yaml2obj takes a YAML description of an object file and converts it to a binary file.

\$ yaml2obj input-file

Outputs the binary to stdout.

2.14.1 COFF Syntax

Here's a sample COFF file.

```
header:
  Machine: IMAGE_FILE_MACHINE_I386 # (0x14C)

sections:

2.15 How to submit an LLVM bug report

2.15.1 Introduction - Got bugs?

If you're working with LLVM and run into a bug, we definitely want to know about it. This document describes what you can do to increase the odds of getting it fixed quickly.

Basically you have to do two things at a minimum. First, decide whether the bug *crashes the compiler* (or an LLVM pass), or if the compiler is *miscompiling* the program (i.e., the compiler successfully produces an executable, but it doesn't run right). Based on what type of bug it is, follow the instructions in the linked section to narrow down the bug so that the person who fixes it will be able to find the problem more easily.

Once you have a reduced test-case, go to [the LLVM Bug Tracking System](#) and fill out the form with the necessary details (note that you don't need to pick a category, just use the "new-bugs" category if you're not sure). The bug description should contain the following information:

- All information necessary to reproduce the problem.
- The reduced test-case that triggers the bug.
- The location where you obtained LLVM (if not from our Subversion repository).

Thanks for helping us make LLVM better!

2.15.2 Crashing Bugs

More often than not, bugs in the compiler cause it to crash---often due to an assertion failure of some sort. The most important piece of the puzzle is to figure out if it is crashing in the Clang front-end or if it is one of the LLVM libraries (e.g. the optimizer or code generator) that has problems.

To figure out which component is crashing (the front-end, optimizer or code generator), run the `clang` command line as you were when the crash occurred, but with the following extra command line options:

- `-O0 -emit-llvm`: If `clang` still crashes when passed these options (which disable the optimizer and code generator), then the crash is in the front-end. Jump ahead to the section on *front-end bugs*.
- `-emit-llvm`: If `clang` crashes with this option (which disables the code generator), you found an optimizer bug. Jump ahead to *compile-time optimization bugs*.
- Otherwise, you have a code generator crash. Jump ahead to *code generator bugs*.

Front-end bugs

If the problem is in the front-end, you should re-run the same `clang` command that resulted in the crash, but add the `-save-temps` option. The compiler will crash again, but it will leave behind a `f00.i` file (containing preprocessed C source code) and possibly `f00.s` for each compiled `f00.c` file. Send us the `f00.i` file, along with the options you passed to `clang`, and a brief description of the error it caused.

The `delta` tool helps to reduce the preprocessed file down to the smallest amount of code that still replicates the problem. You're encouraged to use `delta` to reduce the code to make the developers' lives easier. [This website](#) has instructions on the best way to use `delta`.

Compile-time optimization bugs

If you find that a bug crashes in the optimizer, compile your test-case to a .bc file by passing "-emit-llvm -O1 -Xclang -disable-llvm-passes -c -o foo.bc". Then run:

```
opt -O3 -debug-pass=Arguments foo.bc -disable-output
```

This command should do two things: it should print out a list of passes, and then it should crash in the same way as clang. If it doesn't crash, please follow the instructions for a *front-end bug*.

If this does crash, then you should be able to debug this with the following bugpoint command:

```
bugpoint foo.bc <list of passes printed by opt>
```

Please run this, then file a bug with the instructions and reduced .bc files that bugpoint emits. If something goes wrong with bugpoint, please submit the "foo.bc" file and the list of passes printed by opt.

Code generator bugs

If you find a bug that crashes clang in the code generator, compile your source file to a .bc file by passing "-emit-llvm -c -o foo.bc" to clang (in addition to the options you already pass). Once you have foo.bc, one of the following commands should fail:

1. llc foo.bc
2. llc foo.bc -relocation-model=pic
3. llc foo.bc -relocation-model=static

If none of these crash, please follow the instructions for a *front-end bug*. If one of these do crash, you should be able to reduce this with one of the following bugpoint command lines (use the one corresponding to the command above that failed):

1. bugpoint -run-llc foo.bc
2. bugpoint -run-llc foo.bc --tool-args -relocation-model=pic
3. bugpoint -run-llc foo.bc --tool-args -relocation-model=static

Please run this, then file a bug with the instructions and reduced .bc file that bugpoint emits. If something goes wrong with bugpoint, please submit the "foo.bc" file and the option that llc crashes with.

2.15.3 Miscompilations

If clang successfully produces an executable, but that executable doesn't run right, this is either a bug in the code or a bug in the compiler. The first thing to check is to make sure it is not using undefined behavior (e.g. reading a variable before it is defined). In particular, check to see if the program [valgrind's](#) clean, passes purify, or some other memory checker tool. Many of the "LLVM bugs" that we have chased down ended up being bugs in the program being compiled, not LLVM.

Once you determine that the program itself is not buggy, you should choose which code generator you wish to compile the program with (e.g. LLC or the JIT) and optionally a series of LLVM passes to run. For example:

```
bugpoint -run-llc [... optzn passes ...] file-to-test.bc --args -- [program arguments]
```

bugpoint will try to narrow down your list of passes to the one pass that causes an error, and simplify the bitcode file as much as it can to assist you. It will print a message letting you know how to reproduce the resulting error.

2.15.4 Incorrect code generation

Similarly to debugging incorrect compilation by mis-behaving passes, you can debug incorrect code generation by either LLC or the JIT, using `bugpoint`. The process `bugpoint` follows in this case is to try to narrow the code down to a function that is miscompiled by one or the other method, but since for correctness, the entire program must be run, `bugpoint` will compile the code it deems to not be affected with the C Backend, and then link in the shared object it generates.

To debug the JIT:

```
bugpoint -run-jit -output=[correct output file] [bitcode file] \
--tool-args -- [arguments to pass to lli] \
--args -- [program arguments]
```

Similarly, to debug the LLC, one would run:

```
bugpoint -run-llc -output=[correct output file] [bitcode file] \
--tool-args -- [arguments to pass to llc] \
--args -- [program arguments]
```

Special note: if you are debugging MultiSource or SPEC tests that already exist in the `llvm/test` hierarchy, there is an easier way to debug the JIT, LLC, and CBE, using the pre-written Makefile targets, which will pass the program options specified in the Makefiles:

```
cd llvm/test/../../program
make bugpoint-jit
```

At the end of a successful `bugpoint` run, you will be presented with two bitcode files: a *safe* file which can be compiled with the C backend and the *test* file which either LLC or the JIT mis-codegenerates, and thus causes the error.

To reproduce the error that `bugpoint` found, it is sufficient to do the following:

1. Regenerate the shared object from the safe bitcode file:

```
llc -march=c safe.bc -o safe.c
gcc -shared safe.c -o safe.so
```

2. If debugging LLC, compile test bitcode native and link with the shared object:

```
llc test.bc -o test.s
gcc test.s safe.so -o test.llc
./test.llc [program options]
```

3. If debugging the JIT, load the shared object and supply the test bitcode:

```
lli -load=safe.so test.bc [program options]
```

2.16 Sphinx Quickstart Template

2.16.1 Introduction and Quickstart

This document is meant to get you writing documentation as fast as possible even if you have no previous experience with Sphinx. The goal is to take someone in the state of "I want to write documentation and get it added to LLVM's docs" and turn that into useful documentation mailed to llvm-commits with as little nonsense as possible.

You can find this document in `docs/SphinxQuickstartTemplate.rst`. You should copy it, open the new file in your text editor, write your docs, and then send the new document to llvm-commits for review.

Focus on *content*. It is easy to fix the Sphinx (reStructuredText) syntax later if necessary, although reStructuredText tries to imitate common plain-text conventions so it should be quite natural. A basic knowledge of reStructuredText syntax is useful when writing the document, so the last ~half of this document (starting with *Example Section*) gives examples which should cover 99% of use cases.

Let me say that again: focus on *content*. But if you really need to verify Sphinx's output, see `docs/README.txt` for information.

Once you have finished with the content, please send the `.rst` file to llvm-commits for review.

2.16.2 Guidelines

Try to answer the following questions in your first section:

1. Why would I want to read this document?
2. What should I know to be able to follow along with this document?
3. What will I have learned by the end of this document?

Common names for the first section are *Introduction*, *Overview*, or *Background*.

If possible, make your document a "how to". Give it a name `HowTo*.rst` like the other "how to" documents. This format is usually the easiest for another person to understand and also the most useful.

You generally should not be writing documentation other than a "how to" unless there is already a "how to" about your topic. The reason for this is that without a "how to" document to read first, it is difficult for a person to understand a more advanced document.

Focus on content (yes, I had to say it again).

The rest of this document shows example reStructuredText markup constructs that are meant to be read by you in your text editor after you have copied this file into a new file for the documentation you are about to write.

2.16.3 Example Section

Your text can be *emphasized*, **bold**, or `monospace`.

Use blank lines to separate paragraphs.

Headings (like *Example Section* just above) give your document its structure. Use the same kind of adornments (e.g. ===== vs. -----) as are used in this document. The adornment must be the same length as the text above it. For Vim users, variations of `ypVr=` might be handy.

Example Subsection

Make a link [like this](#). There is also a more sophisticated syntax which [can be more readable](#) for longer links since it disrupts the flow less. You can put the `.. _`link text`: <URL>` block pretty much anywhere later in the document.

Lists can be made like this:

1. A list starting with # . will be automatically numbered.
2. This is a second list element.
 1. Use indentation to create nested lists.

You can also use unordered lists.

- Stuff.
 - Deeper stuff.
- More stuff.

Example Subsubsection

You can make blocks of code like this:

```
int main() {  
    return 0;  
}
```

For a shell session, use a `console` code block (some existing docs use `bash`):

```
$ echo "Goodbye cruel world!"
$ rm -rf /
```

If you need to show LLVM IR use the `llvm` code block.

```
define i32 @test1() {
entry:
    ret i32 0
}
```

Some other common code blocks you might need are `c`, `objc`, `make`, and `cmake`. If you need something beyond that, you can look at the [full list](#) of supported code blocks.

However, don't waste time fiddling with syntax highlighting when you could be adding meaningful content. When in doubt, show preformatted text without any syntax highlighting like this:

```

      .
      +:
    . . : :
      .+++: :+: :.
        .: +      :
          : : . : : : .+
            . . +      :
              . . . . +: .
                :++ .   .
                  .+ : : : :
                    . . . . +

```

(continues on next page)

(continued from previous page)

```

+.:      .:~+.
...+.  .:  .
      .++:..
      ...

```

Hopefully you won't need to be this deep

If you need to do fancier things than what has been shown in this document, you can mail the list or check Sphinx's [reStructuredText Primer](#).

2.17 Markdown Quickstart Template

2.17.1 Introduction and Quickstart

This document is meant to get you writing documentation as fast as possible even if you have no previous experience with Markdown. The goal is to take someone in the state of "I want to write documentation and get it added to LLVM's docs" and turn that into useful documentation mailed to llvm-commits with as little nonsense as possible.

You can find this document in `docs/MarkdownQuickstartTemplate.md`. You should copy it, open the new file in your text editor, write your docs, and then send the new document to llvm-commits for review.

Focus on *content*. It is easy to fix the Markdown syntax later if necessary, although Markdown tries to imitate common plain-text conventions so it should be quite natural. A basic knowledge of Markdown syntax is useful when writing the document, so the last ~half of this document (starting with [Example Section](#)) gives examples which should cover 99% of use cases.

Let me say that again: focus on *content*. But if you really need to verify Sphinx's output, see `docs/README.txt` for information.

Once you have finished with the content, please send the `.md` file to llvm-commits for review.

2.17.2 Guidelines

Try to answer the following questions in your first section:

1. Why would I want to read this document?
2. What should I know to be able to follow along with this document?
3. What will I have learned by the end of this document?

Common names for the first section are `Introduction`, `Overview`, or `Background`.

If possible, make your document a "how to". Give it a name `HowTo*.md` like the other "how to" documents. This format is usually the easiest for another person to understand and also the most useful.

You generally should not be writing documentation other than a "how to" unless there is already a "how to" about your topic. The reason for this is that without a "how to" document to read first, it is difficult for a person to understand a more advanced document.

Focus on content (yes, I had to say it again).

The rest of this document shows example Markdown markup constructs that are meant to be read by you in your text editor after you have copied this file into a new file for the documentation you are about to write.

2.17.3 Example Section

Your text can be *emphasized*, **bold**, or monospace.

Use blank lines to separate paragraphs.

Headings (like `Example Section` just above) give your document its structure.

Example Subsection

Make a link like [this](#). There is also a more sophisticated syntax which [can be more readable](#) for longer links since it disrupts the flow less. You can put the `[link name] : <URL>` block pretty much anywhere later in the document.

Lists can be made like this:

1. A list starting with `[0-9]` . will be automatically numbered.
2. This is a second list element.
 1. Use indentation to create nested lists.

You can also use unordered lists.

- Stuff.
 - Deeper stuff.
- More stuff.

Example Subsubsection

You can make blocks of code like this:

```
int main() {  
    return 0;  
}
```

As an extension to markdown, you can also specify a highlighter to use.

```
int main() {  
    return 0;  
}
```

For a shell session, use a `console` code block.

```
$ echo "Goodbye cruel world!"  
$ rm -rf /
```

If you need to show LLVM IR use the `llvm` code block.

```
define i32 @test1() {  
entry:  
    ret i32 0  
}
```

Some other common code blocks you might need are `c`, `objc`, `make`, and `cmake`. If you need something beyond that, you can look at the [full list](#) of supported code blocks.

However, don't waste time fiddling with syntax highlighting when you could be adding meaningful content. When in doubt, show preformatted text without any syntax highlighting like this:

Hopefully you won't need to be this deep

If you need to do fancier things than what has been shown in this document, you can mail the list or check the [Common Mark spec](#). Sphinx specific integration documentation can be found in the [recommonmark docs](#).

2.18 Code Reviews with Phabricator

- *Sign up*
- *Requesting a review via the command line*
- *Requesting a review via the web interface*
- *Finding potential reviewers*
- *Reviewing code with Phabricator*
- *Committing a change*
 - *Committing someone's change from Phabricator*
 - *Subversion and Arcanist (deprecated)*
- *Abandoning a change*
- *Status*

If you prefer to use a web user interface for code reviews, you can now submit your patches for Clang and LLVM at [LLVM's Phabricator instance](#).

While Phabricator is a useful tool for some, the relevant -commits mailing list is the system of record for all LLVM code review. The mailing list should be added as a subscriber on all reviews, and Phabricator users should be prepared to respond to free-form comments in mail sent to the commits list.

2.18.1 Sign up

To get started with Phabricator, navigate to <https://reviews.llvm.org> and click the power icon in the top right. You can register with a GitHub account, a Google account, or you can create your own profile.

Make *sure* that the email address registered with Phabricator is subscribed to the relevant -commits mailing list. If you are not subscribed to the commit list, all mail sent by Phabricator on your behalf will be held for moderation.

Note that if you use your Subversion user name as Phabricator user name, Phabricator will automatically connect your submits to your Phabricator user in the [Code Repository Browser](#).

2.18.2 Requesting a review via the command line

Phabricator has a tool called *Arcanist* to upload patches from the command line. To get you set up, follow the [Arcanist Quick Start](#) instructions.

You can learn more about how to use arc to interact with Phabricator in the [Arcanist User Guide](#).

2.18.3 Requesting a review via the web interface

The tool to create and review patches in Phabricator is called *Differential*.

Note that you can upload patches created through various diff tools, including git and svn. To make reviews easier, please always include **as much context as possible** with your diff! Don't worry, Phabricator will automatically send a diff with a smaller context in the review email, but having the full file in the web interface will help the reviewer understand your code.

To get a full diff, use one of the following commands (or just use Arcanist to upload your patch):

- `git show HEAD -U999999 > mypatch.patch`
- `git format-patch -U999999 @{u}`
- `svn diff --diff-cmd=diff -x -U999999`

To upload a new patch:

- Click *Differential*.
- Click + *Create Diff*.
- Paste the text diff or browse to the patch file. Click *Create Diff*.
- Leave this first Repository field blank. (We'll fill in the Repository later, when sending the review.)
- Leave the drop down on *Create a new Revision...* and click *Continue*.
- Enter a descriptive title and summary. The title and summary are usually in the form of a *commit message*.
- Add reviewers (see below for advice). (If you set the Repository field correctly, llvm-commits or cfe-commits will be subscribed automatically; otherwise, you will have to manually subscribe them.)
- In the Repository field, enter the name of the project (LLVM, Clang, etc.) to which the review should be sent.
- Click *Save*.

To submit an updated patch:

- Click *Differential*.
- Click + *Create Diff*.
- Paste the updated diff or browse to the updated patch file. Click *Create Diff*.

- Select the review you want to from the *Attach To* dropdown and click *Continue*.
- Leave the Repository field blank. (We previously filled out the Repository for the review request.)
- Add comments about the changes in the new diff. Click *Save*.

Choosing reviewers: You typically pick one or two people as initial reviewers. This choice is not crucial, because you are merely suggesting and not requiring them to participate. Many people will see the email notification on cfe-commits or llvm-commits, and if the subject line suggests the patch is something they should look at, they will.

2.18.4 Finding potential reviewers

Here are a couple of ways to pick the initial reviewer(s):

- Use `svn blame` and the commit log to find names of people who have recently modified the same area of code that you are modifying.
- Look in `CODE_OWNERS.TXT` to see who might be responsible for that area.
- If you've discussed the change on a dev list, the people who participated might be appropriate reviewers.

Even if you think the code owner is the busiest person in the world, it's still okay to put them as a reviewer. Being the code owner means they have accepted responsibility for making sure the review happens.

2.18.5 Reviewing code with Phabricator

Phabricator allows you to add inline comments as well as overall comments to a revision. To add an inline comment, select the lines of code you want to comment on by clicking and dragging the line numbers in the diff pane. When you have added all your comments, scroll to the bottom of the page and click the Submit button.

You can add overall comments in the text box at the bottom of the page. When you're done, click the Submit button.

Phabricator has many useful features, for example allowing you to select diffs between different versions of the patch as it was reviewed in the *Revision Update History*. Most features are self descriptive - explore, and if you have a question, drop by on #llvm in IRC to get help.

Note that as e-mail is the system of reference for code reviews, and some people prefer it over a web interface, we do not generate automated mail when a review changes state, for example by clicking "Accept Revision" in the web interface. Thus, please type LGTM into the comment box to accept a change from Phabricator.

2.18.6 Committing a change

Once a patch has been reviewed and approved on Phabricator it can then be committed to trunk. If you do not have commit access, someone has to commit the change for you (with attribution). It is sufficient to add a comment to the approved review indicating you cannot commit the patch yourself. If you have commit access, there are multiple workflows to commit the change. Whichever method you follow it is recommended that your commit message ends with the line:

```
Differential Revision: <URL>
```

where <URL> is the URL for the code review, starting with `https://reviews.llvm.org/`.

This allows people reading the version history to see the review for context. This also allows Phabricator to detect the commit, close the review, and add a link from the review to the commit.

Note that if you use the Arcanist tool the `Differential Revision` line will be added automatically. If you don't want to use Arcanist, you can add the `Differential Revision` line (as the last line) to the commit message yourself.

Using the Arcanist tool can simplify the process of committing reviewed code as it will retrieve reviewers, the Differential Revision, etc from the review and place it in the commit message. You may also commit an accepted change directly using `git llvm push`, per the section in the *getting started guide*.

Note that if you commit the change without using Arcanist and forget to add the `Differential Revision` line to your commit message then it is recommended that you close the review manually. In the web UI, under "Leap Into Action" put the SVN revision number in the Comment, set the Action to "Close Revision" and click Submit. Note the review must have been Accepted first.

Committing someone's change from Phabricator

On a clean Git repository on an up to date `master` branch run the following (where `<Revision>` is the Phabricator review number):

```
arc patch D<Revision>
```

This will create a new branch called `arcpatch-D<Revision>` based on the current `master` and will create a commit corresponding to `D<Revision>` with a commit message derived from information in the Phabricator review.

Check you are happy with the commit message and amend it if necessary. Then, make sure the commit is up-to-date, and commit it. This can be done by running the following:

```
git pull --rebase origin master
git show # Ensure the patch looks correct.
ninja check-$whatever # Rerun the appropriate tests if needed.
git llvm push
```

Subversion and Arcanist (deprecated)

To download a change from Phabricator and commit it with subversion, you should first make sure you have a clean working directory. Then run the following (where `<Revision>` is the Phabricator review number):

```
arc patch D<Revision>
arc commit --revision D<Revision>
```

The first command will take the latest version of the reviewed patch and apply it to the working copy. The second command will commit this revision to trunk.

2.18.7 Abandoning a change

If you decide you should not commit the patch, you should explicitly abandon the review so that reviewers don't think it is still open. In the web UI, scroll to the bottom of the page where normally you would enter an overall comment. In the drop-down Action list, which defaults to "Comment," you should select "Abandon Revision" and then enter a comment explaining why. Click the Submit button to finish closing the review.

2.18.8 Status

Please let us know whether you like it and what could be improved! We're still working on setting up a bug tracker, but you can email klimek-at-google-dot-com and chandlerc-at-gmail-dot-com and CC the [llvm-dev](#) mailing list with questions until then. We also could use help implementing improvements. This sadly is really painful and hard because the Phabricator codebase is in PHP and not as testable as you might like. However, we've put exactly what we're deploying up on an [llvm-reviews GitHub project](#) where folks can hack on it and post pull requests. We're looking into what the right long-term hosting for this is, but note that it is a derivative of an existing open source project, and so not trivially a good fit for an official LLVM project.

2.19 LLVM Testing Infrastructure Guide

- *Overview*
- *Requirements*
- *LLVM Testing Infrastructure Organization*
 - *Unit tests*
 - *Regression tests*
 - *test-suite*
 - *Debugging Information tests*
- *Quick start*
 - *Unit and Regression tests*
 - *Debugging Information tests*
- *Regression test structure*
 - *Writing new regression tests*
 - *Extra files*
 - *Fragile tests*
 - *Platform-Specific Tests*
 - *Constraining test execution*
 - *Substitutions*
 - *Options*
 - *Other Features*

2.19.1 test-suite Guide

Quickstart

1. The lit test runner is required to run the tests. You can either use one from an LLVM build:

```
% <path to llvm build>/bin/llvm-lit --version
lit 0.8.0dev
```

An alternative is installing it as a python package in a python virtual environment:

```
% mkdir venv
% virtualenv venv
% . venv/bin/activate
% pip install svn+http://llvm.org/svn/llvm-project/llvm/trunk/utils/lit
% lit --version
lit 0.8.0dev
```

2. Check out the test-suite module with:

```
% git clone https://github.com/llvm/llvm-test-suite.git test-suite
```

3. Create a build directory and use CMake to configure the suite. Use the CMAKE_C_COMPILER option to specify the compiler to test. Use a cache file to choose a typical build configuration:

```
% mkdir test-suite-build
% cd test-suite-build
% cmake -DCMAKE_C_COMPILER=<path to llvm build>/bin/clang \
        -C../test-suite/cmake/caches/O3.cmake \
        ../test-suite
```

4. Build the benchmarks:

```
% make
Scanning dependencies of target timeit-target
[ 0%] Building C object tools/CMakeFiles/timeit-target.dir/timeit.c.o
[ 0%] Linking C executable timeit-target
...
```

5. Run the tests with lit:

```
% llvm-lit -v -j 1 -o results.json .
-- Testing: 474 tests, 1 threads --
PASS: test-suite :: MultiSource/Applications/ALAC/decode/alaconvert-decode.test_
↳ (1 of 474)
***** TEST 'test-suite :: MultiSource/Applications/ALAC/decode/alaconvert-
↳ decode.test' RESULTS *****
compile_time: 0.2192
exec_time: 0.0462
hash: "59620e187c6ac38b36382685ccd2b63b"
size: 83348
*****
PASS: test-suite :: MultiSource/Applications/ALAC/encode/alaconvert-encode.test_
↳ (2 of 474)
...
```

6. Show and compare result files (optional):

```
# Make sure pandas is installed. Prepend `sudo` if necessary.
% pip install pandas
# Show a single result file:
% test-suite/utils/compare.py results.json
# Compare two result files:
% test-suite/utils/compare.py results_a.json results_b.json
```

Structure

The test-suite contains benchmark and test programs. The programs come with reference outputs so that their correctness can be checked. The suite comes with tools to collect metrics such as benchmark runtime, compilation time and code size.

The test-suite is divided into several directories:

- `SingleSource/`
Contains test programs that are only a single source file in size. A subdirectory may contain several programs.
- `MultiSource/`
Contains subdirectories which entire programs with multiple source files. Large benchmarks and whole applications go here.
- `MicroBenchmarks/`
Programs using the [google-benchmark](#) library. The programs define functions that are run multiple times until the measurement results are statistically significant.
- `External/`
Contains descriptions and test data for code that cannot be directly distributed with the test-suite. The most prominent members of this directory are the SPEC CPU benchmark suites. See [External Suites](#).
- `Bitcode/`
These tests are mostly written in LLVM bitcode.
- `CTMark/`
Contains symbolic links to other benchmarks forming a representative sample for compilation performance measurements.

Benchmarks

Every program can work as a correctness test. Some programs are unsuitable for performance measurements. Setting the `TEST_SUITE_BENCHMARKING_ONLY` CMake option to `ON` will disable them.

Configuration

The test-suite has configuration options to customize building and running the benchmarks. CMake can print a list of them:

```
% cd test-suite-build
# Print basic options:
% cmake -LH
# Print all options:
% cmake -LAH
```

Common Configuration Options

- CMAKE_C_FLAGS

Specify extra flags to be passed to C compiler invocations. The flags are also passed to the C++ compiler and linker invocations. See https://cmake.org/cmake/help/latest/variable/CMAKE_LANG_FLAGS.html

- CMAKE_C_COMPILER

Select the C compiler executable to be used. Note that the C++ compiler is inferred automatically i.e. when specifying `path/to/clang` CMake will automatically use `path/to/clang++` as the C++ compiler. See https://cmake.org/cmake/help/latest/variable/CMAKE_LANG_COMPILER.html

- CMAKE_BUILD_TYPE

Select a build type like `OPTIMIZE` or `DEBUG` selecting a set of predefined compiler flags. These flags are applied regardless of the `CMAKE_C_FLAGS` option and may be changed by modifying `CMAKE_C_FLAGS_OPTIMIZE` etc. See [\[https://cmake.org/cmake/help/latest/variable/CMAKE_BUILD_TYPE.html\]](https://cmake.org/cmake/help/latest/variable/CMAKE_BUILD_TYPE.html) (<https://cmake.org/cmake/help/latest/variable/CMA>

- TEST_SUITE_RUN_UNDER

Prefix test invocations with the given tool. This is typically used to run cross-compiled tests within a simulator tool.

- TEST_SUITE_BENCHMARKING_ONLY

Disable tests that are unsuitable for performance measurements. The disabled tests either run for a very short time or are dominated by I/O performance making them unsuitable as compiler performance tests.

- TEST_SUITE_SUBDIRS

Semicolon-separated list of directories to include. This can be used to only build parts of the test-suite or to include external suites. This option does not work reliably with deeper subdirectories as it skips intermediate `CMakeLists.txt` files which may be required.

- TEST_SUITE_COLLECT_STATS

Collect internal LLVM statistics. Appends `-save-stats=obj` when invoking the compiler and makes the lit runner collect and merge the statistic files.

- TEST_SUITE_RUN_BENCHMARKS

If this is set to `OFF` then lit will not actually run the tests but just collect build statistics like compile time and code size.

- TEST_SUITE_USE_PERF

Use the `perf` tool for time measurement instead of the `timeit` tool that comes with the test-suite. The `perf` is usually available on linux systems.

- TEST_SUITE_SPEC2000_ROOT, TEST_SUITE_SPEC2006_ROOT, TEST_SUITE_SPEC2017_ROOT, ...

Specify installation directories of external benchmark suites. You can find more information about expected versions or usage in the README files in the External directory (such as External/SPEC/README)

Common CMake Flags

- `-GNinja`
Generate build files for the ninja build tool.
- `-Ctest-suite/cmake/caches/<cachefile.cmake>`
Use a CMake cache. The test-suite comes with several CMake caches which predefine common or tricky build configurations.

Displaying and Analyzing Results

The `compare.py` script displays and compares result files. A result file is produced when invoking `lit` with the `-o filename.json` flag.

Example usage:

- Basic Usage:

```
% test-suite/utils/compare.py baseline.json
Warning: 'test-suite :: External/SPEC/CINT2006/403.gcc/403.gcc.test' has No
↳metrics!
Tests: 508
Metric: exec_time

Program                                baseline

INT2006/456.hmmmer/456.hmmmer          1222.90
INT2006/464.h264ref/464.h264ref        928.70
...
                                baseline
count  506.000000
mean   20.563098
std    111.423325
min    0.003400
25%    0.011200
50%    0.339450
75%    4.067200
max    1222.896800
```

- Show `compile_time` or text segment size metrics:

```
% test-suite/utils/compare.py -m compile_time baseline.json
% test-suite/utils/compare.py -m size.__text baseline.json
```

- Compare two result files and filter short running tests:

```
% test-suite/utils/compare.py --filter-short baseline.json experiment.json
...
Program                                baseline  experiment  diff
```

(continues on next page)

(continued from previous page)

SingleSour.../Benchmarks/Linpack/linpack-pc	5.16	4.30	-16.5%
MultiSour...erolling-dbl/LoopRerolling-dbl	7.01	7.86	12.2%
SingleSour...UnitTests/Vectorizer/gcc-loops	3.89	3.54	-9.0%
...			

- Merge multiple baseline and experiment result files by taking the minimum runtime each:

```
% test-suite/utils/compare.py base0.json base1.json base2.json vs exp0.json exp1.
↪ json exp2.json
```

Continuous Tracking with LNT

LNT is a set of client and server tools for continuously monitoring performance. You can find more information at <http://llvm.org/docs/lnt>. The official LNT instance of the LLVM project is hosted at <http://lnt.llvm.org>.

External Suites

External suites such as SPEC can be enabled by either

- placing (or linking) them into the `test-suite/test-suite-externals/xxx` directory (example: `test-suite/test-suite-externals/speccpu2000`)
- using a configuration option such as `-D TEST_SUITE_SPEC2000_ROOT=path/to/speccpu2000`

You can find further information in the respective README files such as `test-suite/External/SPEC/README`.

For the SPEC benchmarks you can switch between the `test`, `train` and `ref` input datasets via the `TEST_SUITE_RUN_TYPE` configuration option. The `train` dataset is used by default.

Custom Suites

You can build custom suites using the test-suite infrastructure. A custom suite has a `CMakeLists.txt` file at the top directory. The `CMakeLists.txt` will be picked up automatically if placed into a subdirectory of the test-suite or when setting the `TEST_SUITE_SUBDIRS` variable:

```
% cmake -DTEST_SUITE_SUBDIRS=path/to/my/benchmark-suite ../test-suite
```

Profile Guided Optimization

Profile guided optimization requires to compile and run twice. First the benchmark should be compiled with profile generation instrumentation enabled and setup for training data. The lit runner will merge the profile files using `llvm-profdata` so they can be used by the second compilation run.

Example:

```
# Profile generation run:
% cmake -DTEST_SUITE_PROFILE_GENERATE=ON \
        -DTEST_SUITE_RUN_TYPE=train \
        ../test-suite
% make
```

(continues on next page)

(continued from previous page)

```
% llvm-lit .
# Use the profile data for compilation and actual benchmark run:
% cmake -DTEST_SUITE_PROFILE_GENERATE=OFF \
        -DTEST_SUITE_PROFILE_USE=ON \
        -DTEST_SUITE_RUN_TYPE=ref \
        .
% make
% llvm-lit -o result.json .
```

The `TEST_SUITE_RUN_TYPE` setting only affects the SPEC benchmark suites.

Cross Compilation and External Devices

Compilation

CMake allows to cross compile to a different target via toolchain files. More information can be found here:

- <http://llvm.org/docs/Int/tests.html#cross-compiling>
- <https://cmake.org/cmake/help/latest/manual/cmake-toolchains.7.html>

Cross compilation from macOS to iOS is possible with the `test-suite/cmake/caches/target-target-*-iphoneos-internal.cmake` CMake cache files; this requires an internal iOS SDK.

Running

There are two ways to run the tests in a cross compilation setting:

- Via SSH connection to an external device: The `TEST_SUITE_REMOTE_HOST` option should be set to the SSH hostname. The executables and data files need to be transferred to the device after compilation. This is typically done via the `rsync` make target. After this, the lit runner can be used on the host machine. It will prefix the benchmark and verification command lines with an `ssh` command.

Example:

```
% cmake -G Ninja -D CMAKE_C_COMPILER=path/to/clang \
        -C ../test-suite/cmake/caches/target-arm64-iphoneos-internal.cmake \
        -D TEST_SUITE_REMOTE_HOST=mydevice \
        ../test-suite
% ninja
% ninja rsync
% llvm-lit -jl -o result.json .
```

- You can specify a simulator for the target machine with the `TEST_SUITE_RUN_UNDER` setting. The lit runner will prefix all benchmark invocations with it.

Running the test-suite via LNT

The LNT tool can run the test-suite. Use this when submitting test results to an LNT instance. See <http://llvm.org/docs/Lnt/tests.html#llvm-cmake-test-suite> for details.

Running the test-suite via Makefiles (deprecated)

Note: The test-suite comes with a set of Makefiles that are considered deprecated. They do not support newer testing modes like Bitcode or Microbenchmarks and are harder to use.

Old documentation is available in the *test-suite Makefile Guide*.

2.19.2 test-suite Makefile Guide (deprecated)

- *Overview*
- *Configuring External Tests*
- *Running Different Tests*
- *Generating Test Output*
- *Writing Custom Tests for the test-suite*

Overview

First, all tests are executed within the LLVM object directory tree. They *are not* executed inside of the LLVM source tree. This is because the test suite creates temporary files during execution.

To run the test suite, you need to use the following steps:

1. Check out the `test-suite` module with:

```
% git clone https://github.com/llvm/llvm-test-suite.git test-suite
```

2. **FIXME:** these directions are outdated and won't work. Figure out what the correct thing to do is, and write it down here.
3. Configure and build `llvm`.
4. Configure and build `llvm-gcc`.
5. Install `llvm-gcc` somewhere.
6. *Re-configure* `llvm` from the top level of each build tree (LLVM object directory tree) in which you want to run the test suite, just as you do before building LLVM.

During the *re-configuration*, you must either: (1) have `llvm-gcc` you just built in your path, or (2) specify the directory where your just-built `llvm-gcc` is installed using `--with-llvmgccdir=$LLVM_GCC_DIR`.

You must also tell the configure machinery that the test suite is available so it can be configured for your build tree:

```
% cd $LLVM_OBJ_ROOT ; $LLVM_SRC_ROOT/configure [--with-llvmgccdir=$LLVM_GCC_DIR]
```

[Remember that `$LLVM_GCC_DIR` is the directory where you *installed* `llvm-gcc`, not its `src` or `obj` directory.]

7. You can now run the test suite from your build tree as follows:

```
% cd $LLVM_OBJ_ROOT/projects/test-suite
% make
```

Note that the second and third steps only need to be done once. After you have the suite checked out and configured, you don't need to do it again (unless the test code or configure script changes).

Configuring External Tests

In order to run the External tests in the `test-suite` module, you must specify `--with-externals`. This must be done during the *re-configuration* step (see above), and the `llvm` re-configuration must recognize the previously-built `llvm-gcc`. If any of these is missing or neglected, the External tests won't work.

- `--with-externals`
- `--with-externals=<directory>`

This tells LLVM where to find any external tests. They are expected to be in specifically named subdirectories of `<directory>`. If `directory` is left unspecified, `configure` uses the default value `/home/vadve/shared/benchmarks/speccpu2000/benchspec`. Subdirectory names known to LLVM include:

- `spec95`
- `speccpu2000`
- `speccpu2006`
- `povray31`

Others are added from time to time, and can be determined from `configure`.

Running Different Tests

In addition to the regular "whole program" tests, the `test-suite` module also provides a mechanism for compiling the programs in different ways. If the variable `TEST` is defined on the `gmake` command line, the test system will include a Makefile named `TEST.<value of TEST variable>.Makefile`. This Makefile can modify build rules to yield different results.

For example, the LLVM nightly tester uses `TEST.nightly.Makefile` to create the nightly test reports. To run the nightly tests, run `gmake TEST=nightly`.

There are several TEST Makefiles available in the tree. Some of them are designed for internal LLVM research and will not work outside of the LLVM research group. They may still be valuable, however, as a guide to writing your own TEST Makefile for any optimization or analysis passes that you develop with LLVM.

Generating Test Output

There are a number of ways to run the tests and generate output. The most simple one is simply running `gmake` with no arguments. This will compile and run all programs in the tree using a number of different methods and compare results. Any failures are reported in the output, but are likely drowned in the other output. Passes are not reported explicitly.

Somewhat better is running `gmake TEST=sometest test`, which runs the specified test and usually adds per-program summaries to the output (depending on which `sometest` you use). For example, the `nightly` test explicitly outputs `TEST-PASS` or `TEST-FAIL` for every test after each program. Though these lines are still drowned in the output, it's easy to `grep` the output logs in the Output directories.

Even better are the `report` and `report.format targets` (where `format` is one of `html`, `csv`, `text` or `graphs`). The exact contents of the report are dependent on which `TEST` you are running, but the text results are always shown at the end of the run and the results are always stored in the `report.<type>.format` file (when running with `TEST=<type>`). The report also generate a file called `report.<type>.raw.out` containing the output of the entire test run.

Writing Custom Tests for the test-suite

Assuming you can run the test suite, (e.g. `"gmake TEST=nightly report"` should work), it is really easy to run optimizations or code generator components against every program in the tree, collecting statistics or running custom checks for correctness. At base, this is how the nightly tester works, it's just one example of a general framework.

Lets say that you have an LLVM optimization pass, and you want to see how many times it triggers. First thing you should do is add an LLVM [statistic](#) to your pass, which will tally counts of things you care about.

Following this, you can set up a test and a report that collects these and formats them for easy viewing. This consists of two files, a `"test-suite/TEST.XXX.Makefile"` fragment (where `XXX` is the name of your test) and a `"test-suite/TEST.XXX.report"` file that indicates how to format the output into a table. There are many example reports of various levels of sophistication included with the test suite, and the framework is very general.

If you are interested in testing an optimization pass, check out the "libcalls" test as an example. It can be run like this:

```
% cd llvm/projects/test-suite/MultiSource/Benchmarks # or some other level
% make TEST=libcalls report
```

This will do a bunch of stuff, then eventually print a table like this:

Name	total	#exit
...		
FreeBench/analyzer/analyzer	51	6
FreeBench/fourinarow/fourinarow	1	1
FreeBench/neural/neural	19	9
FreeBench/pifft/pifft	5	3
MallocBench/cfrac/cfrac	1	*
MallocBench/espresso/espresso	52	12
MallocBench/gs/gs	4	*
Prolangs-C/TimberWolfMC/timberwolfmc	302	*
Prolangs-C/agrep/agrep	33	12
Prolangs-C/allroots/allroots	*	*
Prolangs-C/assembler/assembler	47	*
Prolangs-C/bison/mybison	74	*
...		

This basically is grepping the `-stats` output and displaying it in a table. You can also use the `"TEST=libcalls report.html"` target to get the table in HTML form, similarly for `report.csv` and `report.tex`.

The source for this is in `test-suite/TEST.libcalls.*`. The format is pretty simple: the Makefile indicates how to run the test (in this case, `"opt -simplify-libcalls -stats"`), and the report contains one line for each column of the output. The first value is the header for the column and the second is the regex to grep the output of the command for. There are lots of example reports that can do fancy stuff.

2.19.3 Overview

This document is the reference manual for the LLVM testing infrastructure. It documents the structure of the LLVM testing infrastructure, the tools needed to use it, and how to add and run tests.

2.19.4 Requirements

In order to use the LLVM testing infrastructure, you will need all of the software required to build LLVM, as well as [Python 2.7](#) or later.

2.19.5 LLVM Testing Infrastructure Organization

The LLVM testing infrastructure contains three major categories of tests: unit tests, regression tests and whole programs. The unit tests and regression tests are contained inside the LLVM repository itself under `llvm/unittests` and `llvm/test` respectively and are expected to always pass -- they should be run before every commit.

The whole programs tests are referred to as the "LLVM test suite" (or "test-suite") and are in the `test-suite` module in subversion. For historical reasons, these tests are also referred to as the "nightly tests" in places, which is less ambiguous than "test-suite" and remains in use although we run them much more often than nightly.

Unit tests

Unit tests are written using [Google Test](#) and [Google Mock](#) and are located in the `llvm/unittests` directory.

Regression tests

The regression tests are small pieces of code that test a specific feature of LLVM or trigger a specific bug in LLVM. The language they are written in depends on the part of LLVM being tested. These tests are driven by the [Lit](#) testing tool (which is part of LLVM), and are located in the `llvm/test` directory.

Typically when a bug is found in LLVM, a regression test containing just enough code to reproduce the problem should be written and placed somewhere underneath this directory. For example, it can be a small piece of LLVM IR distilled from an actual application or benchmark.

test-suite

The test suite contains whole programs, which are pieces of code which can be compiled and linked into a stand-alone program that can be executed. These programs are generally written in high level languages such as C or C++.

These programs are compiled using a user specified compiler and set of flags, and then executed to capture the program output and timing information. The output of these programs is compared to a reference output to ensure that the program is being compiled correctly.

In addition to compiling and executing programs, whole program tests serve as a way of benchmarking LLVM performance, both in terms of the efficiency of the programs generated as well as the speed with which LLVM compiles, optimizes, and generates code.

The test-suite is located in the `test-suite` Subversion module.

See the [test-suite Guide](#) for details.

Debugging Information tests

The test suite contains tests to check quality of debugging information. The test are written in C based languages or in LLVM assembly language.

These tests are compiled and run under a debugger. The debugger output is checked to validate of debugging information. See README.txt in the test suite for more information . This test suite is located in the `debuginfo-tests` Subversion module.

2.19.6 Quick start

The tests are located in two separate Subversion modules. The unit and regression tests are in the main "llvm" module under the directories `llvm/unittests` and `llvm/test` (so you get these tests for free with the main LLVM tree). Use `make check-all` to run the unit and regression tests after building LLVM.

The `test-suite` module contains more comprehensive tests including whole C and C++ programs. See the [test-suite Guide](#) for details.

Unit and Regression tests

To run all of the LLVM unit tests use the `check-llvm-unit` target:

```
% make check-llvm-unit
```

To run all of the LLVM regression tests use the `check-llvm` target:

```
% make check-llvm
```

In order to get reasonable testing performance, build LLVM and subprojects in release mode, i.e.

```
% cmake -DCMAKE_BUILD_TYPE="Release" -DLLVM_ENABLE_ASSERTIONS=On
```

If you have [Clang](#) checked out and built, you can run the LLVM and Clang tests simultaneously using:

```
% make check-all
```

To run the tests with Valgrind (Memcheck by default), use the `LIT_ARGS` make variable to pass the required options to lit. For example, you can use:

```
% make check LIT_ARGS="-v --vg --vg-leak"
```

to enable testing with valgrind and with leak checking enabled.

To run individual tests or subsets of tests, you can use the `llvm-lit` script which is built as part of LLVM. For example, to run the `Integer/BitPacked.ll` test by itself you can run:

```
% llvm-lit ~/llvm/test/Integer/BitPacked.ll
```

or to run all of the ARM CodeGen tests:

```
% llvm-lit ~/llvm/test/CodeGen/ARM
```

For more information on using the `lit` tool, see `llvm-lit --help` or the [lit man page](#).

Debugging Information tests

To run debugging information tests simply add the `debuginfo-tests` project to your `LLVM_ENABLE_PROJECTS` define on the `cmake` command-line.

2.19.7 Regression test structure

The LLVM regression tests are driven by **lit** and are located in the `llvm/test` directory.

This directory contains a large array of small tests that exercise various features of LLVM and to ensure that regressions do not occur. The directory is broken into several sub-directories, each focused on a particular area of LLVM.

Writing new regression tests

The regression test structure is very simple, but does require some information to be set. This information is gathered via `configure` and is written to a file, `test/lit.site.cfg` in the build directory. The `llvm/test` Makefile does this work for you.

In order for the regression tests to work, each directory of tests must have a `lit.local.cfg` file. **lit** looks for this file to determine how to run the tests. This file is just Python code and thus is very flexible, but we've standardized it for the LLVM regression tests. If you're adding a directory of tests, just copy `lit.local.cfg` from another directory to get running. The standard `lit.local.cfg` simply specifies which files to look in for tests. Any directory that contains only directories does not need the `lit.local.cfg` file. Read the [Lit documentation](#) for more information.

Each test file must contain lines starting with "RUN:" that tell **lit** how to run it. If there are no RUN lines, **lit** will issue an error while running a test.

RUN lines are specified in the comments of the test program using the keyword `RUN` followed by a colon, and lastly the command (pipeline) to execute. Together, these lines form the "script" that **lit** executes to run the test case. The syntax of the RUN lines is similar to a shell's syntax for pipelines including I/O redirection and variable substitution. However, even though these lines may *look* like a shell script, they are not. RUN lines are interpreted by **lit**. Consequently, the syntax differs from shell in a few ways. You can specify as many RUN lines as needed.

lit performs substitution on each RUN line to replace LLVM tool names with the full paths to the executable built for each tool (in `$(LLVM_OBJ_ROOT)/$(BuildMode)/bin`). This ensures that **lit** does not invoke any stray LLVM tools in the user's path during testing.

Each RUN line is executed on its own, distinct from other lines unless its last character is `\`. This continuation character causes the RUN line to be concatenated with the next one. In this way you can build up long pipelines of commands without making huge line lengths. The lines ending in `\` are concatenated until a RUN line that doesn't end in `\` is found. This concatenated set of RUN lines then constitutes one execution. **lit** will substitute variables and arrange for the pipeline to be executed. If any process in the pipeline fails, the entire line (and test case) fails too.

Below is an example of legal RUN lines in a `.ll` file:

```
; RUN: llvm-as < %s | llvm-dis > %t1
; RUN: llvm-dis < %s.bc-13 > %t2
; RUN: diff %t1 %t2
```

As with a Unix shell, the RUN lines permit pipelines and I/O redirection to be used.

There are some quoting rules that you must pay attention to when writing your RUN lines. In general nothing needs to be quoted. **lit** won't strip off any quote characters so they will get passed to the invoked program. To avoid this use curly braces to tell **lit** that it should treat everything enclosed as one value.

In general, you should strive to keep your `RUN:` lines as simple as possible, using them only to run tools that generate textual output you can then examine. The recommended way to examine output to figure out if the test passes is using the *FileCheck tool*. *[The usage of `grep` in `RUN` lines is deprecated - please do not send or commit patches that use it.]*

Put related tests into a single file rather than having a separate file per test. Check if there are files already covering your feature and consider adding your code there instead of creating a new file.

Extra files

If your test requires extra files besides the file containing the `RUN:` lines, the idiomatic place to put them is in a subdirectory `Inputs`. You can then refer to the extra files as `%S/Inputs/foo.bar`.

For example, consider `test/Linker/ident.ll`. The directory structure is as follows:

```
test/
  Linker/
    ident.ll
    Inputs/
      ident.a.ll
      ident.b.ll
```

For convenience, these are the contents:

```
;;;; ident.ll:

; RUN: llvm-link %S/Inputs/ident.a.ll %S/Inputs/ident.b.ll -S | FileCheck %s

; Verify that multiple input llvm.ident metadata are linked together.

; CHECK-DAG: !llvm.ident = !{!0, !1, !2}
; CHECK-DAG: "Compiler V1"
; CHECK-DAG: "Compiler V2"
; CHECK-DAG: "Compiler V3"

;;;; Inputs/ident.a.ll:

!llvm.ident = !{!0, !1}
!0 = metadata !{metadata !"Compiler V1"}
!1 = metadata !{metadata !"Compiler V2"}

;;;; Inputs/ident.b.ll:

!llvm.ident = !{!0}
!0 = metadata !{metadata !"Compiler V3"}
```

For symmetry reasons, `ident.ll` is just a dummy file that doesn't actually participate in the test besides holding the `RUN:` lines.

Note: Some existing tests use `RUN: true` in extra files instead of just putting the extra files in an `Inputs/` directory. This pattern is deprecated.

Fragile tests

It is easy to write a fragile test that would fail spuriously if the tool being tested outputs a full path to the input file. For example, `opt` by default outputs a `ModuleID`:

```
$ cat example.ll
define i32 @main() nounwind {
    ret i32 0
}

$ opt -S /path/to/example.ll
; ModuleID = '/path/to/example.ll'

define i32 @main() nounwind {
    ret i32 0
}
```

`ModuleID` can unexpectedly match against `CHECK` lines. For example:

```
; RUN: opt -S %s | FileCheck

define i32 @main() nounwind {
    ; CHECK-NOT: load
    ret i32 0
}
```

This test will fail if placed into a `download` directory.

To make your tests robust, always use `opt ... < %s` in the `RUN` line. `opt` does not output a `ModuleID` when input comes from `stdin`.

Platform-Specific Tests

Whenever adding tests that require the knowledge of a specific platform, either related to code generated, specific output or back-end features, you must make sure to isolate the features, so that buildbots that run on different architectures (and don't even compile all back-ends), don't fail.

The first problem is to check for target-specific output, for example sizes of structures, paths and architecture names, for example:

- Tests containing Windows paths will fail on Linux and vice-versa.
- Tests that check for `x86_64` somewhere in the text will fail anywhere else.
- Tests where the debug information calculates the size of types and structures.

Also, if the test rely on any behaviour that is coded in any back-end, it must go in its own directory. So, for instance, code generator tests for ARM go into `test/CodeGen/ARM` and so on. Those directories contain a special `lit` configuration file that ensure all tests in that directory will only run if a specific back-end is compiled and available.

For instance, on `test/CodeGen/ARM`, the `lit.local.cfg` is:

```
config.suffixes = ['.ll', '.c', '.cpp', '.test']
if not 'ARM' in config.root.targets:
    config.unsupported = True
```

Other platform-specific tests are those that depend on a specific feature of a specific sub-architecture, for example only to Intel chips that support AVX2.

For instance, `test/CodeGen/X86/psubus.ll` tests three sub-architecture variants:

```
; RUN: llc -mcpu=core2 < %s | FileCheck %s -check-prefix=SSE2
; RUN: llc -mcpu=corei7-avx < %s | FileCheck %s -check-prefix=AVX1
; RUN: llc -mcpu=core-avx2 < %s | FileCheck %s -check-prefix=AVX2
```

And the checks are different:

```
; SSE2: @test1
; SSE2: psubusw LCPI0_0(%rip), %xmm0
; AVX1: @test1
; AVX1: vpsubusw LCPI0_0(%rip), %xmm0, %xmm0
; AVX2: @test1
; AVX2: vpsubusw LCPI0_0(%rip), %xmm0, %xmm0
```

So, if you're testing for a behaviour that you know is platform-specific or depends on special features of sub-architectures, you must add the specific triple, test with the specific FileCheck and put it into the specific directory that will filter out all other architectures.

Constraining test execution

Some tests can be run only in specific configurations, such as with debug builds or on particular platforms. Use `REQUIRES` and `UNSUPPORTED` to control when the test is enabled.

Some tests are expected to fail. For example, there may be a known bug that the test detect. Use `XFAIL` to mark a test as an expected failure. An `XFAIL` test will be successful if its execution fails, and will be a failure if its execution succeeds.

```
; This test will be only enabled in the build with asserts.
; REQUIRES: asserts
; This test is disabled on Linux.
; UNSUPPORTED: -linux-
; This test is expected to fail on PowerPC.
; XFAIL: powerpc
```

`REQUIRES` and `UNSUPPORTED` and `XFAIL` all accept a comma-separated list of boolean expressions. The values in each expression may be:

- Features added to `config.available_features` by configuration files such as `lit.cfg`.
- Substrings of the target triple (`UNSUPPORTED` and `XFAIL` only).

`REQUIRES` enables the test if all expressions are true.

`UNSUPPORTED` disables the test if any expression is true.

`XFAIL` expects the test to fail if any expression is true.

As a special case, `XFAIL: *` is expected to fail everywhere.

```
; This test is disabled on Windows,
; and is disabled on Linux, except for Android Linux.
; UNSUPPORTED: windows, linux && !android
; This test is expected to fail on both PowerPC and ARM.
; XFAIL: powerpc || arm
```

Substitutions

Besides replacing LLVM tool names the following substitutions are performed in RUN lines:

%% Replaced by a single `%`. This allows escaping other substitutions.

%s File path to the test case's source. This is suitable for passing on the command line as the input to an LLVM tool.

Example: `/home/user/llvm/test/MC/ELF/foo_test.s`

%S Directory path to the test case's source.

Example: `/home/user/llvm/test/MC/ELF`

%t File path to a temporary file name that could be used for this test case. The file name won't conflict with other test cases. You can append to it if you need multiple temporaries. This is useful as the destination of some redirected output.

Example: `/home/user/llvm.build/test/MC/ELF/Output/foo_test.s.tmp`

%T Directory of `%t`. Deprecated. Shouldn't be used, because it can be easily misused and cause race conditions between tests.

Use `rm -rf %t && mkdir %t` instead if a temporary directory is necessary.

Example: `/home/user/llvm.build/test/MC/ELF/Output`

%{pathsep}

Expands to the path separator, i.e. `:` (or `;` on Windows).

%/s, %/S, %/t, %/T:

Act like the corresponding substitution above but replace any `\` character with a `/`. This is useful to normalize path separators.

Example: `%s: C:\Desktop Files/foo_test.s.tmp`

Example: `%/s: C:/Desktop Files/foo_test.s.tmp`

%:s, %:S, %:t, %:T:

Act like the corresponding substitution above but remove colons at the beginning of Windows paths. This is useful to allow concatenation of absolute paths on Windows to produce a legal path.

Example: `%s: C:\Desktop Files\foo_test.s.tmp`

Example: `%:s: C\Desktop Files\foo_test.s.tmp`

LLVM-specific substitutions:

%shlibext The suffix for the host platforms shared library files. This includes the period as the first character.

Example: `.so` (Linux), `.dylib` (macOS), `.dll` (Windows)

%exeext The suffix for the host platforms executable files. This includes the period as the first character.

Example: `.exe` (Windows), empty on Linux.

%(line), %(line+<number>), %(line-<number>) The number of the line where this substitution is used, with an optional integer offset. This can be used in tests with multiple RUN lines, which reference test file's line numbers.

Clang-specific substitutions:

%clang Invokes the Clang driver.

%clang_cpp Invokes the Clang driver for C++.

%clang_cl Invokes the CL-compatible Clang driver.

%clangxx Invokes the G++-compatible Clang driver.

%clang_cc1 Invokes the Clang frontend.

%itanium_abi_triple, %ms_abi_triple These substitutions can be used to get the current target triple adjusted to the desired ABI. For example, if the test suite is running with the `i686-pc-win32` target, `%itanium_abi_triple` will expand to `i686-pc-mingw32`. This allows a test to run with a specific ABI without constraining it to a specific triple.

To add more substitutions, look at `test/lit.cfg` or `lit.local.cfg`.

Options

The LLVM lit configuration allows to customize some things with user options:

llc, opt, ... Substitute the respective LLVM tool name with a custom command line. This allows to specify custom paths and default arguments for these tools. Example:

```
% llvm-lit "-Dllc=llc -verify-machineinstrs"
```

run_long_tests Enable the execution of long running tests.

llvm_site_config Load the specified lit configuration instead of the default one.

Other Features

To make RUN line writing easier, there are several helper programs. These helpers are in the PATH when running tests, so you can just call them using their name. For example:

not This program runs its arguments and then inverts the result code from it. Zero result codes become 1. Non-zero result codes become 0.

To make the output more useful, **lit** will scan the lines of the test case for ones that contain a pattern that matches `PR[0-9]+`. This is the syntax for specifying a PR (Problem Report) number that is related to the test case. The number after "PR" specifies the LLVM bugzilla number. When a PR number is specified, it will be used in the pass/fail reporting. This is useful to quickly get some context when a test fails.

Finally, any line that contains "END." will cause the special interpretation of lines to terminate. This is generally done right after the last RUN: line. This has two side effects:

- (a) it prevents special interpretation of lines that are part of the test program, not the instructions to the test case, and
- (b) it speeds things up for really big test cases by avoiding interpretation of the remainder of the file.

2.20 LLVM Tutorial: Table of Contents

2.20.1 Kaleidoscope: Implementing a Language with LLVM

Kaleidoscope: Tutorial Introduction and the Lexer

- *Tutorial Introduction*

- *The Basic Language*
- *The Lexer*

Tutorial Introduction

Welcome to the "Implementing a language with LLVM" tutorial. This tutorial runs through the implementation of a simple language, showing how fun and easy it can be. This tutorial will get you up and started as well as help to build a framework you can extend to other languages. The code in this tutorial can also be used as a playground to hack on other LLVM specific things.

The goal of this tutorial is to progressively unveil our language, describing how it is built up over time. This will let us cover a fairly broad range of language design and LLVM-specific usage issues, showing and explaining the code for it all along the way, without overwhelming you with tons of details up front.

It is useful to point out ahead of time that this tutorial is really about teaching compiler techniques and LLVM specifically, *not* about teaching modern and sane software engineering principles. In practice, this means that we'll take a number of shortcuts to simplify the exposition. For example, the code uses global variables all over the place, doesn't use nice design patterns like *visitors*, etc... but it is very simple. If you dig in and use the code as a basis for future projects, fixing these deficiencies shouldn't be hard.

I've tried to put this tutorial together in a way that makes chapters easy to skip over if you are already familiar with or are uninterested in the various pieces. The structure of the tutorial is:

- *Chapter #1*: Introduction to the Kaleidoscope language, and the definition of its Lexer - This shows where we are going and the basic functionality that we want it to do. In order to make this tutorial maximally understandable and hackable, we choose to implement everything in C++ instead of using lexer and parser generators. LLVM obviously works just fine with such tools, feel free to use one if you prefer.
- *Chapter #2*: Implementing a Parser and AST - With the lexer in place, we can talk about parsing techniques and basic AST construction. This tutorial describes recursive descent parsing and operator precedence parsing. Nothing in Chapters 1 or 2 is LLVM-specific, the code doesn't even link in LLVM at this point. :)
- *Chapter #3*: Code generation to LLVM IR - With the AST ready, we can show off how easy generation of LLVM IR really is.
- *Chapter #4*: Adding JIT and Optimizer Support - Because a lot of people are interested in using LLVM as a JIT, we'll dive right into it and show you the 3 lines it takes to add JIT support. LLVM is also useful in many other ways, but this is one simple and "sexy" way to show off its power. :)
- *Chapter #5*: Extending the Language: Control Flow - With the language up and running, we show how to extend it with control flow operations (if/then/else and a 'for' loop). This gives us a chance to talk about simple SSA construction and control flow.
- *Chapter #6*: Extending the Language: User-defined Operators - This is a silly but fun chapter that talks about extending the language to let the user program define their own arbitrary unary and binary operators (with assignable precedence!). This lets us build a significant piece of the "language" as library routines.
- *Chapter #7*: Extending the Language: Mutable Variables - This chapter talks about adding user-defined local variables along with an assignment operator. The interesting part about this is how easy and trivial it is to construct SSA form in LLVM: no, LLVM does *not* require your front-end to construct SSA form!
- *Chapter #8*: Compiling to Object Files - This chapter explains how to take LLVM IR and compile it down to object files.
- *Chapter #9*: Extending the Language: Debug Information - Having built a decent little programming language with control flow, functions and mutable variables, we consider what it takes to add debug information to

standalone executables. This debug information will allow you to set breakpoints in Kaleidoscope functions, print out argument variables, and call functions - all from within the debugger!

- [Chapter #10](#): Conclusion and other useful LLVM tidbits - This chapter wraps up the series by talking about potential ways to extend the language, but also includes a bunch of pointers to info about "special topics" like adding garbage collection support, exceptions, debugging, support for "spaghetti stacks", and a bunch of other tips and tricks.

By the end of the tutorial, we'll have written a bit less than 1000 lines of non-comment, non-blank, lines of code. With this small amount of code, we'll have built up a very reasonable compiler for a non-trivial language including a hand-written lexer, parser, AST, as well as code generation support with a JIT compiler. While other systems may have interesting "hello world" tutorials, I think the breadth of this tutorial is a great testament to the strengths of LLVM and why you should consider it if you're interested in language or compiler design.

A note about this tutorial: we expect you to extend the language and play with it on your own. Take the code and go crazy hacking away at it, compilers don't need to be scary creatures - it can be a lot of fun to play with languages!

The Basic Language

This tutorial will be illustrated with a toy language that we'll call "[Kaleidoscope](#)" (derived from "meaning beautiful, form, and view"). Kaleidoscope is a procedural language that allows you to define functions, use conditionals, math, etc. Over the course of the tutorial, we'll extend Kaleidoscope to support the if/then/else construct, a for loop, user defined operators, JIT compilation with a simple command line interface, etc.

Because we want to keep things simple, the only datatype in Kaleidoscope is a 64-bit floating point type (aka 'double' in C parlance). As such, all values are implicitly double precision and the language doesn't require type declarations. This gives the language a very nice and simple syntax. For example, the following simple example computes [Fibonacci numbers](#):

```
# Compute the x'th fibonacci number.
def fib(x)
  if x < 3 then
    1
  else
    fib(x-1)+fib(x-2)

# This expression will compute the 40th number.
fib(40)
```

We also allow Kaleidoscope to call into standard library functions (the LLVM JIT makes this completely trivial). This means that you can use the 'extern' keyword to define a function before you use it (this is also useful for mutually recursive functions). For example:

```
extern sin(arg);
extern cos(arg);
extern atan2(arg1 arg2);

atan2(sin(.4), cos(42))
```

A more interesting example is included in [Chapter 6](#) where we write a little Kaleidoscope application that [displays a Mandelbrot Set](#) at various levels of magnification.

Lets dive into the implementation of this language!

The Lexer

When it comes to implementing a language, the first thing needed is the ability to process a text file and recognize what it says. The traditional way to do this is to use a "lexer" (aka 'scanner') to break the input up into "tokens". Each token returned by the lexer includes a token code and potentially some metadata (e.g. the numeric value of a number). First, we define the possibilities:

```
// The lexer returns tokens [0-255] if it is an unknown character, otherwise one
// of these for known things.
enum Token {
    tok_eof = -1,

    // commands
    tok_def = -2,
    tok_extern = -3,

    // primary
    tok_identifier = -4,
    tok_number = -5,
};

static std::string IdentifierStr; // Filled in if tok_identifier
static double NumVal;           // Filled in if tok_number
```

Each token returned by our lexer will either be one of the Token enum values or it will be an 'unknown' character like '+', which is returned as its ASCII value. If the current token is an identifier, the IdentifierStr global variable holds the name of the identifier. If the current token is a numeric literal (like 1.0), NumVal holds its value. Note that we use global variables for simplicity, this is not the best choice for a real language implementation :).

The actual implementation of the lexer is a single function named `gettok`. The `gettok` function is called to return the next token from standard input. Its definition starts as:

```
/// gettok - Return the next token from standard input.
static int gettok() {
    static int LastChar = ' ';

    // Skip any whitespace.
    while (isspace(LastChar))
        LastChar = getchar();
```

`gettok` works by calling the C `getchar()` function to read characters one at a time from standard input. It eats them as it recognizes them and stores the last character read, but not processed, in `LastChar`. The first thing that it has to do is ignore whitespace between tokens. This is accomplished with the loop above.

The next thing `gettok` needs to do is recognize identifiers and specific keywords like "def". Kaleidoscope does this with this simple loop:

```
if (isalpha(LastChar)) { // identifier: [a-zA-Z][a-zA-Z0-9]*
    IdentifierStr = LastChar;
    while (isalnum((LastChar = getchar())))
        IdentifierStr += LastChar;

    if (IdentifierStr == "def")
        return tok_def;
    if (IdentifierStr == "extern")
        return tok_extern;
    return tok_identifier;
}
```

Note that this code sets the 'IdentifierStr' global whenever it lexes an identifier. Also, since language keywords are matched by the same loop, we handle them here inline. Numeric values are similar:

```
if (isdigit>LastChar) || LastChar == '.') {    // Number: [0-9.]+
    std::string NumStr;
    do {
        NumStr += LastChar;
        LastChar = getchar();
    } while (isdigit>LastChar) || LastChar == '.');

    NumVal = strtod(NumStr.c_str(), 0);
    return tok_number;
}
```

This is all pretty straight-forward code for processing input. When reading a numeric value from input, we use the C `strtod` function to convert it to a numeric value that we store in `NumVal`. Note that this isn't doing sufficient error checking: it will incorrectly read "1.23.45.67" and handle it as if you typed in "1.23". Feel free to extend it :). Next we handle comments:

```
if (LastChar == '#') {
    // Comment until end of line.
    do
        LastChar = getchar();
    while (LastChar != EOF && LastChar != '\n' && LastChar != '\r');

    if (LastChar != EOF)
        return gettok();
}
```

We handle comments by skipping to the end of the line and then return the next token. Finally, if the input doesn't match one of the above cases, it is either an operator character like '+' or the end of the file. These are handled with this code:

```
// Check for end of file.  Don't eat the EOF.
if (LastChar == EOF)
    return tok_eof;

// Otherwise, just return the character as its ascii value.
int ThisChar = LastChar;
LastChar = getchar();
return ThisChar;
}
```

With this, we have the complete lexer for the basic Kaleidoscope language (the [full code listing](#) for the Lexer is available in the [next chapter](#) of the tutorial). Next we'll [build a simple parser that uses this to build an Abstract Syntax Tree](#). When we have that, we'll include a driver so that you can use the lexer and parser together.

[Next: Implementing a Parser and AST](#)

Kaleidoscope: Implementing a Parser and AST

- *Chapter 2 Introduction*
- *The Abstract Syntax Tree (AST)*
- *Parser Basics*
- *Basic Expression Parsing*
- *Binary Expression Parsing*
- *Parsing the Rest*
- *The Driver*
- *Conclusions*
- *Full Code Listing*

Chapter 2 Introduction

Welcome to Chapter 2 of the "Implementing a language with LLVM" tutorial. This chapter shows you how to use the lexer, built in [Chapter 1](#), to build a full parser for our Kaleidoscope language. Once we have a parser, we'll define and build an [Abstract Syntax Tree \(AST\)](#).

The parser we will build uses a combination of [Recursive Descent Parsing](#) and [Operator-Precedence Parsing](#) to parse the Kaleidoscope language (the latter for binary expressions and the former for everything else). Before we get to parsing though, let's talk about the output of the parser: the Abstract Syntax Tree.

The Abstract Syntax Tree (AST)

The AST for a program captures its behavior in such a way that it is easy for later stages of the compiler (e.g. code generation) to interpret. We basically want one object for each construct in the language, and the AST should closely model the language. In Kaleidoscope, we have expressions, a prototype, and a function object. We'll start with expressions first:

```
/// ExprAST - Base class for all expression nodes.
class ExprAST {
public:
    virtual ~ExprAST() {}
};

/// NumberExprAST - Expression class for numeric literals like "1.0".
class NumberExprAST : public ExprAST {
    double Val;

public:
    NumberExprAST(double Val) : Val(Val) {}
};
```

The code above shows the definition of the base ExprAST class and one subclass which we use for numeric literals. The important thing to note about this code is that the NumberExprAST class captures the numeric value of the literal as an instance variable. This allows later phases of the compiler to know what the stored numeric value is.

Right now we only create the AST, so there are no useful accessor methods on them. It would be very easy to add a virtual method to pretty print the code, for example. Here are the other expression AST node definitions that we'll use in the basic form of the Kaleidoscope language:

```
/// VariableExprAST - Expression class for referencing a variable, like "a".
class VariableExprAST : public ExprAST {
    std::string Name;

public:
    VariableExprAST(const std::string &Name) : Name(Name) {}
};

/// BinaryExprAST - Expression class for a binary operator.
class BinaryExprAST : public ExprAST {
    char Op;
    std::unique_ptr<ExprAST> LHS, RHS;

public:
    BinaryExprAST(char op, std::unique_ptr<ExprAST> LHS,
                  std::unique_ptr<ExprAST> RHS)
        : Op(op), LHS(std::move(LHS)), RHS(std::move(RHS)) {}
};

/// CallExprAST - Expression class for function calls.
class CallExprAST : public ExprAST {
    std::string Callee;
    std::vector<std::unique_ptr<ExprAST>> Args;

public:
    CallExprAST(const std::string &Callee,
                std::vector<std::unique_ptr<ExprAST>> Args)
        : Callee(Callee), Args(std::move(Args)) {}
};
```

This is all (intentionally) rather straight-forward: variables capture the variable name, binary operators capture their opcode (e.g. '+'), and calls capture a function name as well as a list of any argument expressions. One thing that is nice about our AST is that it captures the language features without talking about the syntax of the language. Note that there is no discussion about precedence of binary operators, lexical structure, etc.

For our basic language, these are all of the expression nodes we'll define. Because it doesn't have conditional control flow, it isn't Turing-complete; we'll fix that in a later installment. The two things we need next are a way to talk about the interface to a function, and a way to talk about functions themselves:

```
/// PrototypeAST - This class represents the "prototype" for a function,
/// which captures its name, and its argument names (thus implicitly the number
/// of arguments the function takes).
class PrototypeAST {
    std::string Name;
    std::vector<std::string> Args;

public:
    PrototypeAST(const std::string &name, std::vector<std::string> Args)
        : Name(name), Args(std::move(Args)) {}

    const std::string &getName() const { return Name; }
};

/// FunctionAST - This class represents a function definition itself.
```

(continues on next page)

(continued from previous page)

```

class FunctionAST {
    std::unique_ptr<PrototypeAST> Proto;
    std::unique_ptr<ExprAST> Body;

public:
    FunctionAST(std::unique_ptr<PrototypeAST> Proto,
                std::unique_ptr<ExprAST> Body)
        : Proto(std::move(Proto)), Body(std::move(Body)) {}
};

```

In Kaleidoscope, functions are typed with just a count of their arguments. Since all values are double precision floating point, the type of each argument doesn't need to be stored anywhere. In a more aggressive and realistic language, the "ExprAST" class would probably have a type field.

With this scaffolding, we can now talk about parsing expressions and function bodies in Kaleidoscope.

Parser Basics

Now that we have an AST to build, we need to define the parser code to build it. The idea here is that we want to parse something like "x+y" (which is returned as three tokens by the lexer) into an AST that could be generated with calls like this:

```

auto LHS = llvm::make_unique<VariableExprAST>("x");
auto RHS = llvm::make_unique<VariableExprAST>("y");
auto Result = std::make_unique<BinaryExprAST>('+', std::move(LHS),
                                                std::move(RHS));

```

In order to do this, we'll start by defining some basic helper routines:

```

/// CurTok/getNextToken - Provide a simple token buffer. CurTok is the current
/// token the parser is looking at. getNextToken reads another token from the
/// lexer and updates CurTok with its results.
static int CurTok;
static int getNextToken() {
    return CurTok = gettok();
}

```

This implements a simple token buffer around the lexer. This allows us to look one token ahead at what the lexer is returning. Every function in our parser will assume that CurTok is the current token that needs to be parsed.

```

/// LogError* - These are little helper functions for error handling.
std::unique_ptr<ExprAST> LogError(const char *Str) {
    fprintf(stderr, "LogError: %s\n", Str);
    return nullptr;
}
std::unique_ptr<PrototypeAST> LogErrorP(const char *Str) {
    LogError(Str);
    return nullptr;
}

```

The LogError routines are simple helper routines that our parser will use to handle errors. The error recovery in our parser will not be the best and is not particular user-friendly, but it will be enough for our tutorial. These routines make it easier to handle errors in routines that have various return types: they always return null.

With these basic helper functions, we can implement the first piece of our grammar: numeric literals.

Basic Expression Parsing

We start with numeric literals, because they are the simplest to process. For each production in our grammar, we'll define a function which parses that production. For numeric literals, we have:

```
/// numberexpr ::= number
static std::unique_ptr<ExprAST> ParseNumberExpr() {
    auto Result = llvm::make_unique<NumberExprAST>(NumVal);
    getNextToken(); // consume the number
    return std::move(Result);
}
```

This routine is very simple: it expects to be called when the current token is a `tok_number` token. It takes the current number value, creates a `NumberExprAST` node, advances the lexer to the next token, and finally returns.

There are some interesting aspects to this. The most important one is that this routine eats all of the tokens that correspond to the production and returns the lexer buffer with the next token (which is not part of the grammar production) ready to go. This is a fairly standard way to go for recursive descent parsers. For a better example, the parenthesis operator is defined like this:

```
/// parenexpr ::= '(' expression ')'
static std::unique_ptr<ExprAST> ParseParenExpr() {
    getNextToken(); // eat (.
    auto V = ParseExpression();
    if (!V)
        return nullptr;

    if (CurTok != ')')
        return LogError("expected ')'");
    getNextToken(); // eat ).
    return V;
}
```

This function illustrates a number of interesting things about the parser:

- 1) It shows how we use the `LogError` routines. When called, this function expects that the current token is a '(' token, but after parsing the subexpression, it is possible that there is no ')' waiting. For example, if the user types in "(4 x" instead of "(4)", the parser should emit an error. Because errors can occur, the parser needs a way to indicate that they happened: in our parser, we return null on an error.
- 2) Another interesting aspect of this function is that it uses recursion by calling `ParseExpression` (we will soon see that `ParseExpression` can call `ParseParenExpr`). This is powerful because it allows us to handle recursive grammars, and keeps each production very simple. Note that parentheses do not cause construction of AST nodes themselves. While we could do it this way, the most important role of parentheses are to guide the parser and provide grouping. Once the parser constructs the AST, parentheses are not needed.

The next simple production is for handling variable references and function calls:

```
/// identifierexpr
/// ::= identifier
/// ::= identifier '(' expression* ')'
static std::unique_ptr<ExprAST> ParseIdentifierExpr() {
    std::string IdName = IdentifierStr;

    getNextToken(); // eat identifier.

    if (CurTok != '(') // Simple variable ref.
        return llvm::make_unique<VariableExprAST>(IdName);
```

(continues on next page)

(continued from previous page)

```

// Call.
getNextToken(); // eat (
std::vector<std::unique_ptr<ExprAST>> Args;
if (CurTok != ')') {
    while (1) {
        if (auto Arg = ParseExpression())
            Args.push_back(std::move(Arg));
        else
            return nullptr;

        if (CurTok == ')')
            break;

        if (CurTok != ',')
            return LogError("Expected ')' or ',' in argument list");
        getNextToken();
    }
}

// Eat the ')'.
getNextToken();

return llvm::make_unique<CallExprAST>(IdName, std::move(Args));
}

```

This routine follows the same style as the other routines. (It expects to be called if the current token is a `tok_identifier` token). It also has recursion and error handling. One interesting aspect of this is that it uses *look-ahead* to determine if the current identifier is a stand alone variable reference or if it is a function call expression. It handles this by checking to see if the token after the identifier is a `'` token, constructing either a `VariableExprAST` or `CallExprAST` node as appropriate.

Now that we have all of our simple expression-parsing logic in place, we can define a helper function to wrap it together into one entry point. We call this class of expressions "primary" expressions, for reasons that will become more clear [later in the tutorial](#). In order to parse an arbitrary primary expression, we need to determine what sort of expression it is:

```

/// primary
/// ::= identifierexpr
/// ::= numberexpr
/// ::= parenexpr
static std::unique_ptr<ExprAST> ParsePrimary() {
    switch (CurTok) {
    default:
        return LogError("unknown token when expecting an expression");
    case tok_identifier:
        return ParseIdentifierExpr();
    case tok_number:
        return ParseNumberExpr();
    case '(':
        return ParseParenExpr();
    }
}

```

Now that you see the definition of this function, it is more obvious why we can assume the state of `CurTok` in the various functions. This uses look-ahead to determine which sort of expression is being inspected, and then parses it with a function call.

Now that basic expressions are handled, we need to handle binary expressions. They are a bit more complex.

Binary Expression Parsing

Binary expressions are significantly harder to parse because they are often ambiguous. For example, when given the string "x+y*z", the parser can choose to parse it as either "(x+y)*z" or "x+(y*z)". With common definitions from mathematics, we expect the later parse, because "*" (multiplication) has higher *precedence* than "+" (addition).

There are many ways to handle this, but an elegant and efficient way is to use [Operator-Precedence Parsing](#). This parsing technique uses the precedence of binary operators to guide recursion. To start with, we need a table of precedences:

```

/// BinopPrecedence - This holds the precedence for each binary operator that is
/// defined.
static std::map<char, int> BinopPrecedence;

/// GetTokPrecedence - Get the precedence of the pending binary operator token.
static int GetTokPrecedence() {
    if (!isascii(CurTok))
        return -1;

    // Make sure it's a declared binop.
    int TokPrec = BinopPrecedence[CurTok];
    if (TokPrec <= 0) return -1;
    return TokPrec;
}

int main() {
    // Install standard binary operators.
    // 1 is lowest precedence.
    BinopPrecedence['<'] = 10;
    BinopPrecedence['+'] = 20;
    BinopPrecedence['-'] = 20;
    BinopPrecedence['*'] = 40; // highest.
    ...
}

```

For the basic form of Kaleidoscope, we will only support 4 binary operators (this can obviously be extended by you, our brave and intrepid reader). The `GetTokPrecedence` function returns the precedence for the current token, or -1 if the token is not a binary operator. Having a map makes it easy to add new operators and makes it clear that the algorithm doesn't depend on the specific operators involved, but it would be easy enough to eliminate the map and do the comparisons in the `GetTokPrecedence` function. (Or just use a fixed-size array).

With the helper above defined, we can now start parsing binary expressions. The basic idea of operator precedence parsing is to break down an expression with potentially ambiguous binary operators into pieces. Consider, for example, the expression "a+b+(c+d)*e*f+g". Operator precedence parsing considers this as a stream of primary expressions separated by binary operators. As such, it will first parse the leading primary expression "a", then it will see the pairs [+ , b] [+ , (c+d)] [* , e] [* , f] and [+ , g]. Note that because parentheses are primary expressions, the binary expression parser doesn't need to worry about nested subexpressions like (c+d) at all.

To start, an expression is a primary expression potentially followed by a sequence of [binop,primaryexpr] pairs:

```

/// expression
/// ::= primary binoprhs
///
static std::unique_ptr<ExprAST> ParseExpression() {

```

(continues on next page)

(continued from previous page)

```

auto LHS = ParsePrimary();
if (!LHS)
    return nullptr;

return ParseBinOpRHS(0, std::move(LHS));
}

```

ParseBinOpRHS is the function that parses the sequence of pairs for us. It takes a precedence and a pointer to an expression for the part that has been parsed so far. Note that "x" is a perfectly valid expression: As such, "binoprhs" is allowed to be empty, in which case it returns the expression that is passed into it. In our example above, the code passes the expression for "a" into ParseBinOpRHS and the current token is "+".

The precedence value passed into ParseBinOpRHS indicates the *minimal operator precedence* that the function is allowed to eat. For example, if the current pair stream is [+ , x] and ParseBinOpRHS is passed in a precedence of 40, it will not consume any tokens (because the precedence of '+' is only 20). With this in mind, ParseBinOpRHS starts with:

```

/// binoprhs
/// ::= ('+' primary)*
static std::unique_ptr<ExprAST> ParseBinOpRHS(int ExprPrec,
                                              std::unique_ptr<ExprAST> LHS) {
    // If this is a binop, find its precedence.
    while (1) {
        int TokPrec = GetTokPrecedence();

        // If this is a binop that binds at least as tightly as the current binop,
        // consume it, otherwise we are done.
        if (TokPrec < ExprPrec)
            return LHS;
    }
}

```

This code gets the precedence of the current token and checks to see if it is too low. Because we defined invalid tokens to have a precedence of -1, this check implicitly knows that the pair-stream ends when the token stream runs out of binary operators. If this check succeeds, we know that the token is a binary operator and that it will be included in this expression:

```

// Okay, we know this is a binop.
int BinOp = CurTok;
getNextToken(); // eat binop

// Parse the primary expression after the binary operator.
auto RHS = ParsePrimary();
if (!RHS)
    return nullptr;

```

As such, this code eats (and remembers) the binary operator and then parses the primary expression that follows. This builds up the whole pair, the first of which is [+ , b] for the running example.

Now that we parsed the left-hand side of an expression and one pair of the RHS sequence, we have to decide which way the expression associates. In particular, we could have "(a+b) binop unparsed" or "a + (b binop unparsed)". To determine this, we look ahead at "binop" to determine its precedence and compare it to BinOp's precedence (which is '+' in this case):

```

// If BinOp binds less tightly with RHS than the operator after RHS, let
// the pending operator take RHS as its LHS.
int NextPrec = GetTokPrecedence();
if (TokPrec < NextPrec) {

```

If the precedence of the binop to the right of "RHS" is lower or equal to the precedence of our current operator, then we know that the parentheses associate as "(a+b) binop ...". In our example, the current operator is "+" and the next operator is "+", we know that they have the same precedence. In this case we'll create the AST node for "a+b", and then continue parsing:

```
    ... if body omitted ...
}

// Merge LHS/RHS.
LHS = llvm::make_unique<BinaryExprAST>(BinOp, std::move(LHS),
                                       std::move(RHS));
} // loop around to the top of the while loop.
}
```

In our example above, this will turn "a+b+" into "(a+b)" and execute the next iteration of the loop, with "+" as the current token. The code above will eat, remember, and parse "(c+d)" as the primary expression, which makes the current pair equal to [+, (c+d)]. It will then evaluate the 'if' conditional above with "*" as the binop to the right of the primary. In this case, the precedence of "*" is higher than the precedence of "+" so the if condition will be entered.

The critical question left here is "how can the if condition parse the right hand side in full"? In particular, to build the AST correctly for our example, it needs to get all of "(c+d)*e*f" as the RHS expression variable. The code to do this is surprisingly simple (code from the above two blocks duplicated for context):

```
// If BinOp binds less tightly with RHS than the operator after RHS, let
// the pending operator take RHS as its LHS.
int NextPrec = GetTokPrecedence();
if (TokPrec < NextPrec) {
    RHS = ParseBinOpRHS(TokPrec+1, std::move(RHS));
    if (!RHS)
        return nullptr;
}
// Merge LHS/RHS.
LHS = llvm::make_unique<BinaryExprAST>(BinOp, std::move(LHS),
                                       std::move(RHS));
} // loop around to the top of the while loop.
}
```

At this point, we know that the binary operator to the RHS of our primary has higher precedence than the binop we are currently parsing. As such, we know that any sequence of pairs whose operators are all higher precedence than "+" should be parsed together and returned as "RHS". To do this, we recursively invoke the `ParseBinOpRHS` function specifying "TokPrec+1" as the minimum precedence required for it to continue. In our example above, this will cause it to return the AST node for "(c+d)*e*f" as RHS, which is then set as the RHS of the '+' expression.

Finally, on the next iteration of the while loop, the "+g" piece is parsed and added to the AST. With this little bit of code (14 non-trivial lines), we correctly handle fully general binary expression parsing in a very elegant way. This was a whirlwind tour of this code, and it is somewhat subtle. I recommend running through it with a few tough examples to see how it works.

This wraps up handling of expressions. At this point, we can point the parser at an arbitrary token stream and build an expression from it, stopping at the first token that is not part of the expression. Next up we need to handle function definitions, etc.

Parsing the Rest

The next thing missing is handling of function prototypes. In Kaleidoscope, these are used both for 'extern' function declarations as well as function body definitions. The code to do this is straight-forward and not very interesting (once you've survived expressions):

```
/// prototype
/// ::= id '(' id* ')'
static std::unique_ptr<PrototypeAST> ParsePrototype() {
    if (CurTok != tok_identifier)
        return LogErrorP("Expected function name in prototype");

    std::string FnName = IdentifierStr;
    getNextToken();

    if (CurTok != '(')
        return LogErrorP("Expected '(' in prototype");

    // Read the list of argument names.
    std::vector<std::string> ArgNames;
    while (getNextToken() == tok_identifier)
        ArgNames.push_back(IdentifierStr);
    if (CurTok != ')')
        return LogErrorP("Expected ')' in prototype");

    // success.
    getNextToken(); // eat ')'.

    return llvm::make_unique<PrototypeAST>(FnName, std::move(ArgNames));
}
```

Given this, a function definition is very simple, just a prototype plus an expression to implement the body:

```
/// definition ::= 'def' prototype expression
static std::unique_ptr<FunctionAST> ParseDefinition() {
    getNextToken(); // eat def.
    auto Proto = ParsePrototype();
    if (!Proto) return nullptr;

    if (auto E = ParseExpression())
        return llvm::make_unique<FunctionAST>(std::move(Proto), std::move(E));
    return nullptr;
}
```

In addition, we support 'extern' to declare functions like 'sin' and 'cos' as well as to support forward declaration of user functions. These 'extern's are just prototypes with no body:

```
/// external ::= 'extern' prototype
static std::unique_ptr<PrototypeAST> ParseExtern() {
    getNextToken(); // eat extern.
    return ParsePrototype();
}
```

Finally, we'll also let the user type in arbitrary top-level expressions and evaluate them on the fly. We will handle this by defining anonymous nullary (zero argument) functions for them:

```
/// toplevelexpr ::= expression
static std::unique_ptr<FunctionAST> ParseTopLevelExpr() {
    if (auto E = ParseExpression()) {
        // Make an anonymous proto.
        auto Proto = llvm::make_unique<PrototypeAST>("", std::vector<std::string>());
        return llvm::make_unique<FunctionAST>(std::move(Proto), std::move(E));
    }
    return nullptr;
}
```

Now that we have all the pieces, let's build a little driver that will let us actually *execute* this code we've built!

The Driver

The driver for this simply invokes all of the parsing pieces with a top-level dispatch loop. There isn't much interesting here, so I'll just include the top-level loop. See *below* for full code in the "Top-Level Parsing" section.

```
/// top ::= definition | external | expression | ';'
static void MainLoop() {
    while (1) {
        fprintf(stderr, "ready> ");
        switch (CurTok) {
            case tok_eof:
                return;
            case ';': // ignore top-level semicolons.
                getNextToken();
                break;
            case tok_def:
                HandleDefinition();
                break;
            case tok_extern:
                HandleExtern();
                break;
            default:
                HandleTopLevelExpression();
                break;
        }
    }
}
```

The most interesting part of this is that we ignore top-level semicolons. Why is this, you ask? The basic reason is that if you type "4 + 5" at the command line, the parser doesn't know whether that is the end of what you will type or not. For example, on the next line you could type "def foo..." in which case 4+5 is the end of a top-level expression. Alternatively you could type "* 6", which would continue the expression. Having top-level semicolons allows you to type "4+5;", and the parser will know you are done.

Conclusions

With just under 400 lines of commented code (240 lines of non-comment, non-blank code), we fully defined our minimal language, including a lexer, parser, and AST builder. With this done, the executable will validate Kaleidoscope code and tell us if it is grammatically invalid. For example, here is a sample interaction:

```
$ ./a.out
ready> def foo(x y) x+foo(y, 4.0);
Parsed a function definition.
ready> def foo(x y) x+y y;
Parsed a function definition.
Parsed a top-level expr
ready> def foo(x y) x+y );
Parsed a function definition.
Error: unknown token when expecting an expression
ready> extern sin(a);
ready> Parsed an extern
ready> ^D
$
```

There is a lot of room for extension here. You can define new AST nodes, extend the language in many ways, etc. In the [next installment](#), we will describe how to generate LLVM Intermediate Representation (IR) from the AST.

Full Code Listing

Here is the complete code listing for our running example. Because this uses the LLVM libraries, we need to link them in. To do this, we use the `llvm-config` tool to inform our makefile/command line about which options to use:

```
# Compile
clang++ -g -O3 toy.cpp `llvm-config --cxxflags`
# Run
./a.out
```

Here is the code:

```
#include "llvm/ADT/STLExtras.h"
#include <algorithm>
#include <cctype>
#include <cstdio>
#include <cstdlib>
#include <map>
#include <memory>
#include <string>
#include <vector>

//=====//
// Lexer
//=====//

// The lexer returns tokens [0-255] if it is an unknown character, otherwise one
// of these for known things.
enum Token {
    tok_eof = -1,

    // commands
    tok_def = -2,
```

(continues on next page)

(continued from previous page)

```

tok_extern = -3,

// primary
tok_identifier = -4,
tok_number = -5
};

static std::string IdentifierStr; // Filled in if tok_identifier
static double NumVal;           // Filled in if tok_number

/// gettok - Return the next token from standard input.
static int gettok() {
    static int LastChar = ' ';

    // Skip any whitespace.
    while (isspace(LastChar))
        LastChar = getchar();

    if (isalpha(LastChar)) { // identifier: [a-zA-Z][a-zA-Z0-9]*
        IdentifierStr = LastChar;
        while (isalnum((LastChar = getchar())))
            IdentifierStr += LastChar;

        if (IdentifierStr == "def")
            return tok_def;
        if (IdentifierStr == "extern")
            return tok_extern;
        return tok_identifier;
    }

    if (isdigit(LastChar) || LastChar == '.') { // Number: [0-9.]+
        std::string NumStr;
        do {
            NumStr += LastChar;
            LastChar = getchar();
        } while (isdigit(LastChar) || LastChar == '.');

        NumVal = strtod(NumStr.c_str(), nullptr);
        return tok_number;
    }

    if (LastChar == '#') {
        // Comment until end of line.
        do
            LastChar = getchar();
        while (LastChar != EOF && LastChar != '\n' && LastChar != '\r');

        if (LastChar != EOF)
            return gettok();
    }

    // Check for end of file. Don't eat the EOF.
    if (LastChar == EOF)
        return tok_eof;

    // Otherwise, just return the character as its ascii value.
    int ThisChar = LastChar;

```

(continues on next page)

(continued from previous page)

```

    LastChar = getchar();
    return ThisChar;
}

- *Expression Code Generation*
- *Function Code Generation*
- *Driver Changes and Closing Thoughts*
- *Full Code Listing*

Chapter 3 Introduction

Welcome to Chapter 3 of the "Implementing a language with LLVM" tutorial. This chapter shows you how to transform the [Abstract Syntax Tree](#), built in Chapter 2, into LLVM IR. This will teach you a little bit about how LLVM does things, as well as demonstrate how easy it is to use. It's much more work to build a lexer and parser than it is to generate LLVM IR code. :)

Please note: the code in this chapter and later require LLVM 3.7 or later. LLVM 3.6 and before will not work with it. Also note that you need to use a version of this tutorial that matches your LLVM release: If you are using an official LLVM release, use the version of the documentation included with your release or on the [llvm.org releases](http://llvm.org/releases) page.

Code Generation Setup

In order to generate LLVM IR, we want some simple setup to get started. First we define virtual code generation (codegen) methods in each AST class:

```
/// ExprAST - Base class for all expression nodes.
class ExprAST {
public:
    virtual ~ExprAST() {}
    virtual Value *codegen() = 0;
};

/// NumberExprAST - Expression class for numeric literals like "1.0".
class NumberExprAST : public ExprAST {
    double Val;

public:
    NumberExprAST(double Val) : Val(Val) {}
    virtual Value *codegen();
};
...
```

The codegen() method says to emit IR for that AST node along with all the things it depends on, and they all return an LLVM Value object. "Value" is the class used to represent a "Static Single Assignment (SSA) register" or "SSA value" in LLVM. The most distinct aspect of SSA values is that their value is computed as the related instruction executes, and it does not get a new value until (and if) the instruction re-executes. In other words, there is no way to "change" an SSA value. For more information, please read up on [Static Single Assignment](#) - the concepts are really quite natural once you grok them.

Note that instead of adding virtual methods to the ExprAST class hierarchy, it could also make sense to use a [visitor pattern](#) or some other way to model this. Again, this tutorial won't dwell on good software engineering practices: for our purposes, adding a virtual method is simplest.

The second thing we want is an "LogError" method like we used for the parser, which will be used to report errors found during code generation (for example, use of an undeclared parameter):

```
static LLVMContext TheContext;
static IRBuilder<> Builder(TheContext);
static std::unique_ptr<Module> TheModule;
static std::map<std::string, Value *> NamedValues;

Value *LogErrorV(const char *Str) {
    LogError(Str);
    return nullptr;
}
```

The static variables will be used during code generation. `TheContext` is an opaque object that owns a lot of core LLVM data structures, such as the type and constant value tables. We don't need to understand it in detail, we just need a single instance to pass into APIs that require it.

The `Builder` object is a helper object that makes it easy to generate LLVM instructions. Instances of the `IRBuilder` class template keep track of the current place to insert instructions and has methods to create new instructions.

`TheModule` is an LLVM construct that contains functions and global variables. In many ways, it is the top-level structure that the LLVM IR uses to contain code. It will own the memory for all of the IR that we generate, which is why the `codegen()` method returns a raw `Value*`, rather than a `unique_ptr<Value>`.

The `NamedValues` map keeps track of which values are defined in the current scope and what their LLVM representation is. (In other words, it is a symbol table for the code). In this form of Kaleidoscope, the only things that can be referenced are function parameters. As such, function parameters will be in this map when generating code for their function body.

With these basics in place, we can start talking about how to generate code for each expression. Note that this assumes that the `Builder` has been set up to generate code *into* something. For now, we'll assume that this has already been done, and we'll just use it to emit code.

Expression Code Generation

Generating LLVM code for expression nodes is very straightforward: less than 45 lines of commented code for all four of our expression nodes. First we'll do numeric literals:

```
Value *NumberExprAST::codegen() {
    return ConstantFP::get(TheContext, APFloat(Val));
}
```

In the LLVM IR, numeric constants are represented with the `ConstantFP` class, which holds the numeric value in an `APFloat` internally (`APFloat` has the capability of holding floating point constants of Arbitrary Precision). This code basically just creates and returns a `ConstantFP`. Note that in the LLVM IR that constants are all uniqued together and shared. For this reason, the API uses the "`foo::get(...)`" idiom instead of "`new foo(..)`" or "`foo::Create(..)`".

```
Value *VariableExprAST::codegen() {
    // Look this variable up in the function.
    Value *V = NamedValues[Name];
    if (!V)
        LogErrorV("Unknown variable name");
    return V;
}
```

References to variables are also quite simple using LLVM. In the simple version of Kaleidoscope, we assume that the variable has already been emitted somewhere and its value is available. In practice, the only values that can be in the `NamedValues` map are function arguments. This code simply checks to see that the specified name is in the map (if not, an unknown variable is being referenced) and returns the value for it. In future chapters, we'll add support for [loop induction variables](#) in the symbol table, and for [local variables](#).

```
Value *BinaryExprAST::codegen() {
    Value *L = LHS->codegen();
    Value *R = RHS->codegen();
    if (!L || !R)
        return nullptr;

    switch (Op) {
    case '+':
```

(continues on next page)

(continued from previous page)

```

    return Builder.CreateFAdd(L, R, "addtmp");
case '-':
    return Builder.CreateFSub(L, R, "subtmp");
case '*':
    return Builder.CreateFMul(L, R, "multmp");
case '<':
    L = Builder.CreateFCmpULT(L, R, "cmptmp");
    // Convert bool 0/1 to double 0.0 or 1.0
    return Builder.CreateUIToFP(L, Type::getDoubleTy(TheContext),
                                "booltmp");
default:
    return LogErrorV("invalid binary operator");
}
}

```

Binary operators start to get more interesting. The basic idea here is that we recursively emit code for the left-hand side of the expression, then the right-hand side, then we compute the result of the binary expression. In this code, we do a simple switch on the opcode to create the right LLVM instruction.

In the example above, the LLVM builder class is starting to show its value. IRBuilder knows where to insert the newly created instruction, all you have to do is specify what instruction to create (e.g. with `CreateFAdd`), which operands to use (L and R here) and optionally provide a name for the generated instruction.

One nice thing about LLVM is that the name is just a hint. For instance, if the code above emits multiple "addtmp" variables, LLVM will automatically provide each one with an increasing, unique numeric suffix. Local value names for instructions are purely optional, but it makes it much easier to read the IR dumps.

LLVM instructions are constrained by strict rules: for example, the Left and Right operators of an `add instruction` must have the same type, and the result type of the add must match the operand types. Because all values in Kaleidoscope are doubles, this makes for very simple code for add, sub and mul.

On the other hand, LLVM specifies that the `fcmp instruction` always returns an 'i1' value (a one bit integer). The problem with this is that Kaleidoscope wants the value to be a 0.0 or 1.0 value. In order to get these semantics, we combine the `fcmp instruction` with a `uitofp instruction`. This instruction converts its input integer into a floating point value by treating the input as an unsigned value. In contrast, if we used the `sitofp instruction`, the Kaleidoscope '<' operator would return 0.0 and -1.0, depending on the input value.

```

Value *CallExprAST::codegen() {
    // Look up the name in the global module table.
    Function *CalleeF = TheModule->getFunction(Callee);
    if (!CalleeF)
        return LogErrorV("Unknown function referenced");

    // If argument mismatch error.
    if (CalleeF->arg_size() != Args.size())
        return LogErrorV("Incorrect # arguments passed");

    std::vector<Value *> ArgsV;
    for (unsigned i = 0, e = Args.size(); i != e; ++i) {
        ArgsV.push_back(Args[i]->codegen());
        if (!ArgsV.back())
            return nullptr;
    }

    return Builder.CreateCall(CalleeF, ArgsV, "calltmp");
}

```

Code generation for function calls is quite straightforward with LLVM. The code above initially does a function name

lookup in the LLVM Module's symbol table. Recall that the LLVM Module is the container that holds the functions we are JIT'ing. By giving each function the same name as what the user specifies, we can use the LLVM symbol table to resolve function names for us.

Once we have the function to call, we recursively codegen each argument that is to be passed in, and create an LLVM [call instruction](#). Note that LLVM uses the native C calling conventions by default, allowing these calls to also call into standard library functions like "sin" and "cos", with no additional effort.

This wraps up our handling of the four basic expressions that we have so far in Kaleidoscope. Feel free to go in and add some more. For example, by browsing the [LLVM language reference](#) you'll find several other interesting instructions that are really easy to plug into our basic framework.

Function Code Generation

Code generation for prototypes and functions must handle a number of details, which make their code less beautiful than expression code generation, but allows us to illustrate some important points. First, let's talk about code generation for prototypes: they are used both for function bodies and external function declarations. The code starts with:

```
Function *PrototypeAST::codegen() {
    // Make the function type: double(double,double) etc.
    std::vector<Type*> Doubles(Args.size(),
                               Type::getDoubleTy(TheContext));

    FunctionType *FT =
        FunctionType::get(Type::getDoubleTy(TheContext), Doubles, false);

    Function *F =
        Function::Create(FT, Function::ExternalLinkage, Name, TheModule.get());
```

This code packs a lot of power into a few lines. Note first that this function returns a "Function*" instead of a "Value*". Because a "prototype" really talks about the external interface for a function (not the value computed by an expression), it makes sense for it to return the LLVM Function it corresponds to when codegen'd.

The call to `FunctionType::get` creates the `FunctionType` that should be used for a given Prototype. Since all function arguments in Kaleidoscope are of type double, the first line creates a vector of "N" LLVM double types. It then uses the `FunctionType::get` method to create a function type that takes "N" doubles as arguments, returns one double as a result, and that is not vararg (the false parameter indicates this). Note that Types in LLVM are unique just like Constants are, so you don't "new" a type, you "get" it.

The final line above actually creates the IR Function corresponding to the Prototype. This indicates the type, linkage and name to use, as well as which module to insert into. "external linkage" means that the function may be defined outside the current module and/or that it is callable by functions outside the module. The Name passed in is the name the user specified: since "TheModule" is specified, this name is registered in "TheModule"s symbol table.

```
// Set names for all arguments.
unsigned Idx = 0;
for (auto &Arg : F->args())
    Arg.setName(Args[Idx++]);

return F;
```

Finally, we set the name of each of the function's arguments according to the names given in the Prototype. This step isn't strictly necessary, but keeping the names consistent makes the IR more readable, and allows subsequent code to refer directly to the arguments for their names, rather than having to look up them up in the Prototype AST.

At this point we have a function prototype with no body. This is how LLVM IR represents function declarations. For extern statements in Kaleidoscope, this is as far as we need to go. For function definitions however, we need to codegen and attach a function body.

```
Function *FunctionAST::codegen() {
    // First, check for an existing function from a previous 'extern' declaration.
    Function *TheFunction = TheModule->getFunction(Proto->getName());

    if (!TheFunction)
        TheFunction = Proto->codegen();

    if (!TheFunction)
        return nullptr;

    if (!TheFunction->empty())
        return (Function*)LogErrorV("Function cannot be redefined.");
}
```

For function definitions, we start by searching `TheModule`'s symbol table for an existing version of this function, in case one has already been created using an 'extern' statement. If `Module::getFunction` returns null then no previous version exists, so we'll codegen one from the Prototype. In either case, we want to assert that the function is empty (i.e. has no body yet) before we start.

```
// Create a new basic block to start insertion into.
BasicBlock *BB = BasicBlock::Create(TheContext, "entry", TheFunction);
Builder.SetInsertPoint(BB);

// Record the function arguments in the NamedValues map.
NamedValues.clear();
for (auto &Arg : TheFunction->args())
    NamedValues[Arg.getName()] = &Arg;
```

Now we get to the point where the `Builder` is set up. The first line creates a new **basic block** (named "entry"), which is inserted into `TheFunction`. The second line then tells the builder that new instructions should be inserted into the end of the new basic block. Basic blocks in LLVM are an important part of functions that define the **Control Flow Graph**. Since we don't have any control flow, our functions will only contain one block at this point. We'll fix this in [Chapter 5](#) :).

Next we add the function arguments to the `NamedValues` map (after first clearing it out) so that they're accessible to `VariableExprAST` nodes.

```
if (Value *RetVal = Body->codegen()) {
    // Finish off the function.
    Builder.CreateRet(RetVal);

    // Validate the generated code, checking for consistency.
    verifyFunction(*TheFunction);

    return TheFunction;
}
```

Once the insertion point has been set up and the `NamedValues` map populated, we call the `codegen()` method for the root expression of the function. If no error happens, this emits code to compute the expression into the entry block and returns the value that was computed. Assuming no error, we then create an LLVM **ret instruction**, which completes the function. Once the function is built, we call `verifyFunction`, which is provided by LLVM. This function does a variety of consistency checks on the generated code, to determine if our compiler is doing everything right. Using this is important: it can catch a lot of bugs. Once the function is finished and validated, we return it.

```
// Error reading body, remove function.
TheFunction->eraseFromParent();
return nullptr;
}
```

The only piece left here is handling of the error case. For simplicity, we handle this by merely deleting the function we produced with the `eraseFromParent` method. This allows the user to redefine a function that they incorrectly typed in before: if we didn't delete it, it would live in the symbol table, with a body, preventing future redefinition.

This code does have a bug, though: If the `FunctionAST::codegen()` method finds an existing IR Function, it does not validate its signature against the definition's own prototype. This means that an earlier 'extern' declaration will take precedence over the function definition's signature, which can cause `codegen` to fail, for instance if the function arguments are named differently. There are a number of ways to fix this bug, see what you can come up with! Here is a testcase:

```
extern foo(a);           # ok, defines foo.
def foo(b) b;           # Error: Unknown variable name. (decl using 'a' takes precedence).
```

Driver Changes and Closing Thoughts

For now, code generation to LLVM doesn't really get us much, except that we can look at the pretty IR calls. The sample code inserts calls to `codegen` into the "HandleDefinition", "HandleExtern" etc functions, and then dumps out the LLVM IR. This gives a nice way to look at the LLVM IR for simple functions. For example:

```
ready> 4+5;
Read top-level expression:
define double @0() {
entry:
  ret double 9.000000e+00
}
```

Note how the parser turns the top-level expression into anonymous functions for us. This will be handy when we add [JIT support](#) in the next chapter. Also note that the code is very literally transcribed, no optimizations are being performed except simple constant folding done by `IRBuilder`. We will [add optimizations](#) explicitly in the next chapter.

```
ready> def foo(a b) a*a + 2*a*b + b*b;
Read function definition:
define double @foo(double %a, double %b) {
entry:
  %multmp = fmul double %a, %a
  %multmp1 = fmul double 2.000000e+00, %a
  %multmp2 = fmul double %multmp1, %b
  %addtmp = fadd double %multmp, %multmp2
  %multmp3 = fmul double %b, %b
  %addtmp4 = fadd double %addtmp, %multmp3
  ret double %addtmp4
}
```

This shows some simple arithmetic. Notice the striking similarity to the LLVM builder calls that we use to create the instructions.

```
ready> def bar(a) foo(a, 4.0) + bar(31337);
Read function definition:
define double @bar(double %a) {
entry:
  %calltmp = call double @foo(double %a, double 4.000000e+00)
  %calltmp1 = call double @bar(double 3.133700e+04)
  %addtmp = fadd double %calltmp, %calltmp1
  ret double %addtmp
}
```

This shows some function calls. Note that this function will take a long time to execute if you call it. In the future we'll add conditional control flow to actually make recursion useful :).

```
ready> extern cos(x);
Read extern:
declare double @cos(double)

ready> cos(1.234);
Read top-level expression:
define double @1() {
entry:
  %calltmp = call double @cos(double 1.234000e+00)
  ret double %calltmp
}
```

This shows an extern for the libm "cos" function, and a call to it.

```
ready> ^D
; ModuleID = 'my cool jit'

define double @0() {
entry:
  %addtmp = fadd double 4.000000e+00, 5.000000e+00
  ret double %addtmp
}

define double @foo(double %a, double %b) {
entry:
  %multmp = fmul double %a, %a
  %multmp1 = fmul double 2.000000e+00, %a
  %multmp2 = fmul double %multmp1, %b
  %addtmp = fadd double %multmp, %multmp2
  %multmp3 = fmul double %b, %b
  %addtmp4 = fadd double %addtmp, %multmp3
  ret double %addtmp4
}

define double @bar(double %a) {
entry:
  %calltmp = call double @foo(double %a, double 4.000000e+00)
  %calltmp1 = call double @bar(double 3.133700e+04)
  %addtmp = fadd double %calltmp, %calltmp1
  ret double %addtmp
}

declare double @cos(double)

define double @1() {
entry:
  %calltmp = call double @cos(double 1.234000e+00)
  ret double %calltmp
}
```

When you quit the current demo (by sending an EOF via CTRL+D on Linux or CTRL+Z and ENTER on Windows), it dumps out the IR for the entire module generated. Here you can see the big picture with all the functions referencing each other.

This wraps up the third chapter of the Kaleidoscope tutorial. Up next, we'll describe how to [add JIT codegen and optimizer support](#) to this so we can actually start running code!

Full Code Listing

Here is the complete code listing for our running example, enhanced with the LLVM code generator. Because this uses the LLVM libraries, we need to link them in. To do this, we use the `llvm-config` tool to inform our makefile/command line about which options to use:

```
# Compile
clang++ -g -O3 toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core` -o_
↪toy
# Run
./toy
```

Here is the code:

```
#include "llvm/ADT/APFloat.h"
#include "llvm/ADT/STExtras.h"
#include "llvm/IR/BasicBlock.h"
#include "llvm/IR/Constants.h"
#include "llvm/IR/DerivedTypes.h"
#include "llvm/IR/Function.h"
#include "llvm/IR/IRBuilder.h"
#include "llvm/IR/LLVMContext.h"
#include "llvm/IR/Module.h"
#include "llvm/IR/Type.h"
#include "llvm/IR/Verifier.h"
#include <algorithm>
#include <cctype>
#include <cstdio>
#include <cstdlib>
#include <map>
#include <memory>
#include <string>
#include <vector>

using namespace llvm;

//=====//
// Lexer
//=====//

- *Adding a JIT Compiler*
- *Full Code Listing*

Chapter 4 Introduction

Welcome to Chapter 4 of the "Implementing a language with LLVM" tutorial. Chapters 1-3 described the implementation of a simple language and added support for generating LLVM IR. This chapter describes two new techniques: adding optimizer support to your language, and adding JIT compiler support. These additions will demonstrate how to get nice, efficient code for the Kaleidoscope language.

Trivial Constant Folding

Our demonstration for Chapter 3 is elegant and easy to extend. Unfortunately, it does not produce wonderful code. The IRBuilder, however, does give us obvious optimizations when compiling simple code:

```
ready> def test(x) 1+2+x;
Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double 3.000000e+00, %x
    ret double %addtmp
}
```

This code is not a literal transcription of the AST built by parsing the input. That would be:

```
ready> def test(x) 1+2+x;
Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double 2.000000e+00, 1.000000e+00
    %addtmp1 = fadd double %addtmp, %x
    ret double %addtmp1
}
```

Constant folding, as seen above, in particular, is a very common and very important optimization: so much so that many language implementors implement constant folding support in their AST representation.

With LLVM, you don't need this support in the AST. Since all calls to build LLVM IR go through the LLVM IR builder, the builder itself checked to see if there was a constant folding opportunity when you call it. If so, it just does the constant fold and return the constant instead of creating an instruction.

Well, that was easy :). In practice, we recommend always using `IRBuilder` when generating code like this. It has no "syntactic overhead" for its use (you don't have to uglify your compiler with constant checks everywhere) and it can dramatically reduce the amount of LLVM IR that is generated in some cases (particular for languages with a macro preprocessor or that use a lot of constants).

On the other hand, the `IRBuilder` is limited by the fact that it does all of its analysis inline with the code as it is built. If you take a slightly more complex example:

```
ready> def test(x) (1+2+x)*(x+(1+2));
ready> Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double 3.000000e+00, %x
    %addtmp1 = fadd double %x, 3.000000e+00
    %multmp = fmul double %addtmp, %addtmp1
    ret double %multmp
}
```

In this case, the LHS and RHS of the multiplication are the same value. We'd really like to see this generate `"tmp = x+3; result = tmp*tmp;"` instead of computing `"x+3"` twice.

Unfortunately, no amount of local analysis will be able to detect and correct this. This requires two transformations: reassociation of expressions (to make the add's lexically identical) and Common Subexpression Elimination (CSE) to delete the redundant add instruction. Fortunately, LLVM provides a broad range of optimizations that you can use, in the form of "passes".

LLVM Optimization Passes

Warning: Due to the transition to the new `PassManager` infrastructure this tutorial is based on `llvm::legacy::FunctionPassManager` which can be found in [LegacyPassManager.h](#). For the purpose of this tutorial the above should be used until the pass manager transition is complete.

LLVM provides many optimization passes, which do many different sorts of things and have different tradeoffs. Unlike other systems, LLVM doesn't hold to the mistaken notion that one set of optimizations is right for all languages and for all situations. LLVM allows a compiler implementor to make complete decisions about what optimizations to use, in which order, and in what situation.

As a concrete example, LLVM supports both "whole module" passes, which look across as large of body of code as they can (often a whole file, but if run at link time, this can be a substantial portion of the whole program). It also supports and includes "per-function" passes which just operate on a single function at a time, without looking at other functions. For more information on passes and how they are run, see the [How to Write a Pass](#) document and the [List of LLVM Passes](#).

For Kaleidoscope, we are currently generating functions on the fly, one at a time, as the user types them in. We aren't shooting for the ultimate optimization experience in this setting, but we also want to catch the easy and quick stuff where possible. As such, we will choose to run a few per-function optimizations as the user types the function in. If we wanted to make a "static Kaleidoscope compiler", we would use exactly the code we have now, except that we would defer running the optimizer until the entire file has been parsed.

In order to get per-function optimizations going, we need to set up a `FunctionPassManager` to hold and organize the LLVM optimizations that we want to run. Once we have that, we can add a set of optimizations to run. We'll need a new `FunctionPassManager` for each module that we want to optimize, so we'll write a function to create and initialize both the module and pass manager for us:

```
void InitializeModuleAndPassManager(void) {
    // Open a new module.
    TheModule = llvm::make_unique<Module>("my cool jit", TheContext);

    // Create a new pass manager attached to it.
```

(continues on next page)

(continued from previous page)

```

TheFPM = llvm::make_unique<FunctionPassManager>(TheModule.get());

// Do simple "peephole" optimizations and bit-twiddling optzns.
TheFPM->add(createInstructionCombiningPass());
// Reassociate expressions.
TheFPM->add(createReassociatePass());
// Eliminate Common SubExpressions.
TheFPM->add(createGVNPass());
// Simplify the control flow graph (deleting unreachable blocks, etc).
TheFPM->add(createCFGSimplificationPass());

TheFPM->doInitialization();
}

```

This code initializes the global module `TheModule`, and the function pass manager `TheFPM`, which is attached to `TheModule`. Once the pass manager is set up, we use a series of "add" calls to add a bunch of LLVM passes.

In this case, we choose to add four optimization passes. The passes we choose here are a pretty standard set of "cleanup" optimizations that are useful for a wide variety of code. I won't delve into what they do but, believe me, they are a good starting place :).

Once the `PassManager` is set up, we need to make use of it. We do this by running it after our newly created function is constructed (in `FunctionAST::codegen()`), but before it is returned to the client:

```

if (Value *RetVal = Body->codegen()) {
    // Finish off the function.
    Builder.CreateRet(RetVal);

    // Validate the generated code, checking for consistency.
    verifyFunction(*TheFunction);

    // Optimize the function.
    TheFPM->run(*TheFunction);

    return TheFunction;
}

```

As you can see, this is pretty straightforward. The `FunctionPassManager` optimizes and updates the LLVM `Function*` in place, improving (hopefully) its body. With this in place, we can try our test above again:

```

ready> def test(x) (1+2+x)*(x+(1+2));
ready> Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double %x, 3.000000e+00
    %multmp = fmul double %addtmp, %addtmp
    ret double %multmp
}

```

As expected, we now get our nicely optimized code, saving a floating point add instruction from every execution of this function.

LLVM provides a wide variety of optimizations that can be used in certain circumstances. Some [documentation about the various passes](#) is available, but it isn't very complete. Another good source of ideas can come from looking at the passes that Clang runs to get started. The "opt" tool allows you to experiment with passes from the command line, so you can see if they do anything.

Now that we have reasonable code coming out of our front-end, let's talk about executing it!

Adding a JIT Compiler

Code that is available in LLVM IR can have a wide variety of tools applied to it. For example, you can run optimizations on it (as we did above), you can dump it out in textual or binary forms, you can compile the code to an assembly file (.s) for some target, or you can JIT compile it. The nice thing about the LLVM IR representation is that it is the "common currency" between many different parts of the compiler.

In this section, we'll add JIT compiler support to our interpreter. The basic idea that we want for Kaleidoscope is to have the user enter function bodies as they do now, but immediately evaluate the top-level expressions they type in. For example, if they type in "1 + 2;", we should evaluate and print out 3. If they define a function, they should be able to call it from the command line.

In order to do this, we first prepare the environment to create code for the current native target and declare and initialize the JIT. This is done by calling some `InitializeNativeTarget*` functions and adding a global variable `TheJIT`, and initializing it in `main`:

```
static std::unique_ptr<KaleidoscopeJIT> TheJIT;
...
int main() {
    InitializeNativeTarget();
    InitializeNativeTargetAsmPrinter();
    InitializeNativeTargetAsmParser();

    // Install standard binary operators.
    // 1 is lowest precedence.
    BinopPrecedence['<'] = 10;
    BinopPrecedence['+'] = 20;
    BinopPrecedence['-'] = 20;
    BinopPrecedence['*'] = 40; // highest.

    // Prime the first token.
    fprintf(stderr, "ready> ");
    getNextToken();

    TheJIT = llvm::make_unique<KaleidoscopeJIT>();

    // Run the main "interpreter loop" now.
    MainLoop();

    return 0;
}
```

We also need to setup the data layout for the JIT:

```
void InitializeModuleAndPassManager(void) {
    // Open a new module.
    TheModule = llvm::make_unique<Module>("my cool jit", TheContext);
    TheModule->setDataLayout(TheJIT->getTargetMachine().createDataLayout());

    // Create a new pass manager attached to it.
    TheFPM = llvm::make_unique<FunctionPassManager>(TheModule.get());
    ...
}
```

The `KaleidoscopeJIT` class is a simple JIT built specifically for these tutorials, available inside the LLVM source code at `llvm-src/examples/Kaleidoscope/include/KaleidoscopeJIT.h`. In later chapters we will look at how it works and extend it with new features, but for now we will take it as given. Its API is very simple: `addModule` adds an LLVM IR module to the JIT, making its functions available for execution; `removeModule` removes a module, freeing any memory associated with the code in that module; and `findSymbol` allows us to look up pointers to the compiled

code.

We can take this simple API and change our code that parses top-level expressions to look like this:

```
static void HandleTopLevelExpression() {
    // Evaluate a top-level expression into an anonymous function.
    if (auto FnAST = ParseTopLevelExpr()) {
        if (FnAST->codegen()) {

            // JIT the module containing the anonymous expression, keeping a handle so
            // we can free it later.
            auto H = TheJIT->addModule(std::move(TheModule));
            InitializeModuleAndPassManager();

            // Search the JIT for the __anon_expr symbol.
            auto ExprSymbol = TheJIT->findSymbol("__anon_expr");
            assert(ExprSymbol && "Function not found");

            // Get the symbol's address and cast it to the right type (takes no
            // arguments, returns a double) so we can call it as a native function.
            double (*FP)() = (double (*)(intptr_t))ExprSymbol.getAddress();
            fprintf(stderr, "Evaluated to %f\n", FP());

            // Delete the anonymous expression module from the JIT.
            TheJIT->removeModule(H);
        }
    }
}
```

If parsing and codegen succeed, the next step is to add the module containing the top-level expression to the JIT. We do this by calling `addModule`, which triggers code generation for all the functions in the module, and returns a handle that can be used to remove the module from the JIT later. Once the module has been added to the JIT it can no longer be modified, so we also open a new module to hold subsequent code by calling `InitializeModuleAndPassManager()`.

Once we've added the module to the JIT we need to get a pointer to the final generated code. We do this by calling the JIT's `findSymbol` method, and passing the name of the top-level expression function: `__anon_expr`. Since we just added this function, we assert that `findSymbol` returned a result.

Next, we get the in-memory address of the `__anon_expr` function by calling `getAddress()` on the symbol. Recall that we compile top-level expressions into a self-contained LLVM function that takes no arguments and returns the computed double. Because the LLVM JIT compiler matches the native platform ABI, this means that you can just cast the result pointer to a function pointer of that type and call it directly. This means, there is no difference between JIT compiled code and native machine code that is statically linked into your application.

Finally, since we don't support re-evaluation of top-level expressions, we remove the module from the JIT when we're done to free the associated memory. Recall, however, that the module we created a few lines earlier (via `InitializeModuleAndPassManager`) is still open and waiting for new code to be added.

With just these two changes, let's see how Kaleidoscope works now!

```
ready> 4+5;
Read top-level expression:
define double @0() {
entry:
    ret double 9.000000e+00
}

Evaluated to 9.000000
```

Well this looks like it is basically working. The dump of the function shows the "no argument function that always

returns double" that we synthesize for each top-level expression that is typed in. This demonstrates very basic functionality, but can we do more?

```
ready> def testfunc(x y) x + y*2;
Read function definition:
define double @testfunc(double %x, double %y) {
entry:
    %multmp = fmul double %y, 2.000000e+00
    %addtmp = fadd double %multmp, %x
    ret double %addtmp
}

ready> testfunc(4, 10);
Read top-level expression:
define double @1() {
entry:
    %calltmp = call double @testfunc(double 4.000000e+00, double 1.000000e+01)
    ret double %calltmp
}

Evaluated to 24.000000

ready> testfunc(5, 10);
ready> LLVM ERROR: Program used external function 'testfunc' which could not be
→resolved!
```

Function definitions and calls also work, but something went very wrong on that last line. The call looks valid, so what happened? As you may have guessed from the API a Module is a unit of allocation for the JIT, and `testfunc` was part of the same module that contained anonymous expression. When we removed that module from the JIT to free the memory for the anonymous expression, we deleted the definition of `testfunc` along with it. Then, when we tried to call `testfunc` a second time, the JIT could no longer find it.

The easiest way to fix this is to put the anonymous expression in a separate module from the rest of the function definitions. The JIT will happily resolve function calls across module boundaries, as long as each of the functions called has a prototype, and is added to the JIT before it is called. By putting the anonymous expression in a different module we can delete it without affecting the rest of the functions.

In fact, we're going to go a step further and put every function in its own module. Doing so allows us to exploit a useful property of the KaleidoscopeJIT that will make our environment more REPL-like: Functions can be added to the JIT more than once (unlike a module where every function must have a unique definition). When you look up a symbol in KaleidoscopeJIT it will always return the most recent definition:

```
ready> def foo(x) x + 1;
Read function definition:
define double @foo(double %x) {
entry:
    %addtmp = fadd double %x, 1.000000e+00
    ret double %addtmp
}

ready> foo(2);
Evaluated to 3.000000

ready> def foo(x) x + 2;
define double @foo(double %x) {
entry:
    %addtmp = fadd double %x, 2.000000e+00
    ret double %addtmp
}
```

(continues on next page)

(continued from previous page)

```

}

ready> foo(2);
Evaluated to 4.000000

```

To allow each function to live in its own module we'll need a way to re-generate previous function declarations into each new module we open:

```

static std::unique_ptr<KaleidoscopeJIT> TheJIT;

...

Function *getFunction(std::string Name) {
    // First, see if the function has already been added to the current module.
    if (auto *F = TheModule->getFunction(Name))
        return F;

    // If not, check whether we can codegen the declaration from some existing
    // prototype.
    auto FI = FunctionProtos.find(Name);
    if (FI != FunctionProtos.end())
        return FI->second->codegen();

    // If no existing prototype exists, return null.
    return nullptr;
}

...

Value *CallExprAST::codegen() {
    // Look up the name in the global module table.
    Function *CalleeF = getFunction(Callee);

    ...

Function *FunctionAST::codegen() {
    // Transfer ownership of the prototype to the FunctionProtos map, but keep a
    // reference to it for use below.
    auto &P = *Proto;
    FunctionProtos[Proto->getName()] = std::move(Proto);
    Function *TheFunction = getFunction(P.getName());
    if (!TheFunction)
        return nullptr;
}

```

To enable this, we'll start by adding a new global, `FunctionProtos`, that holds the most recent prototype for each function. We'll also add a convenience method, `getFunction()`, to replace calls to `TheModule->getFunction()`. Our convenience method searches `TheModule` for an existing function declaration, falling back to generating a new declaration from `FunctionProtos` if it doesn't find one. In `CallExprAST::codegen()` we just need to replace the call to `TheModule->getFunction()`. In `FunctionAST::codegen()` we need to update the `FunctionProtos` map first, then call `getFunction()`. With this done, we can always obtain a function declaration in the current module for any previously declared function.

We also need to update `HandleDefinition` and `HandleExtern`:

```

static void HandleDefinition() {
    if (auto FnAST = ParseDefinition()) {

```

(continues on next page)

(continued from previous page)

```

    if (auto *FnIR = FnAST->codegen()) {
        fprintf(stderr, "Read function definition:");
        FnIR->print(errs());
        fprintf(stderr, "\n");
        TheJIT->addModule(std::move(TheModule));
        InitializeModuleAndPassManager();
    }
    else {
        // Skip token for error recovery.
        getNextToken();
    }
}

static void HandleExtern() {
    if (auto ProtoAST = ParseExtern()) {
        if (auto *FnIR = ProtoAST->codegen()) {
            fprintf(stderr, "Read extern: ");
            FnIR->print(errs());
            fprintf(stderr, "\n");
            FunctionProtos[ProtoAST->getName()] = std::move(ProtoAST);
        }
        else {
            // Skip token for error recovery.
            getNextToken();
        }
    }
}

```

In `HandleDefinition`, we add two lines to transfer the newly defined function to the JIT and open a new module. In `HandleExtern`, we just need to add one line to add the prototype to `FunctionProtos`.

With these changes made, let's try our REPL again (I removed the dump of the anonymous functions this time, you should get the idea by now :) :

```

ready> def foo(x) x + 1;
ready> foo(2);
Evaluated to 3.000000

ready> def foo(x) x + 2;
ready> foo(2);
Evaluated to 4.000000

```

It works!

Even with this simple code, we get some surprisingly powerful capabilities - check this out:

```

ready> extern sin(x);
Read extern:
declare double @sin(double)

ready> extern cos(x);
Read extern:
declare double @cos(double)

ready> sin(1.0);
Read top-level expression:
define double @2() {
entry:

```

(continues on next page)

(continued from previous page)

```

    ret double 0x3FEAED548F090CEE
}

Evaluated to 0.841471

ready> def foo(x) sin(x)*sin(x) + cos(x)*cos(x);
Read function definition:
define double @foo(double %x) {
entry:
    %calltmp = call double @sin(double %x)
    %multmp = fmul double %calltmp, %calltmp
    %calltmp2 = call double @cos(double %x)
    %multmp4 = fmul double %calltmp2, %calltmp2
    %addtmp = fadd double %multmp, %multmp4
    ret double %addtmp
}

ready> foo(4.0);
Read top-level expression:
define double @3() {
entry:
    %calltmp = call double @foo(double 4.000000e+00)
    ret double %calltmp
}

Evaluated to 1.000000

```

Whoa, how does the JIT know about `sin` and `cos`? The answer is surprisingly simple: The KaleidoscopeJIT has a straightforward symbol resolution rule that it uses to find symbols that aren't available in any given module: First it searches all the modules that have already been added to the JIT, from the most recent to the oldest, to find the newest definition. If no definition is found inside the JIT, it falls back to calling `dlsym("sin")` on the Kaleidoscope process itself. Since `sin` is defined within the JIT's address space, it simply patches up calls in the module to call the `libm` version of `sin` directly. But in some cases this even goes further: as `sin` and `cos` are names of standard math functions, the constant folder will directly evaluate the function calls to the correct result when called with constants like in the `sin(1.0)` above.

In the future we'll see how tweaking this symbol resolution rule can be used to enable all sorts of useful features, from security (restricting the set of symbols available to JIT'd code), to dynamic code generation based on symbol names, and even lazy compilation.

One immediate benefit of the symbol resolution rule is that we can now extend the language by writing arbitrary C++ code to implement operations. For example, if we add:

```

#ifdef _WIN32
#define DLLEXPORT __declspec(dllexport)
#else
#define DLLEXPORT
#endif

/// putchar - putchar that takes a double and returns 0.
extern "C" DLLEXPORT double putchar(double X) {
    fputc((char)X, stderr);
    return 0;
}

```

Note, that for Windows we need to actually export the functions because the dynamic symbol loader will use `GetProcAddress` to find the symbols.

Now we can produce simple output to the console by using things like: `"extern putchar(x); putchar(120);"`, which prints a lowercase 'x' on the console (120 is the ASCII code for 'x'). Similar code could be used to implement file I/O, console input, and many other capabilities in Kaleidoscope.

This completes the JIT and optimizer chapter of the Kaleidoscope tutorial. At this point, we can compile a non-Turing-complete programming language, optimize and JIT compile it in a user-driven way. Next up we'll look into [extending the language with control flow constructs](#), tackling some interesting LLVM IR issues along the way.

Full Code Listing

Here is the complete code listing for our running example, enhanced with the LLVM JIT and optimizer. To build this example, use:

```
# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core mcjit_
↪native` -O3 -o toy
# Run
./toy
```

If you are compiling this on Linux, make sure to add the `"-rdynamic"` option as well. This makes sure that the external functions are resolved properly at runtime.

Here is the code:

```
#include "../include/KaleidoscopeJIT.h"
#include "llvm/ADT/APFloat.h"
#include "llvm/ADT/STLExtras.h"
#include "llvm/IR/BasicBlock.h"
#include "llvm/IR/Constants.h"
#include "llvm/IR/DerivedTypes.h"
#include "llvm/IR/Function.h"
#include "llvm/IR/IRBuilder.h"
#include "llvm/IR/LLVMSContext.h"
#include "llvm/IR/LegacyPassManager.h"
#include "llvm/IR/Module.h"
#include "llvm/IR/Type.h"
#include "llvm/IR/Verifier.h"
#include "llvm/Support/TargetSelect.h"
#include "llvm/Target/TargetMachine.h"

Chapter 5 Introduction

Welcome to Chapter 5 of the "Implementing a language with LLVM" tutorial. Parts 1-4 described the implementation of the simple Kaleidoscope language and included support for generating LLVM IR, followed by optimizations and a JIT compiler. Unfortunately, as presented, Kaleidoscope is mostly useless: it has no control flow other than call and return. This means that you can't have conditional branches in the code, significantly limiting its power. In this episode of "build that compiler", we'll extend Kaleidoscope to have an if/then/else expression plus a simple 'for' loop.

If/Then/Else

Extending Kaleidoscope to support if/then/else is quite straightforward. It basically requires adding support for this "new" concept to the lexer, parser, AST, and LLVM code emitter. This example is nice, because it shows how easy it is to "grow" a language over time, incrementally extending it as new ideas are discovered.

Before we get going on "how" we add this extension, let's talk about "what" we want. The basic idea is that we want to be able to write this sort of thing:

```
def fib(x)
  if x < 3 then
    1
  else
    fib(x-1)+fib(x-2);
```

In Kaleidoscope, every construct is an expression: there are no statements. As such, the if/then/else expression needs to return a value like any other. Since we're using a mostly functional form, we'll have it evaluate its conditional, then return the 'then' or 'else' value based on how the condition was resolved. This is very similar to the C "?" expression.

The semantics of the if/then/else expression is that it evaluates the condition to a boolean equality value: 0.0 is considered to be false and everything else is considered to be true. If the condition is true, the first subexpression is evaluated and returned, if the condition is false, the second subexpression is evaluated and returned. Since Kaleidoscope allows side-effects, this behavior is important to nail down.

Now that we know what we "want", let's break this down into its constituent pieces.

Lexer Extensions for If/Then/Else

The lexer extensions are straightforward. First we add new enum values for the relevant tokens:

```
// control
tok_if = -6,
tok_then = -7,
tok_else = -8,
```

Once we have that, we recognize the new keywords in the lexer. This is pretty simple stuff:

```
...
if (IdentifierStr == "def")
    return tok_def;
if (IdentifierStr == "extern")
    return tok_extern;
if (IdentifierStr == "if")
    return tok_if;
if (IdentifierStr == "then")
    return tok_then;
if (IdentifierStr == "else")
    return tok_else;
return tok_identifier;
```

AST Extensions for If/Then/Else

To represent the new expression we add a new AST node for it:

```
/// IfExprAST - Expression class for if/then/else.
class IfExprAST : public ExprAST {
    std::unique_ptr<ExprAST> Cond, Then, Else;

public:
    IfExprAST(std::unique_ptr<ExprAST> Cond, std::unique_ptr<ExprAST> Then,
              std::unique_ptr<ExprAST> Else)
        : Cond(std::move(Cond)), Then(std::move(Then)), Else(std::move(Else)) {}

    Value *codegen() override;
};
```

The AST node just has pointers to the various subexpressions.

Parser Extensions for If/Then/Else

Now that we have the relevant tokens coming from the lexer and we have the AST node to build, our parsing logic is relatively straightforward. First we define a new parsing function:

```
/// ifexpr ::= 'if' expression 'then' expression 'else' expression
static std::unique_ptr<ExprAST> ParseIfExpr() {
    getNextToken(); // eat the if.

    // condition.
    auto Cond = ParseExpression();
    if (!Cond)
```

(continues on next page)

(continued from previous page)

```

    return nullptr;

    if (CurTok != tok_then)
        return LogError("expected then");
    getNextToken(); // eat the then

    auto Then = ParseExpression();
    if (!Then)
        return nullptr;

    if (CurTok != tok_else)
        return LogError("expected else");

    getNextToken();

    auto Else = ParseExpression();
    if (!Else)
        return nullptr;

    return llvm::make_unique<IfExprAST>(std::move(Cond), std::move(Then),
                                       std::move(Else));
}

```

Next we hook it up as a primary expression:

```

static std::unique_ptr<ExprAST> ParsePrimary() {
    switch (CurTok) {
    default:
        return LogError("unknown token when expecting an expression");
    case tok_identifier:
        return ParseIdentifierExpr();
    case tok_number:
        return ParseNumberExpr();
    case '(':
        return ParseParenExpr();
    case tok_if:
        return ParseIfExpr();
    }
}

```

LLVM IR for If/Then/Else

Now that we have it parsing and building the AST, the final piece is adding LLVM code generation support. This is the most interesting part of the if/then/else example, because this is where it starts to introduce new concepts. All of the code above has been thoroughly described in previous chapters.

To motivate the code we want to produce, let's take a look at a simple example. Consider:

```

extern foo();
extern bar();
def baz(x) if x then foo() else bar();

```

If you disable optimizations, the code you'll (soon) get from Kaleidoscope looks like this:

```

declare double @foo()

declare double @bar()

define double @baz(double %x) {
entry:
    %ifcond = fcmp one double %x, 0.000000e+00
    br i1 %ifcond, label %then, label %else

then:
    ; preds = %entry
    %calltmp = call double @foo()
    br label %ifcont

else:
    ; preds = %entry
    %calltmp1 = call double @bar()
    br label %ifcont

ifcont:
    ; preds = %else, %then
    %iftmp = phi double [ %calltmp, %then ], [ %calltmp1, %else ]
    ret double %iftmp
}

```

To visualize the control flow graph, you can use a nifty feature of the LLVM 'opt' tool. If you put this LLVM IR into "t.ll" and run "llvm-as < t.ll | opt -analyze -view-cfg", a window will pop up and you'll see this graph:

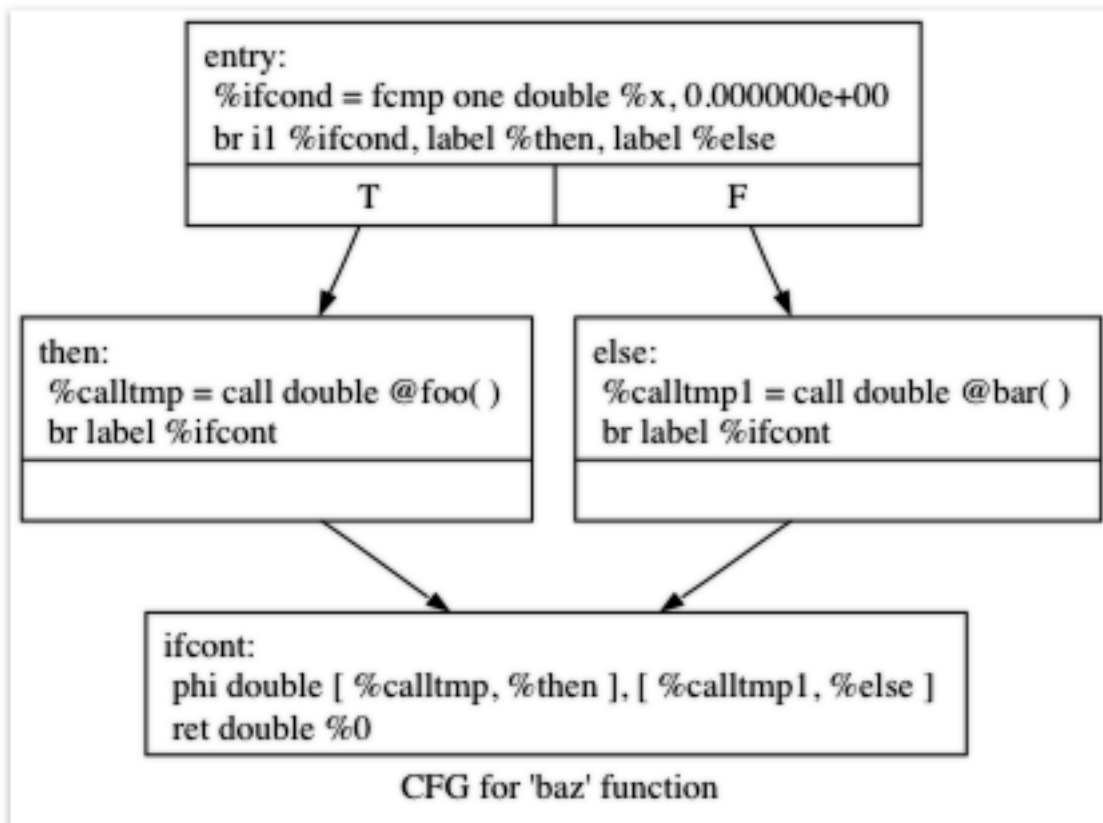

Fig. 1: Example CFG

Another way to get this is to call `F->viewCFG()` or `F->viewCFGOnly()` (where `F` is a `Function*`) either by inserting actual calls into the code and recompiling or by calling these in the debugger. LLVM has many nice features for visualizing various graphs.

Getting back to the generated code, it is fairly simple: the entry block evaluates the conditional expression ("`x`" in our case here) and compares the result to 0.0 with the `fcmp one` instruction ('one' is "Ordered and Not Equal"). Based on the result of this expression, the code jumps to either the "then" or "else" blocks, which contain the expressions for the true/false cases.

Once the then/else blocks are finished executing, they both branch back to the 'ifcont' block to execute the code that happens after the if/then/else. In this case the only thing left to do is to return to the caller of the function. The question then becomes: how does the code know which expression to return?

The answer to this question involves an important SSA operation: the [Phi operation](#). If you're not familiar with SSA, [the wikipedia article](#) is a good introduction and there are various other introductions to it available on your favorite search engine. The short version is that "execution" of the Phi operation requires "remembering" which block control came from. The Phi operation takes on the value corresponding to the input control block. In this case, if control comes in from the "then" block, it gets the value of `calltmp`. If control comes from the "else" block, it gets the value of `calltmp1`.

At this point, you are probably starting to think "Oh no! This means my simple and elegant front-end will have to start generating SSA form in order to use LLVM!". Fortunately, this is not the case, and we strongly advise *not* implementing an SSA construction algorithm in your front-end unless there is an amazingly good reason to do so. In practice, there are two sorts of values that float around in code written for your average imperative programming language that might need Phi nodes:

1. Code that involves user variables: `x = 1; x = x + 1;`
2. Values that are implicit in the structure of your AST, such as the Phi node in this case.

In [Chapter 7](#) of this tutorial ("mutable variables"), we'll talk about #1 in depth. For now, just believe me that you don't need SSA construction to handle this case. For #2, you have the choice of using the techniques that we will describe for #1, or you can insert Phi nodes directly, if convenient. In this case, it is really easy to generate the Phi node, so we choose to do it directly.

Okay, enough of the motivation and overview, let's generate code!

Code Generation for If/Then/Else

In order to generate code for this, we implement the `codegen` method for `IfExprAST`:

```
Value *IfExprAST::codegen() {
    Value *CondV = Cond->codegen();
    if (!CondV)
        return nullptr;

    // Convert condition to a bool by comparing non-equal to 0.0.
    CondV = Builder.CreateFCmpONE(
        CondV, ConstantFP::get(TheContext, APFloat(0.0)), "ifcond");
```

This code is straightforward and similar to what we saw before. We emit the expression for the condition, then compare that value to zero to get a truth value as a 1-bit (bool) value.

```
Function *TheFunction = Builder.GetInsertBlock()->getParent();

// Create blocks for the then and else cases. Insert the 'then' block at the
// end of the function.
BasicBlock *ThenBB =
```

(continues on next page)

(continued from previous page)

```

    BasicBlock::Create(TheContext, "then", TheFunction);
    BasicBlock *ElseBB = BasicBlock::Create(TheContext, "else");
    BasicBlock *MergeBB = BasicBlock::Create(TheContext, "ifcont");

    Builder.CreateCondBr(CondV, ThenBB, ElseBB);

```

This code creates the basic blocks that are related to the if/then/else statement, and correspond directly to the blocks in the example above. The first line gets the current Function object that is being built. It gets this by asking the builder for the current BasicBlock, and asking that block for its "parent" (the function it is currently embedded into).

Once it has that, it creates three blocks. Note that it passes "TheFunction" into the constructor for the "then" block. This causes the constructor to automatically insert the new block into the end of the specified function. The other two blocks are created, but aren't yet inserted into the function.

Once the blocks are created, we can emit the conditional branch that chooses between them. Note that creating new blocks does not implicitly affect the IRBuilder, so it is still inserting into the block that the condition went into. Also note that it is creating a branch to the "then" block and the "else" block, even though the "else" block isn't inserted into the function yet. This is all ok: it is the standard way that LLVM supports forward references.

```

// Emit then value.
Builder.SetInsertPoint(ThenBB);

Value *ThenV = Then->codegen();
if (!ThenV)
    return nullptr;

Builder.CreateBr(MergeBB);
// Codegen of 'Then' can change the current block, update ThenBB for the PHI.
ThenBB = Builder.GetInsertBlock();

```

After the conditional branch is inserted, we move the builder to start inserting into the "then" block. Strictly speaking, this call moves the insertion point to be at the end of the specified block. However, since the "then" block is empty, it also starts out by inserting at the beginning of the block. :)

Once the insertion point is set, we recursively codegen the "then" expression from the AST. To finish off the "then" block, we create an unconditional branch to the merge block. One interesting (and very important) aspect of the LLVM IR is that it **requires all basic blocks to be "terminated"** with a **control flow instruction** such as return or branch. This means that all control flow, *including fall throughs* must be made explicit in the LLVM IR. If you violate this rule, the verifier will emit an error.

The final line here is quite subtle, but is very important. The basic issue is that when we create the Phi node in the merge block, we need to set up the block/value pairs that indicate how the Phi will work. Importantly, the Phi node expects to have an entry for each predecessor of the block in the CFG. Why then, are we getting the current block when we just set it to ThenBB 5 lines above? The problem is that the "Then" expression may actually itself change the block that the Builder is emitting into if, for example, it contains a nested "if/then/else" expression. Because calling `codegen()` recursively could arbitrarily change the notion of the current block, we are required to get an up-to-date value for code that will set up the Phi node.

```

// Emit else block.
TheFunction->getBasicBlockList().push_back(ElseBB);
Builder.SetInsertPoint(ElseBB);

Value *ElseV = Else->codegen();
if (!ElseV)
    return nullptr;

```

(continues on next page)

(continued from previous page)

```
Builder.CreateBr(MergeBB);
// codegen of 'Else' can change the current block, update ElseBB for the PHI.
ElseBB = Builder.GetInsertBlock();
```

Code generation for the 'else' block is basically identical to codegen for the 'then' block. The only significant difference is the first line, which adds the 'else' block to the function. Recall previously that the 'else' block was created, but not added to the function. Now that the 'then' and 'else' blocks are emitted, we can finish up with the merge code:

```
// Emit merge block.
TheFunction->getBasicBlockList().push_back(MergeBB);
Builder.SetInsertPoint(MergeBB);
PHINode *PN =
    Builder.CreatePHI(Type::getDoubleTy(TheContext), 2, "iftmp");

PN->addIncoming(ThenV, ThenBB);
PN->addIncoming(ElseV, ElseBB);
return PN;
}
```

The first two lines here are now familiar: the first adds the "merge" block to the Function object (it was previously floating, like the else block above). The second changes the insertion point so that newly created code will go into the "merge" block. Once that is done, we need to create the PHI node and set up the block/value pairs for the PHI.

Finally, the CodeGen function returns the phi node as the value computed by the if/then/else expression. In our example above, this returned value will feed into the code for the top-level function, which will create the return instruction.

Overall, we now have the ability to execute conditional code in Kaleidoscope. With this extension, Kaleidoscope is a fairly complete language that can calculate a wide variety of numeric functions. Next up we'll add another useful expression that is familiar from non-functional languages...

'for' Loop Expression

Now that we know how to add basic control flow constructs to the language, we have the tools to add more powerful things. Let's add something more aggressive, a 'for' expression:

```
extern putchar(char);
def printstar(n)
    for i = 1, i < n, 1.0 in
        putchar(42); # ascii 42 = '*'

# print 100 '*' characters
printstar(100);
```

This expression defines a new variable ("i" in this case) which iterates from a starting value, while the condition ("i < n" in this case) is true, incrementing by an optional step value ("1.0" in this case). If the step value is omitted, it defaults to 1.0. While the loop is true, it executes its body expression. Because we don't have anything better to return, we'll just define the loop as always returning 0.0. In the future when we have mutable variables, it will get more useful.

As before, let's talk about the changes that we need to Kaleidoscope to support this.

Lexer Extensions for the 'for' Loop

The lexer extensions are the same sort of thing as for if/then/else:

```
... in enum Token ...
// control
tok_if = -6, tok_then = -7, tok_else = -8,
tok_for = -9, tok_in = -10

... in gettok ...
if (IdentifierStr == "def")
    return tok_def;
if (IdentifierStr == "extern")
    return tok_extern;
if (IdentifierStr == "if")
    return tok_if;
if (IdentifierStr == "then")
    return tok_then;
if (IdentifierStr == "else")
    return tok_else;
if (IdentifierStr == "for")
    return tok_for;
if (IdentifierStr == "in")
    return tok_in;
return tok_identifier;
```

AST Extensions for the 'for' Loop

The AST node is just as simple. It basically boils down to capturing the variable name and the constituent expressions in the node.

```
/// ForExprAST - Expression class for for/in.
class ForExprAST : public ExprAST {
    std::string VarName;
    std::unique_ptr<ExprAST> Start, End, Step, Body;

public:
    ForExprAST(const std::string &VarName, std::unique_ptr<ExprAST> Start,
               std::unique_ptr<ExprAST> End, std::unique_ptr<ExprAST> Step,
               std::unique_ptr<ExprAST> Body)
        : VarName(VarName), Start(std::move(Start)), End(std::move(End)),
          Step(std::move(Step)), Body(std::move(Body)) {}

    Value *codegen() override;
};
```

Parser Extensions for the 'for' Loop

The parser code is also fairly standard. The only interesting thing here is handling of the optional step value. The parser code handles it by checking to see if the second comma is present. If not, it sets the step value to null in the AST node:

```
/// forexpr ::= 'for' identifier '=' expr ',' expr (',' expr)? 'in' expression
static std::unique_ptr<ExprAST> ParseForExpr() {
    getNextToken(); // eat the for.

    if (CurTok != tok_identifier)
        return LogError("expected identifier after for");

    std::string IdName = IdentifierStr;
    getNextToken(); // eat identifier.

    if (CurTok != '=')
        return LogError("expected '=' after for");
    getNextToken(); // eat '='.

    auto Start = ParseExpression();
    if (!Start)
        return nullptr;
    if (CurTok != ',')
        return LogError("expected ',' after for start value");
    getNextToken();

    auto End = ParseExpression();
    if (!End)
        return nullptr;

    // The step value is optional.
    std::unique_ptr<ExprAST> Step;
    if (CurTok == ',') {
        getNextToken();
        Step = ParseExpression();
        if (!Step)
            return nullptr;
    }

    if (CurTok != tok_in)
        return LogError("expected 'in' after for");
    getNextToken(); // eat 'in'.

    auto Body = ParseExpression();
    if (!Body)
        return nullptr;

    return llvm::make_unique<ForExprAST>(IdName, std::move(Start),
                                         std::move(End), std::move(Step),
                                         std::move(Body));
}
```

And again we hook it up as a primary expression:

```
static std::unique_ptr<ExprAST> ParsePrimary() {
```

(continues on next page)

(continued from previous page)

```

switch (CurTok) {
default:
    return LogError("unknown token when expecting an expression");
case tok_identifier:
    return ParseIdentifierExpr();
case tok_number:
    return ParseNumberExpr();
case '(':
    return ParseParenExpr();
case tok_if:
    return ParseIfExpr();
case tok_for:
    return ParseForExpr();
}
}

```

LLVM IR for the 'for' Loop

Now we get to the good part: the LLVM IR we want to generate for this thing. With the simple example above, we get this LLVM IR (note that this dump is generated with optimizations disabled for clarity):

```

declare double @putchar(double)

define double @printstar(double %n) {
entry:
    ; initial value = 1.0 (inlined into phi)
    br label %loop

loop:          ; preds = %loop, %entry
    %i = phi double [ 1.000000e+00, %entry ], [ %nextvar, %loop ]
    ; body
    %calltmp = call double @putchar(double 4.200000e+01)
    ; increment
    %nextvar = fadd double %i, 1.000000e+00

    ; termination test
    %cmptmp = fcmp ult double %i, %n
    %booltmp = uitofp i1 %cmptmp to double
    %loopcond = fcmp one double %booltmp, 0.000000e+00
    br i1 %loopcond, label %loop, label %afterloop

afterloop:     ; preds = %loop
    ; loop always returns 0.0
    ret double 0.000000e+00
}

```

This loop contains all the same constructs we saw before: a phi node, several expressions, and some basic blocks. Let's see how this fits together.

Code Generation for the 'for' Loop

The first part of codegen is very simple: we just output the start expression for the loop value:

```
Value *ForExprAST::codegen() {
    // Emit the start code first, without 'variable' in scope.
    Value *StartVal = Start->codegen();
    if (!StartVal)
        return nullptr;
```

With this out of the way, the next step is to set up the LLVM basic block for the start of the loop body. In the case above, the whole loop body is one block, but remember that the body code itself could consist of multiple blocks (e.g. if it contains an if/then/else or a for/in expression).

```
// Make the new basic block for the loop header, inserting after current
// block.
Function *TheFunction = Builder.GetInsertBlock()->getParent();
BasicBlock *PreheaderBB = Builder.GetInsertBlock();
BasicBlock *LoopBB =
    BasicBlock::Create(TheContext, "loop", TheFunction);

// Insert an explicit fall through from the current block to the LoopBB.
Builder.CreateBr(LoopBB);
```

This code is similar to what we saw for if/then/else. Because we will need it to create the Phi node, we remember the block that falls through into the loop. Once we have that, we create the actual block that starts the loop and create an unconditional branch for the fall-through between the two blocks.

```
// Start insertion in LoopBB.
Builder.SetInsertPoint(LoopBB);

// Start the PHI node with an entry for Start.
PHINode *Variable = Builder.CreatePHI(Type::getDoubleTy(TheContext),
                                       2, VarName.c_str());
Variable->addIncoming(StartVal, PreheaderBB);
```

Now that the "preheader" for the loop is set up, we switch to emitting code for the loop body. To begin with, we move the insertion point and create the PHI node for the loop induction variable. Since we already know the incoming value for the starting value, we add it to the Phi node. Note that the Phi will eventually get a second value for the backedge, but we can't set it up yet (because it doesn't exist!).

```
// Within the loop, the variable is defined equal to the PHI node. If it
// shadows an existing variable, we have to restore it, so save it now.
Value *OldVal = NamedValues[VarName];
NamedValues[VarName] = Variable;

// Emit the body of the loop. This, like any other expr, can change the
// current BB. Note that we ignore the value computed by the body, but don't
// allow an error.
if (!Body->codegen())
    return nullptr;
```

Now the code starts to get more interesting. Our 'for' loop introduces a new variable to the symbol table. This means that our symbol table can now contain either function arguments or loop variables. To handle this, before we codegen the body of the loop, we add the loop variable as the current value for its name. Note that it is possible that there is a variable of the same name in the outer scope. It would be easy to make this an error (emit an error and return null if there is already an entry for VarName) but we choose to allow shadowing of variables. In order to handle this

correctly, we remember the Value that we are potentially shadowing in OldVal (which will be null if there is no shadowed variable).

Once the loop variable is set into the symbol table, the code recursively codegen's the body. This allows the body to use the loop variable: any references to it will naturally find it in the symbol table.

```
// Emit the step value.
Value *StepVal = nullptr;
if (Step) {
    StepVal = Step->codegen();
    if (!StepVal)
        return nullptr;
} else {
    // If not specified, use 1.0.
    StepVal = ConstantFP::get(TheContext, APFloat(1.0));
}

Value *NextVar = Builder.CreateFAdd(Variable, StepVal, "nextvar");
```

Now that the body is emitted, we compute the next value of the iteration variable by adding the step value, or 1.0 if it isn't present. 'NextVar' will be the value of the loop variable on the next iteration of the loop.

```
// Compute the end condition.
Value *EndCond = End->codegen();
if (!EndCond)
    return nullptr;

// Convert condition to a bool by comparing non-equal to 0.0.
EndCond = Builder.CreateFCmpONE(
    EndCond, ConstantFP::get(TheContext, APFloat(0.0)), "loopcond");
```

Finally, we evaluate the exit value of the loop, to determine whether the loop should exit. This mirrors the condition evaluation for the if/then/else statement.

```
// Create the "after loop" block and insert it.
BasicBlock *LoopEndBB = Builder.GetInsertBlock();
BasicBlock *AfterBB =
    BasicBlock::Create(TheContext, "afterloop", TheFunction);

// Insert the conditional branch into the end of LoopEndBB.
Builder.CreateCondBr(EndCond, LoopBB, AfterBB);

// Any new code will be inserted in AfterBB.
Builder.SetInsertPoint(AfterBB);
```

With the code for the body of the loop complete, we just need to finish up the control flow for it. This code remembers the end block (for the phi node), then creates the block for the loop exit ("afterloop"). Based on the value of the exit condition, it creates a conditional branch that chooses between executing the loop again and exiting the loop. Any future code is emitted in the "afterloop" block, so it sets the insertion position to it.

```
// Add a new entry to the PHI node for the backedge.
Variable->addIncoming(NextVar, LoopEndBB);

// Restore the unshadowed variable.
if (OldVal)
    NamedValues[VarName] = OldVal;
else
    NamedValues.erase(VarName);
```

(continues on next page)

(continued from previous page)

```
// for expr always returns 0.0.
return Constant::getNullValue(Type::getDoubleTy(TheContext));
}
```

The final code handles various cleanups: now that we have the "NextVar" value, we can add the incoming value to the loop PHI node. After that, we remove the loop variable from the symbol table, so that it isn't in scope after the for loop. Finally, code generation of the for loop always returns 0.0, so that is what we return from `ForExprAST::codegen()`.

With this, we conclude the "adding control flow to Kaleidoscope" chapter of the tutorial. In this chapter we added two control flow constructs, and used them to motivate a couple of aspects of the LLVM IR that are important for front-end implementors to know. In the next chapter of our saga, we will get a bit crazier and add [user-defined operators](#) to our poor innocent language.

Full Code Listing

Here is the complete code listing for our running example, enhanced with the if/then/else and for expressions. To build this example, use:

```
# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core mcjit_
↪native` -O3 -o toy
# Run
./toy
```

Here is the code:

```
#include "../include/KaleidoscopeJIT.h"
#include "llvm/ADT/APFloat.h"
#include "llvm/ADT/STLExtras.h"
#include "llvm/IR/BasicBlock.h"
#include "llvm/IR/Constants.h"
#include "llvm/IR/DerivedTypes.h"
#include "llvm/IR/Function.h"
#include "llvm/IR/IRBuilder.h"
#include "llvm/IR/Instructions.h"
#include "llvm/IR/LLVMContext.h"
#include "llvm/IR/LegacyPassManager.h"
#include "llvm/IR/Module.h"
#include "llvm/IR/Type.h"
#include "llvm/IR/Verifier.h"
#include "llvm/Support/TargetSelect.h"
#include "llvm/Target/TargetMachine.h"
#include "llvm/Transforms/InstCombine/InstCombine.h"
#include "llvm/Transforms/Scalar.h"
#include "llvm/Transforms/Scalar/GVN.h"
#include <algorithm>
#include <cassert>
#include <cctype>
#include <cstdlib>
#include <cstdio>
#include <cstdlib>
#include <map>
#include <memory>

Chapter 6 Introduction

Welcome to Chapter 6 of the "Implementing a language with LLVM" tutorial. At this point in our tutorial, we now have a fully functional language that is fairly minimal, but also useful. There is still one big problem with it, however. Our language doesn't have many useful operators (like division, logical negation, or even any comparisons besides less-than).

This chapter of the tutorial takes a wild digression into adding user-defined operators to the simple and beautiful Kaleidoscope language. This digression now gives us a simple and ugly language in some ways, but also a powerful one at the same time. One of the great things about creating your own language is that you get to decide what is good or bad. In this tutorial we'll assume that it is okay to use this as a way to show some interesting parsing techniques.

At the end of this tutorial, we'll run through an example Kaleidoscope application that *renders the Mandelbrot set*. This gives an example of what you can build with Kaleidoscope and its feature set.

User-defined Operators: the Idea

The "operator overloading" that we will add to Kaleidoscope is more general than in languages like C++. In C++, you are only allowed to redefine existing operators: you can't programmatically change the grammar, introduce new operators, change precedence levels, etc. In this chapter, we will add this capability to Kaleidoscope, which will let the user round out the set of operators that are supported.

The point of going into user-defined operators in a tutorial like this is to show the power and flexibility of using a hand-written parser. Thus far, the parser we have been implementing uses recursive descent for most parts of the grammar and operator precedence parsing for the expressions. See [Chapter 2](#) for details. By using operator precedence parsing, it is very easy to allow the programmer to introduce new operators into the grammar: the grammar is dynamically extensible as the JIT runs.

The two specific features we'll add are programmable unary operators (right now, Kaleidoscope has no unary operators at all) as well as binary operators. An example of this is:

```
# Logical unary not.
def unary! (v)
  if v then
    0
  else
    1;

# Define > with the same precedence as <.
def binary> 10 (LHS RHS)
  RHS < LHS;

# Binary "logical or", (note that it does not "short circuit")
def binary| 5 (LHS RHS)
  if LHS then
    1
  else if RHS then
    1
  else
    0;

# Define = with slightly lower precedence than relationals.
def binary= 9 (LHS RHS)
  !(LHS < RHS | LHS > RHS);
```

Many languages aspire to being able to implement their standard runtime library in the language itself. In Kaleidoscope, we can implement significant parts of the language in the library!

We will break down implementation of these features into two parts: implementing support for user-defined binary operators and adding unary operators.

User-defined Binary Operators

Adding support for user-defined binary operators is pretty simple with our current framework. We'll first add support for the unary/binary keywords:

```
enum Token {
    ...
    // operators
    tok_binary = -11,
    tok_unary = -12
};
...
static int gettok() {
    ...
    if (IdentifierStr == "for")
        return tok_for;
    if (IdentifierStr == "in")
        return tok_in;
    if (IdentifierStr == "binary")
        return tok_binary;
    if (IdentifierStr == "unary")
        return tok_unary;
    return tok_identifier;
}
```

This just adds lexer support for the unary and binary keywords, like we did in [previous chapters](#). One nice thing about our current AST, is that we represent binary operators with full generalisation by using their ASCII code as the opcode. For our extended operators, we'll use this same representation, so we don't need any new AST or parser support.

On the other hand, we have to be able to represent the definitions of these new operators, in the "def binary| 5" part of the function definition. In our grammar so far, the "name" for the function definition is parsed as the "prototype" production and into the PrototypeAST AST node. To represent our new user-defined operators as prototypes, we have to extend the PrototypeAST AST node like this:

```
/// PrototypeAST - This class represents the "prototype" for a function,
/// which captures its argument names as well as if it is an operator.
class PrototypeAST {
    std::string Name;
    std::vector<std::string> Args;
    bool IsOperator;
    unsigned Precedence; // Precedence if a binary op.

public:
    PrototypeAST(const std::string &name, std::vector<std::string> Args,
                bool IsOperator = false, unsigned Prec = 0)
        : Name(name), Args(std::move(Args)), IsOperator(IsOperator),
          Precedence(Prec) {}

    Function *codegen();
    const std::string &getName() const { return Name; }

    bool isUnaryOp() const { return IsOperator && Args.size() == 1; }
    bool isBinaryOp() const { return IsOperator && Args.size() == 2; }
```

(continues on next page)

(continued from previous page)

```

char getOperatorName() const {
    assert(isUnaryOp() || isBinaryOp());
    return Name[Name.size() - 1];
}

unsigned getBinaryPrecedence() const { return Precedence; }
};

```

Basically, in addition to knowing a name for the prototype, we now keep track of whether it was an operator, and if it was, what precedence level the operator is at. The precedence is only used for binary operators (as you'll see below, it just doesn't apply for unary operators). Now that we have a way to represent the prototype for a user-defined operator, we need to parse it:

```

// prototype
// ::= id '(' id* ')'
// ::= binary LETTER number? (id, id)
static std::unique_ptr<PrototypeAST> ParsePrototype() {
    std::string FnName;

    unsigned Kind = 0; // 0 = identifier, 1 = unary, 2 = binary.
    unsigned BinaryPrecedence = 30;

    switch (CurTok) {
    default:
        return LogErrorP("Expected function name in prototype");
    case tok_identifier:
        FnName = IdentifierStr;
        Kind = 0;
        getNextToken();
        break;
    case tok_binary:
        getNextToken();
        if (!isascii(CurTok))
            return LogErrorP("Expected binary operator");
        FnName = "binary";
        FnName += (char)CurTok;
        Kind = 2;
        getNextToken();

        // Read the precedence if present.
        if (CurTok == tok_number) {
            if (NumVal < 1 || NumVal > 100)
                return LogErrorP("Invalid precedence: must be 1..100");
            BinaryPrecedence = (unsigned)NumVal;
            getNextToken();
        }
        break;
    }

    if (CurTok != '(')
        return LogErrorP("Expected '(' in prototype");

    std::vector<std::string> ArgNames;
    while (getNextToken() == tok_identifier)
        ArgNames.push_back(IdentifierStr);
    if (CurTok != ')')

```

(continues on next page)

(continued from previous page)

```

    return LogErrorP("Expected ' ' in prototype");

    // success.
    getNextToken(); // eat ' '.

    // Verify right number of names for operator.
    if (Kind && ArgNames.size() != Kind)
        return LogErrorP("Invalid number of operands for operator");

    return llvm::make_unique<PrototypeAST>(FnName, std::move(ArgNames), Kind != 0,
                                           BinaryPrecedence);
}

```

This is all fairly straightforward parsing code, and we have already seen a lot of similar code in the past. One interesting part about the code above is the couple lines that set up `FnName` for binary operators. This builds names like "binary@" for a newly defined "@" operator. It then takes advantage of the fact that symbol names in the LLVM symbol table are allowed to have any character in them, including embedded nul characters.

The next interesting thing to add, is codegen support for these binary operators. Given our current structure, this is a simple addition of a default case for our existing binary operator node:

```

Value *BinaryExprAST::codegen() {
    Value *L = LHS->codegen();
    Value *R = RHS->codegen();
    if (!L || !R)
        return nullptr;

    switch (Op) {
    case '+':
        return Builder.CreateFAdd(L, R, "addtmp");
    case '-':
        return Builder.CreateFSub(L, R, "subtmp");
    case '*':
        return Builder.CreateFMul(L, R, "multmp");
    case '<':
        L = Builder.CreateFCmpULT(L, R, "cmptmp");
        // Convert bool 0/1 to double 0.0 or 1.0
        return Builder.CreateUIToFP(L, Type::getDoubleTy(TheContext),
                                    "booltmp");
    default:
        break;
    }

    // If it wasn't a builtin binary operator, it must be a user defined one. Emit
    // a call to it.
    Function *F = getFunction(std::string("binary") + Op);
    assert(F && "binary operator not found!");

    Value *Ops[2] = { L, R };
    return Builder.CreateCall(F, Ops, "binop");
}

```

As you can see above, the new code is actually really simple. It just does a lookup for the appropriate operator in the symbol table and generates a function call to it. Since user-defined operators are just built as normal functions (because the "prototype" boils down to a function with the right name) everything falls into place.

The final piece of code we are missing, is a bit of top-level magic:

```
Function *FunctionAST::codegen() {
    // Transfer ownership of the prototype to the FunctionProtos map, but keep a
    // reference to it for use below.
    auto &P = *Proto;
    FunctionProtos[Proto->getName()] = std::move(Proto);
    Function *TheFunction = getFunction(P.getName());
    if (!TheFunction)
        return nullptr;

    // If this is an operator, install it.
    if (P.isBinaryOp())
        BinopPrecedence[P.getOperatorName()] = P.getBinaryPrecedence();

    // Create a new basic block to start insertion into.
    BasicBlock *BB = BasicBlock::Create(TheContext, "entry", TheFunction);
    ...
}
```

Basically, before codegening a function, if it is a user-defined operator, we register it in the precedence table. This allows the binary operator parsing logic we already have in place to handle it. Since we are working on a fully-general operator precedence parser, this is all we need to do to "extend the grammar".

Now we have useful user-defined binary operators. This builds a lot on the previous framework we built for other operators. Adding unary operators is a bit more challenging, because we don't have any framework for it yet - let's see what it takes.

User-defined Unary Operators

Since we don't currently support unary operators in the Kaleidoscope language, we'll need to add everything to support them. Above, we added simple support for the 'unary' keyword to the lexer. In addition to that, we need an AST node:

```
/// UnaryExprAST - Expression class for a unary operator.
class UnaryExprAST : public ExprAST {
    char Opcode;
    std::unique_ptr<ExprAST> Operand;

public:
    UnaryExprAST(char Opcode, std::unique_ptr<ExprAST> Operand)
        : Opcode(Opcode), Operand(std::move(Operand)) {}

    Value *codegen() override;
};
```

This AST node is very simple and obvious by now. It directly mirrors the binary operator AST node, except that it only has one child. With this, we need to add the parsing logic. Parsing a unary operator is pretty simple: we'll add a new function to do it:

```
/// unary
/// ::= primary
/// ::= '!' unary
static std::unique_ptr<ExprAST> ParseUnary() {
    // If the current token is not an operator, it must be a primary expr.
    if (!isascii(CurTok) || CurTok == '(' || CurTok == ',')
        return ParsePrimary();

    // If this is a unary operator, read it.
    int Opc = CurTok;
```

(continues on next page)

(continued from previous page)

```
getNextToken();
if (auto Operand = ParseUnary())
    return llvm::make_unique<UnaryExprAST>(Opc, std::move(Operand));
return nullptr;
}
```

The grammar we add is pretty straightforward here. If we see a unary operator when parsing a primary operator, we eat the operator as a prefix and parse the remaining piece as another unary operator. This allows us to handle multiple unary operators (e.g. "!!x"). Note that unary operators can't have ambiguous parses like binary operators can, so there is no need for precedence information.

The problem with this function, is that we need to call `ParseUnary` from somewhere. To do this, we change previous callers of `ParsePrimary` to call `ParseUnary` instead:

```
/// binoprhs
/// ::= ('+' unary)*
static std::unique_ptr<ExprAST> ParseBinOpRHS(int ExprPrec,
                                              std::unique_ptr<ExprAST> LHS) {
    ...
    // Parse the unary expression after the binary operator.
    auto RHS = ParseUnary();
    if (!RHS)
        return nullptr;
    ...
}
/// expression
/// ::= unary binoprhs
///
static std::unique_ptr<ExprAST> ParseExpression() {
    auto LHS = ParseUnary();
    if (!LHS)
        return nullptr;

    return ParseBinOpRHS(0, std::move(LHS));
}
```

With these two simple changes, we are now able to parse unary operators and build the AST for them. Next up, we need to add parser support for prototypes, to parse the unary operator prototype. We extend the binary operator code above with:

```
/// prototype
/// ::= id '(' id* ')'
/// ::= binary LETTER number? (id, id)
/// ::= unary LETTER (id)
static std::unique_ptr<PrototypeAST> ParsePrototype() {
    std::string FnName;

    unsigned Kind = 0; // 0 = identifier, 1 = unary, 2 = binary.
    unsigned BinaryPrecedence = 30;

    switch (CurTok) {
    default:
        return LogErrorP("Expected function name in prototype");
    case tok_identifier:
        FnName = IdentifierStr;
        Kind = 0;
```

(continues on next page)

(continued from previous page)

```

    getNextToken();
    break;
case tok_unary:
    getNextToken();
    if (!isascii(CurTok))
        return LogErrorP("Expected unary operator");
    FnName = "unary";
    FnName += (char)CurTok;
    Kind = 1;
    getNextToken();
    break;
case tok_binary:
    ...

```

As with binary operators, we name unary operators with a name that includes the operator character. This assists us at code generation time. Speaking of, the final piece we need to add is codegen support for unary operators. It looks like this:

```

Value *UnaryExprAST::codegen() {
    Value *OperandV = Operand->codegen();
    if (!OperandV)
        return nullptr;

    Function *F = getFunction(std::string("unary") + Opcode);
    if (!F)
        return LogErrorV("Unknown unary operator");

    return Builder.CreateCall(F, OperandV, "unop");
}

```

This code is similar to, but simpler than, the code for binary operators. It is simpler primarily because it doesn't need to handle any predefined operators.

Kicking the Tires

It is somewhat hard to believe, but with a few simple extensions we've covered in the last chapters, we have grown a real-ish language. With this, we can do a lot of interesting things, including I/O, math, and a bunch of other things. For example, we can now add a nice sequencing operator (`printd` is defined to print out the specified value and a newline):

```

ready> extern printd(x);
Read extern:
declare double @printd(double)

ready> def binary : 1 (x y) 0; # Low-precedence operator that ignores operands.
...
ready> printd(123) : printd(456) : printd(789);
123.000000
456.000000
789.000000
Evaluated to 0.000000

```

We can also define a bunch of other "primitive" operations, such as:

```

# Logical unary not.
def unary!(v)

```

(continues on next page)

(continued from previous page)

```

    if v then
        0
    else
        1;

# Unary negate.
def unary-(v)
    0-v;

# Define > with the same precedence as <.
def binary> 10 (LHS RHS)
    RHS < LHS;

# Binary logical or, which does not short circuit.
def binary| 5 (LHS RHS)
    if LHS then
        1
    else if RHS then
        1
    else
        0;

# Binary logical and, which does not short circuit.
def binary& 6 (LHS RHS)
    if !LHS then
        0
    else
        !!RHS;

# Define = with slightly lower precedence than relationals.
def binary = 9 (LHS RHS)
    !(LHS < RHS | LHS > RHS);

# Define ':' for sequencing: as a low-precedence operator that ignores operands
# and just returns the RHS.
def binary : 1 (x y) y;

```

Given the previous if/then/else support, we can also define interesting functions for I/O. For example, the following prints out a character whose "density" reflects the value passed in: the lower the value, the denser the character:

```

ready> extern putchar(char);
...
ready> def printdensity(d)
    if d > 8 then
        putchar(32) # ' '
    else if d > 4 then
        putchar(46) # '.'
    else if d > 2 then
        putchar(43) # '+'
    else
        putchar(42); # '*'
...
ready> printdensity(1): printdensity(2): printdensity(3):
    printdensity(4): printdensity(5): printdensity(9):
    putchar(10);
****.
Evaluated to 0.000000

```

Based on these simple primitive operations, we can start to define more interesting things. For example, here's a little function that determines the number of iterations it takes for a certain function in the complex plane to diverge:

```
# Determine whether the specific location diverges.
# Solve for  $z = z^2 + c$  in the complex plane.
def mandelconverger(real imag iters creal cimag)
    if iters > 255 | (real*real + imag*imag > 4) then
        iters
    else
        mandelconverger(real*real - imag*imag + creal,
                        2*real*imag + cimag,
                        iters+1, creal, cimag);

# Return the number of iterations required for the iteration to escape
def mandelconverge(real imag)
    mandelconverger(real, imag, 0, real, imag);
```

This "z = z2 + c" function is a beautiful little creature that is the basis for computation of the [Mandelbrot Set](#). Our `mandelconverge` function returns the number of iterations that it takes for a complex orbit to escape, saturating to 255. This is not a very useful function by itself, but if you plot its value over a two-dimensional plane, you can see the Mandelbrot set. Given that we are limited to using `putchart` here, our amazing graphical output is limited, but we can whip together something using the density plotter above:

```
# Compute and plot the mandelbrot set with the specified 2 dimensional range
# info.
def mandelhelp(xmin xmax xstep  ymin ymax ystep)
    for y = ymin, y < ymax, ystep in (
        (for x = xmin, x < xmax, xstep in
            printdensity(mandelconverge(x,y)))
        : putchar(10)
    )

# mandel - This is a convenient helper function for plotting the mandelbrot set
# from the specified position with the specified Magnification.
def mandel(realstart imagstart realmag imagmag)
    mandelhelp(realstart, realstart+realmag*78, realmag,
                imagstart, imagstart+imagmag*40, imagmag);
```

Given this, we can try plotting out the mandelbrot set! Lets try it out:

[illegible]

(continues on next page)

```
Evaluated to 0.000000
ready> mandel(-2, -1, 0.02, 0.04);
```

(continues)

(continued from previous page)

[illegible]

At this point, you may be starting to realize that Kaleidoscope is a real and powerful language. It may not be self-

similar :), but it can be used to plot things that are!

With this, we conclude the "adding user-defined operators" chapter of the tutorial. We have successfully augmented our language, adding the ability to extend the language in the library, and we have shown how this can be used to build a simple but interesting end-user application in Kaleidoscope. At this point, Kaleidoscope can build a variety of applications that are functional and can call functions with side-effects, but it can't actually define and mutate a variable itself.

Strikingly, variable mutation is an important feature of some languages, and it is not at all obvious how to [add support for mutable variables](#) without having to add an "SSA construction" phase to your front-end. In the next chapter, we will describe how you can add variable mutation without building SSA in your front-end.

Full Code Listing

Here is the complete code listing for our running example, enhanced with the support for user-defined operators. To build this example, use:

```
# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core mcjit`
↪native` -O3 -o toy
# Run
./toy
```

On some platforms, you will need to specify `-rdynamic` or `-Wl,--export-dynamic` when linking. This ensures that symbols defined in the main executable are exported to the dynamic linker and so are available for symbol resolution at run time. This is not needed if you compile your support code into a shared library, although doing that will cause problems on Windows.

Here is the code:

```
#include "../include/KaleidoscopeJIT.h"
#include "llvm/ADT/APFloat.h"
#include "llvm/ADT/STLExtras.h"
#include "llvm/IR/BasicBlock.h"
#include "llvm/IR/Constants.h"

Chapter 7 Introduction

Welcome to Chapter 7 of the "Implementing a language with LLVM" tutorial. In chapters 1 through 6, we've built a very respectable, albeit simple, [functional programming language](#). In our journey, we learned some parsing techniques, how to build and represent an AST, how to build LLVM IR, and how to optimize the resultant code as well as JIT compile it.

While Kaleidoscope is interesting as a functional language, the fact that it is functional makes it "too easy" to generate LLVM IR for it. In particular, a functional language makes it very easy to build LLVM IR directly in [SSA form](#). Since LLVM requires that the input code be in SSA form, this is a very nice property and it is often unclear to newcomers how to generate code for an imperative language with mutable variables.

The short (and happy) summary of this chapter is that there is no need for your front-end to build SSA form: LLVM provides highly tuned and well tested support for this, though the way it works is a bit unexpected for some.

Why is this a hard problem?

To understand why mutable variables cause complexities in SSA construction, consider this extremely simple C example:

```
int G, H;
int test(_Bool Condition) {
    int X;
    if (Condition)
        X = G;
    else
        X = H;
    return X;
}
```

In this case, we have the variable "X", whose value depends on the path executed in the program. Because there are two different possible values for X before the return instruction, a PHI node is inserted to merge the two values. The LLVM IR that we want for this example looks like this:

```
@G = weak global i32 0 ; type of @G is i32*
@H = weak global i32 0 ; type of @H is i32*

define i32 @test(i1 %Condition) {
entry:
    br i1 %Condition, label %cond_true, label %cond_false

cond_true:
    %X.0 = load i32* @G
    br label %cond_next

cond_false:
    %X.1 = load i32* @H
    br label %cond_next

cond_next:
```

(continues on next page)

(continued from previous page)

```

    %X.2 = phi i32 [ %X.1, %cond_false ], [ %X.0, %cond_true ]
    ret i32 %X.2
}

```

In this example, the loads from the G and H global variables are explicit in the LLVM IR, and they live in the then/else branches of the if statement (cond_true/cond_false). In order to merge the incoming values, the X.2 phi node in the cond_next block selects the right value to use based on where control flow is coming from: if control flow comes from the cond_false block, X.2 gets the value of X.1. Alternatively, if control flow comes from cond_true, it gets the value of X.0. The intent of this chapter is not to explain the details of SSA form. For more information, see one of the many [online references](#).

The question for this article is "who places the phi nodes when lowering assignments to mutable variables?". The issue here is that LLVM *requires* that its IR be in SSA form: there is no "non-ssa" mode for it. However, SSA construction requires non-trivial algorithms and data structures, so it is inconvenient and wasteful for every front-end to have to reproduce this logic.

Memory in LLVM

The 'trick' here is that while LLVM does require all register values to be in SSA form, it does not require (or permit) memory objects to be in SSA form. In the example above, note that the loads from G and H are direct accesses to G and H: they are not renamed or versioned. This differs from some other compiler systems, which do try to version memory objects. In LLVM, instead of encoding dataflow analysis of memory into the LLVM IR, it is handled with [Analysis Passes](#) which are computed on demand.

With this in mind, the high-level idea is that we want to make a stack variable (which lives in memory, because it is on the stack) for each mutable object in a function. To take advantage of this trick, we need to talk about how LLVM represents stack variables.

In LLVM, all memory accesses are explicit with load/store instructions, and it is carefully designed not to have (or need) an "address-of" operator. Notice how the type of the @G/@H global variables is actually "i32*" even though the variable is defined as "i32". What this means is that @G defines *space* for an i32 in the global data area, but its *name* actually refers to the address for that space. Stack variables work the same way, except that instead of being declared with global variable definitions, they are declared with the [LLVM alloca instruction](#):

```

define i32 @example() {
entry:
    %X = alloca i32           ; type of %X is i32*.
    ...
    %tmp = load i32* %X       ; load the stack value %X from the stack.
    %tmp2 = add i32 %tmp, 1    ; increment it
    store i32 %tmp2, i32* %X  ; store it back
    ...
}

```

This code shows an example of how you can declare and manipulate a stack variable in the LLVM IR. Stack memory allocated with the alloca instruction is fully general: you can pass the address of the stack slot to functions, you can store it in other variables, etc. In our example above, we could rewrite the example to use the alloca technique to avoid using a PHI node:

```

@G = weak global i32 0      ; type of @G is i32*
@H = weak global i32 0      ; type of @H is i32*

define i32 @test(i1 %Condition) {
entry:
    %X = alloca i32          ; type of %X is i32*.

```

(continues on next page)

(continued from previous page)

```

    br i1 %Condition, label %cond_true, label %cond_false

cond_true:
    %X.0 = load i32* @G
    store i32 %X.0, i32* %X    ; Update X
    br label %cond_next

cond_false:
    %X.1 = load i32* @H
    store i32 %X.1, i32* %X    ; Update X
    br label %cond_next

cond_next:
    %X.2 = load i32* %X        ; Read X
    ret i32 %X.2
}

```

With this, we have discovered a way to handle arbitrary mutable variables without the need to create Phi nodes at all:

1. Each mutable variable becomes a stack allocation.
2. Each read of the variable becomes a load from the stack.
3. Each update of the variable becomes a store to the stack.
4. Taking the address of a variable just uses the stack address directly.

While this solution has solved our immediate problem, it introduced another one: we have now apparently introduced a lot of stack traffic for very simple and common operations, a major performance problem. Fortunately for us, the LLVM optimizer has a highly-tuned optimization pass named "mem2reg" that handles this case, promoting allocas like this into SSA registers, inserting Phi nodes as appropriate. If you run this example through the pass, for example, you'll get:

```

$ llvm-as < example.ll | opt -mem2reg | llvm-dis
@G = weak global i32 0
@H = weak global i32 0

define i32 @test(i1 %Condition) {
entry:
    br i1 %Condition, label %cond_true, label %cond_false

cond_true:
    %X.0 = load i32* @G
    br label %cond_next

cond_false:
    %X.1 = load i32* @H
    br label %cond_next

cond_next:
    %X.01 = phi i32 [ %X.1, %cond_false ], [ %X.0, %cond_true ]
    ret i32 %X.01
}

```

The mem2reg pass implements the standard "iterated dominance frontier" algorithm for constructing SSA form and has a number of optimizations that speed up (very common) degenerate cases. The mem2reg optimization pass is the answer to dealing with mutable variables, and we highly recommend that you depend on it. Note that mem2reg only works on variables in certain circumstances:

1. mem2reg is alloca-driven: it looks for allocas and if it can handle them, it promotes them. It does not apply to global variables or heap allocations.
2. mem2reg only looks for alloca instructions in the entry block of the function. Being in the entry block guarantees that the alloca is only executed once, which makes analysis simpler.
3. mem2reg only promotes allocas whose uses are direct loads and stores. If the address of the stack object is passed to a function, or if any funny pointer arithmetic is involved, the alloca will not be promoted.
4. mem2reg only works on allocas of [first class](#) values (such as pointers, scalars and vectors), and only if the array size of the allocation is 1 (or missing in the .ll file). mem2reg is not capable of promoting structs or arrays to registers. Note that the "sroa" pass is more powerful and can promote structs, "unions", and arrays in many cases.

All of these properties are easy to satisfy for most imperative languages, and we'll illustrate it below with Kaleidoscope. The final question you may be asking is: should I bother with this nonsense for my front-end? Wouldn't it be better if I just did SSA construction directly, avoiding use of the mem2reg optimization pass? In short, we strongly recommend that you use this technique for building SSA form, unless there is an extremely good reason not to. Using this technique is:

- Proven and well tested: clang uses this technique for local mutable variables. As such, the most common clients of LLVM are using this to handle a bulk of their variables. You can be sure that bugs are found fast and fixed early.
- Extremely Fast: mem2reg has a number of special cases that make it fast in common cases as well as fully general. For example, it has fast-paths for variables that are only used in a single block, variables that only have one assignment point, good heuristics to avoid insertion of unneeded phi nodes, etc.
- Needed for debug info generation: [Debug information in LLVM](#) relies on having the address of the variable exposed so that debug info can be attached to it. This technique dovetails very naturally with this style of debug info.

If nothing else, this makes it much easier to get your front-end up and running, and is very simple to implement. Let's extend Kaleidoscope with mutable variables now!

Mutable Variables in Kaleidoscope

Now that we know the sort of problem we want to tackle, let's see what this looks like in the context of our little Kaleidoscope language. We're going to add two features:

1. The ability to mutate variables with the '=' operator.
2. The ability to define new variables.

While the first item is really what this is about, we only have variables for incoming arguments as well as for induction variables, and redefining those only goes so far :). Also, the ability to define new variables is a useful thing regardless of whether you will be mutating them. Here's a motivating example that shows how we could use these:

```
# Define ':' for sequencing: as a low-precedence operator that ignores operands
# and just returns the RHS.
def binary : 1 (x y) y;

# Recursive fib, we could do this before.
def fib(x)
  if (x < 3) then
    1
  else
    fib(x-1)+fib(x-2);
```

(continues on next page)

(continued from previous page)

```
# Iterative fib.
def fibi(x)
  var a = 1, b = 1, c in
    (for i = 3, i < x in
      c = a + b :
      a = b :
      b = c) :
  b;

# Call it.
fibi(10);
```

In order to mutate variables, we have to change our existing variables to use the "alloca trick". Once we have that, we'll add our new operator, then extend Kaleidoscope to support new variable definitions.

Adjusting Existing Variables for Mutation

The symbol table in Kaleidoscope is managed at code generation time by the 'NamedValues' map. This map currently keeps track of the LLVM "Value*" that holds the double value for the named variable. In order to support mutation, we need to change this slightly, so that NamedValues holds the *memory location* of the variable in question. Note that this change is a refactoring: it changes the structure of the code, but does not (by itself) change the behavior of the compiler. All of these changes are isolated in the Kaleidoscope code generator.

At this point in Kaleidoscope's development, it only supports variables for two things: incoming arguments to functions and the induction variable of 'for' loops. For consistency, we'll allow mutation of these variables in addition to other user-defined variables. This means that these will both need memory locations.

To start our transformation of Kaleidoscope, we'll change the NamedValues map so that it maps to AllocaInst* instead of Value*. Once we do this, the C++ compiler will tell us what parts of the code we need to update:

```
static std::map<std::string, AllocaInst*> NamedValues;
```

Also, since we will need to create these allocas, we'll use a helper function that ensures that the allocas are created in the entry block of the function:

```
/// CreateEntryBlockAlloca - Create an alloca instruction in the entry block of
/// the function. This is used for mutable variables etc.
static AllocaInst *CreateEntryBlockAlloca(Function *TheFunction,
                                           const std::string &VarName) {
  IRBuilder<> TmpB(&TheFunction->getEntryBlock(),
                  TheFunction->getEntryBlock().begin());
  return TmpB.CreateAlloca(Type::getDoubleTy(TheContext), 0,
                           VarName.c_str());
}
```

This funny looking code creates an IRBuilder object that is pointing at the first instruction (.begin()) of the entry block. It then creates an alloca with the expected name and returns it. Because all values in Kaleidoscope are doubles, there is no need to pass in a type to use.

With this in place, the first functionality change we want to make belongs to variable references. In our new scheme, variables live on the stack, so code generating a reference to them actually needs to produce a load from the stack slot:

```
Value *VariableExprAST::codegen() {
  // Look this variable up in the function.
  Value *V = NamedValues[Name];
```

(continues on next page)

(continued from previous page)

```

if (!V)
    return LogErrorV("Unknown variable name");

// Load the value.
return Builder.CreateLoad(V, Name.c_str());
}

```

As you can see, this is pretty straightforward. Now we need to update the things that define the variables to set up the alloca. We'll start with `ForExprAST::codegen()` (see the [full code listing](#) for the unabridged code):

```

Function *TheFunction = Builder.GetInsertBlock()->getParent();

// Create an alloca for the variable in the entry block.
AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, VarName);

// Emit the start code first, without 'variable' in scope.
Value *StartVal = Start->codegen();
if (!StartVal)
    return nullptr;

// Store the value into the alloca.
Builder.CreateStore(StartVal, Alloca);
...

// Compute the end condition.
Value *EndCond = End->codegen();
if (!EndCond)
    return nullptr;

// Reload, increment, and restore the alloca. This handles the case where
// the body of the loop mutates the variable.
Value *CurVar = Builder.CreateLoad(Alloca);
Value *NextVar = Builder.CreateFAdd(CurVar, StepVal, "nextvar");
Builder.CreateStore(NextVar, Alloca);
...

```

This code is virtually identical to the code [before we allowed mutable variables](#). The big difference is that we no longer have to construct a PHI node, and we use load/store to access the variable as needed.

To support mutable argument variables, we need to also make allocas for them. The code for this is also pretty simple:

```

Function *FunctionAST::codegen() {
    ...
    Builder.SetInsertPoint(BB);

    // Record the function arguments in the NamedValues map.
    NamedValues.clear();
    for (auto &Arg : TheFunction->args()) {
        // Create an alloca for this variable.
        AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, Arg.getName());

        // Store the initial value into the alloca.
        Builder.CreateStore(&Arg, Alloca);

        // Add arguments to variable symbol table.
        NamedValues[Arg.getName()] = Alloca;
    }
}

```

(continues on next page)

(continued from previous page)

```
if (Value *RetVal = Body->codegen()) {
    ...
}
```

For each argument, we make an alloca, store the input value to the function into the alloca, and register the alloca as the memory location for the argument. This method gets invoked by `FunctionAST::codegen()` right after it sets up the entry block for the function.

The final missing piece is adding the mem2reg pass, which allows us to get good codegen once again:

```
// Promote allocas to registers.
TheFPM->add(createPromoteMemoryToRegisterPass());
// Do simple "peephole" optimizations and bit-twiddling optzns.
TheFPM->add(createInstructionCombiningPass());
// Reassociate expressions.
TheFPM->add(createReassociatePass());
...
```

It is interesting to see what the code looks like before and after the mem2reg optimization runs. For example, this is the before/after code for our recursive fib function. Before the optimization:

```
define double @fib(double %x) {
entry:
    %x1 = alloca double
    store double %x, double* %x1
    %x2 = load double, double* %x1
    %cmptmp = fcmp ult double %x2, 3.000000e+00
    %booltmp = uitofp i1 %cmptmp to double
    %ifcond = fcmp one double %booltmp, 0.000000e+00
    br i1 %ifcond, label %then, label %else

then:                ; preds = %entry
    br label %ifcont

else:                ; preds = %entry
    %x3 = load double, double* %x1
    %subtmp = fsub double %x3, 1.000000e+00
    %calltmp = call double @fib(double %subtmp)
    %x4 = load double, double* %x1
    %subtmp5 = fsub double %x4, 2.000000e+00
    %calltmp6 = call double @fib(double %subtmp5)
    %addtmp = fadd double %calltmp, %calltmp6
    br label %ifcont

ifcont:              ; preds = %else, %then
    %iftmp = phi double [ 1.000000e+00, %then ], [ %addtmp, %else ]
    ret double %iftmp
}
```

Here there is only one variable (x, the input argument) but you can still see the extremely simple-minded code generation strategy we are using. In the entry block, an alloca is created, and the initial input value is stored into it. Each reference to the variable does a reload from the stack. Also, note that we didn't modify the if/then/else expression, so it still inserts a PHI node. While we could make an alloca for it, it is actually easier to create a PHI node for it, so we still just make the PHI.

Here is the code after the mem2reg pass runs:

```
define double @fib(double %x) {
entry:
  %cmptmp = fcmp ult double %x, 3.000000e+00
  %booltmp = uitofp i1 %cmptmp to double
  %ifcond = fcmp one double %booltmp, 0.000000e+00
  br i1 %ifcond, label %then, label %else

then:
  br label %ifcont

else:
  %subtmp = fsub double %x, 1.000000e+00
  %calltmp = call double @fib(double %subtmp)
  %subtmp5 = fsub double %x, 2.000000e+00
  %calltmp6 = call double @fib(double %subtmp5)
  %addtmp = fadd double %calltmp, %calltmp6
  br label %ifcont

ifcont:      ; preds = %else, %then
  %iftmp = phi double [ 1.000000e+00, %then ], [ %addtmp, %else ]
  ret double %iftmp
}
```

This is a trivial case for mem2reg, since there are no redefinitions of the variable. The point of showing this is to calm your tension about inserting such blatant inefficiencies :).

After the rest of the optimizers run, we get:

```
define double @fib(double %x) {
entry:
  %cmptmp = fcmp ult double %x, 3.000000e+00
  %booltmp = uitofp i1 %cmptmp to double
  %ifcond = fcmp ueq double %booltmp, 0.000000e+00
  br i1 %ifcond, label %else, label %ifcont

else:
  %subtmp = fsub double %x, 1.000000e+00
  %calltmp = call double @fib(double %subtmp)
  %subtmp5 = fsub double %x, 2.000000e+00
  %calltmp6 = call double @fib(double %subtmp5)
  %addtmp = fadd double %calltmp, %calltmp6
  ret double %addtmp

ifcont:
  ret double 1.000000e+00
}
```

Here we see that the simplifycfg pass decided to clone the return instruction into the end of the 'else' block. This allowed it to eliminate some branches and the PHI node.

Now that all symbol table references are updated to use stack variables, we'll add the assignment operator.

New Assignment Operator

With our current framework, adding a new assignment operator is really simple. We will parse it just like any other binary operator, but handle it internally (instead of allowing the user to define it). The first step is to set a precedence:

```
int main() {
    // Install standard binary operators.
    // 1 is lowest precedence.
    BinopPrecedence['='] = 2;
    BinopPrecedence['<'] = 10;
    BinopPrecedence['+'] = 20;
    BinopPrecedence['-'] = 20;
```

Now that the parser knows the precedence of the binary operator, it takes care of all the parsing and AST generation. We just need to implement codegen for the assignment operator. This looks like:

```
Value *BinaryExprAST::codegen() {
    // Special case '=' because we don't want to emit the LHS as an expression.
    if (Op == '=') {
        // Assignment requires the LHS to be an identifier.
        VariableExprAST *LHSE = dynamic_cast<VariableExprAST*>(LHS.get());
        if (!LHSE)
            return LogErrorV("destination of '=' must be a variable");
```

Unlike the rest of the binary operators, our assignment operator doesn't follow the "emit LHS, emit RHS, do computation" model. As such, it is handled as a special case before the other binary operators are handled. The other strange thing is that it requires the LHS to be a variable. It is invalid to have "(x+1) = expr" - only things like "x = expr" are allowed.

```
    // Codegen the RHS.
    Value *Val = RHS->codegen();
    if (!Val)
        return nullptr;

    // Look up the name.
    Value *Variable = NamedValues[LHSE->getName()];
    if (!Variable)
        return LogErrorV("Unknown variable name");

    Builder.CreateStore(Val, Variable);
    return Val;
}
...
```

Once we have the variable, codegen'ing the assignment is straightforward: we emit the RHS of the assignment, create a store, and return the computed value. Returning a value allows for chained assignments like "X = (Y = Z)".

Now that we have an assignment operator, we can mutate loop variables and arguments. For example, we can now run code like this:

```
# Function to print a double.
extern printfd(x);

# Define ':' for sequencing: as a low-precedence operator that ignores operands
# and just returns the RHS.
def binary : 1 (x y) y;
```

(continues on next page)

(continued from previous page)

```
def test(x)
  printf(x) :
  x = 4 :
  printf(x);

test(123);
```

When run, this example prints "123" and then "4", showing that we did actually mutate the value! Okay, we have now officially implemented our goal: getting this to work requires SSA construction in the general case. However, to be really useful, we want the ability to define our own local variables, let's add this next!

User-defined Local Variables

Adding `var/in` is just like any other extension we made to Kaleidoscope: we extend the lexer, the parser, the AST and the code generator. The first step for adding our new '`var/in`' construct is to extend the lexer. As before, this is pretty trivial, the code looks like this:

```
enum Token {
  ...
  // var definition
  tok_var = -13
  ...
}
...
static int gettok() {
  ...
  if (IdentifierStr == "in")
    return tok_in;
  if (IdentifierStr == "binary")
    return tok_binary;
  if (IdentifierStr == "unary")
    return tok_unary;
  if (IdentifierStr == "var")
    return tok_var;
  return tok_identifier;
  ...
}
```

The next step is to define the AST node that we will construct. For `var/in`, it looks like this:

```
/// VarExprAST - Expression class for var/in
class VarExprAST : public ExprAST {
  std::vector<std::pair<std::string, std::unique_ptr<ExprAST>>> VarNames;
  std::unique_ptr<ExprAST> Body;

public:
  VarExprAST(std::vector<std::pair<std::string, std::unique_ptr<ExprAST>>> VarNames,
             std::unique_ptr<ExprAST> Body)
    : VarNames(std::move(VarNames)), Body(std::move(Body)) {}

  Value *codegen() override;
};
```

`var/in` allows a list of names to be defined all at once, and each name can optionally have an initializer value. As such, we capture this information in the `VarNames` vector. Also, `var/in` has a body, this body is allowed to access the variables defined by the `var/in`.

With this in place, we can define the parser pieces. The first thing we do is add it as a primary expression:

```

/// primary
/// ::= identifierexpr
/// ::= numberexpr
/// ::= parenexpr
/// ::= ifexpr
/// ::= forexpr
/// ::= varexpr
static std::unique_ptr<ExprAST> ParsePrimary() {
    switch (CurTok) {
    default:
        return LogError("unknown token when expecting an expression");
    case tok_identifier:
        return ParseIdentifierExpr();
    case tok_number:
        return ParseNumberExpr();
    case '(':
        return ParseParenExpr();
    case tok_if:
        return ParseIfExpr();
    case tok_for:
        return ParseForExpr();
    case tok_var:
        return ParseVarExpr();
    }
}

```

Next we define ParseVarExpr:

```

/// varexpr ::= 'var' identifier ('=' expression)?
//           (' identifier ('=' expression)?)* 'in' expression
static std::unique_ptr<ExprAST> ParseVarExpr() {
    getNextToken(); // eat the var.

    std::vector<std::pair<std::string, std::unique_ptr<ExprAST>>> VarNames;

    // At least one variable name is required.
    if (CurTok != tok_identifier)
        return LogError("expected identifier after var");
}

```

The first part of this code parses the list of identifier/expr pairs into the local VarNames vector.

```

while (1) {
    std::string Name = IdentifierStr;
    getNextToken(); // eat identifier.

    // Read the optional initializer.
    std::unique_ptr<ExprAST> Init;
    if (CurTok == '=') {
        getNextToken(); // eat the '='.

        Init = ParseExpression();
        if (!Init) return nullptr;
    }

    VarNames.push_back(std::make_pair(Name, std::move(Init)));
}

```

(continues on next page)

(continued from previous page)

```

// End of var list, exit loop.
if (CurTok != ',') break;
getNextToken(); // eat the ','.

if (CurTok != tok_identifier)
    return LogError("expected identifier list after var");
}

```

Once all the variables are parsed, we then parse the body and create the AST node:

```

// At this point, we have to have 'in'.
if (CurTok != tok_in)
    return LogError("expected 'in' keyword after 'var'");
getNextToken(); // eat 'in'.

auto Body = ParseExpression();
if (!Body)
    return nullptr;

return llvm::make_unique<VarExprAST>(std::move(VarNames),
                                     std::move(Body));
}

```

Now that we can parse and represent the code, we need to support emission of LLVM IR for it. This code starts out with:

```

Value *VarExprAST::codegen() {
    std::vector<AllocaInst *> OldBindings;

    Function *TheFunction = Builder.GetInsertBlock()->getParent();

    // Register all variables and emit their initializer.
    for (unsigned i = 0, e = VarNames.size(); i != e; ++i) {
        const std::string &VarName = VarNames[i].first;
        ExprAST *Init = VarNames[i].second.get();
    }
}

```

Basically it loops over all the variables, installing them one at a time. For each variable we put into the symbol table, we remember the previous value that we replace in OldBindings.

```

// Emit the initializer before adding the variable to scope, this prevents
// the initializer from referencing the variable itself, and permits stuff
// like this:
//   var a = 1 in
//   var a = a in ... # refers to outer 'a'.
Value *InitVal;
if (Init) {
    InitVal = Init->codegen();
    if (!InitVal)
        return nullptr;
} else { // If not specified, use 0.0.
    InitVal = ConstantFP::get(TheContext, APFloat(0.0));
}

AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, VarName);
Builder.CreateStore(InitVal, Alloca);

```

(continues on next page)

(continued from previous page)

```

// Remember the old variable binding so that we can restore the binding when
// we unrecurse.
OldBindings.push_back(NamedValues[VarName]);

// Remember this binding.
NamedValues[VarName] = Alloca;
}

```

There are more comments here than code. The basic idea is that we emit the initializer, create the alloca, then update the symbol table to point to it. Once all the variables are installed in the symbol table, we evaluate the body of the var/in expression:

```

// Codegen the body, now that all vars are in scope.
Value *BodyVal = Body->codegen();
if (!BodyVal)
    return nullptr;

```

Finally, before returning, we restore the previous variable bindings:

```

// Pop all our variables from scope.
for (unsigned i = 0, e = VarNames.size(); i != e; ++i)
    NamedValues[VarNames[i].first] = OldBindings[i];

// Return the body computation.
return BodyVal;
}

```

The end result of all of this is that we get properly scoped variable definitions, and we even (trivially) allow mutation of them :).

With this, we completed what we set out to do. Our nice iterative fib example from the intro compiles and runs just fine. The mem2reg pass optimizes all of our stack variables into SSA registers, inserting PHI nodes where needed, and our front-end remains simple: no "iterated dominance frontier" computation anywhere in sight.

Full Code Listing

Here is the complete code listing for our running example, enhanced with mutable variables and var/in support. To build this example, use:

```

# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core mcjit_
↪native` -O3 -o toy
# Run
./toy

```

Here is the code:

```

#include "../include/KaleidoscopeJIT.h"
#include "llvm/ADT/APFloat.h"
#include "llvm/ADT/STLExtras.h"
#include "llvm/IR/BasicBlock.h"
#include "llvm/IR/Constants.h"
#include "llvm/IR/DerivedTypes.h"
#include "llvm/IR/Function.h"
#include "llvm/IR/IRBuilder.h"

```

- *Target Machine*
- *Configuring the Module*
- *Emit Object Code*
- *Putting It All Together*
- *Full Code Listing*

Chapter 8 Introduction

Welcome to Chapter 8 of the "[Implementing a language with LLVM](#)" tutorial. This chapter describes how to compile our language down to object files.

Choosing a target

LLVM has native support for cross-compilation. You can compile to the architecture of your current machine, or just as easily compile for other architectures. In this tutorial, we'll target the current machine.

To specify the architecture that you want to target, we use a string called a "target triple". This takes the form `<arch><sub>-<vendor>-<sys>-<abi>` (see the [cross compilation docs](#)).

As an example, we can see what clang thinks is our current target triple:

```
$ clang --version | grep Target
Target: x86_64-unknown-linux-gnu
```

Running this command may show something different on your machine as you might be using a different architecture or operating system to me.

Fortunately, we don't need to hard-code a target triple to target the current machine. LLVM provides `sys::getDefaultTargetTriple`, which returns the target triple of the current machine.

```
auto TargetTriple = sys::getDefaultTargetTriple();
```

LLVM doesn't require us to link in all the target functionality. For example, if we're just using the JIT, we don't need the assembly printers. Similarly, if we're only targeting certain architectures, we can only link in the functionality for those architectures.

For this example, we'll initialize all the targets for emitting object code.

```
InitializeAllTargetInfos();
InitializeAllTargets();
InitializeAllTargetMCs();
InitializeAllAsmParsers();
InitializeAllAsmPrinters();
```

We can now use our target triple to get a Target:

```
std::string Error;
auto Target = TargetRegistry::lookupTarget(TargetTriple, Error);

// Print an error and exit if we couldn't find the requested target.
// This generally occurs if we've forgotten to initialise the
// TargetRegistry or we have a bogus target triple.
if (!Target) {
    errs() << Error;
    return 1;
}
```

Target Machine

We will also need a TargetMachine. This class provides a complete machine description of the machine we're targeting. If we want to target a specific feature (such as SSE) or a specific CPU (such as Intel's SandyLake), we do so now.

To see which features and CPUs that LLVM knows about, we can use `llc`. For example, let's look at x86:

```
$ llvm-as < /dev/null | llc -march=x86 -mattr=help
Available CPUs for this target:

    amdfam10      - Select the amdfam10 processor.
    athlon        - Select the athlon processor.
    athlon-4      - Select the athlon-4 processor.
    ...

Available features for this target:

    16bit-mode    - 16-bit mode (i8086).
    32bit-mode    - 32-bit mode (80386).
    3dnow         - Enable 3DNow! instructions.
    3dnowa        - Enable 3DNow! Athlon instructions.
    ...
```

For our example, we'll use the generic CPU without any additional features, options or relocation model.

```
auto CPU = "generic";
auto Features = "";

TargetOptions opt;
auto RM = Optional<Reloc::Model>();
auto TargetMachine = Target->createTargetMachine(TargetTriple, CPU, Features, opt,
    ↪RM);
```

Configuring the Module

We're now ready to configure our module, to specify the target and data layout. This isn't strictly necessary, but the [frontend performance guide](#) recommends this. Optimizations benefit from knowing about the target and data layout.

```
TheModule->setDataLayout(TargetMachine->createDataLayout());
TheModule->setTargetTriple(TargetTriple);
```

Emit Object Code

We're ready to emit object code! Let's define where we want to write our file to:

```
auto Filename = "output.o";
std::error_code EC;
raw_fd_ostream dest(Filename, EC, sys::fs::F_None);

if (EC) {
    errs() << "Could not open file: " << EC.message();
    return 1;
}
```

Finally, we define a pass that emits object code, then we run that pass:

```
legacy::PassManager pass;
auto FileType = TargetMachine::CGFT_ObjectFile;

if (TargetMachine->addPassesToEmitFile(pass, dest, nullptr, FileType)) {
    errs() << "TargetMachine can't emit a file of this type";
    return 1;
}

pass.run(*TheModule);
dest.flush();
```

Putting It All Together

Does it work? Let's give it a try. We need to compile our code, but note that the arguments to `llvm-config` are different to the previous chapters.

```
$ clang++ -g -O3 toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs all` -
-o toy
```

Let's run it, and define a simple average function. Press Ctrl-D when you're done.

```
$ ./toy
ready> def average(x y) (x + y) * 0.5;
^D
Wrote output.o
```

We have an object file! To test it, let's write a simple program and link it with our output. Here's the source code:

```
#include <iostream>
```

(continues on next page)

(continued from previous page)

```
extern "C" {
    double average(double, double);
}

int main() {
    std::cout << "average of 3.0 and 4.0: " << average(3.0, 4.0) << std::endl;
}
```

We link our program to output.o and check the result is what we expected:

```
$ clang++ main.cpp output.o -o main
$ ./main
average of 3.0 and 4.0: 3.5
```

Chapter 9 Introduction

Welcome to Chapter 9 of the "Implementing a language with LLVM" tutorial. In chapters 1 through 8, we've built a decent little programming language with functions and variables. What happens if something goes wrong though, how do you debug your program?

Source level debugging uses formatted data that helps a debugger translate from binary and the state of the machine back to the source that the programmer wrote. In LLVM we generally use a format called [DWARF](#). DWARF is a compact encoding that represents types, source locations, and variable locations.

The short summary of this chapter is that we'll go through the various things you have to add to a programming language to support debug info, and how you translate that into DWARF.

Caveat: For now we can't debug via the JIT, so we'll need to compile our program down to something small and standalone. As part of this we'll make a few modifications to the running of the language and how programs are compiled. This means that we'll have a source file with a simple program written in Kaleidoscope rather than the interactive JIT. It does involve a limitation that we can only have one "top level" command at a time to reduce the number of changes necessary.

Here's the sample program we'll be compiling:

```
def fib(x)
  if x < 3 then
    1
  else
    fib(x-1)+fib(x-2);
fib(10)
```

Why is this a hard problem?

Debug information is a hard problem for a few different reasons - mostly centered around optimized code. First, optimization makes keeping source locations more difficult. In LLVM IR we keep the original source location for each IR level instruction on the instruction. Optimization passes should keep the source locations for newly created instructions, but merged instructions only get to keep a single location - this can cause jumping around when stepping through optimized programs. Secondly, optimization can move variables in ways that are either optimized out, shared in memory with other variables, or difficult to track. For the purposes of this tutorial we're going to avoid optimization (as you'll see with one of the next sets of patches).

Ahead-of-Time Compilation Mode

To highlight only the aspects of adding debug information to a source language without needing to worry about the complexities of JIT debugging we're going to make a few changes to Kaleidoscope to support compiling the IR emitted by the front end into a simple standalone program that you can execute, debug, and see results.

First we make our anonymous function that contains our top level statement be our "main":

```
- auto Proto = llvm::make_unique<PrototypeAST>("", std::vector<std::string>());
+ auto Proto = llvm::make_unique<PrototypeAST>("main", std::vector<std::string>());
```

just with the simple change of giving it a name.

Then we're going to remove the command line code wherever it exists:

```

```

Lastly we're going to disable all of the optimization passes and the JIT so that the only thing that happens after we're done parsing and generating code is that the LLVM IR goes to standard error:

```

    OurFPM.doInitialization();

    // Set the global so the code gen can use this.

```

This relatively small set of changes get us to the point that we can compile our piece of Kaleidoscope language down to an executable program via this command line:

```
Kaleidoscope-Ch9 < fib.ks | & clang -x ir -
```

which gives an a.out/a.exe in the current working directory.

Compile Unit

The top level container for a section of code in DWARF is a compile unit. This contains the type and function data for an individual translation unit (read: one file of source code). So the first thing we need to do is construct one for our fib.ks file.

DWARF Emission Setup

Similar to the `IRBuilder` class we have a `DIBuilder` class that helps in constructing debug metadata for an LLVM IR file. It corresponds 1:1 similarly to `IRBuilder` and LLVM IR, but with nicer names. Using it does require that you be more familiar with DWARF terminology than you needed to be with `IRBuilder` and `Instruction` names, but if you read through the general documentation on the [Metadata Format](#) it should be a little more clear. We'll be using this class to construct all of our IR level descriptions. Construction for it takes a module so we need to construct it shortly after we construct our module. We've left it as a global static variable to make it a bit easier to use.

Next we're going to create a small container to cache some of our frequent data. The first will be our compile unit, but we'll also write a bit of code for our one type since we won't have to worry about multiple typed expressions:

```
static DIBuilder *DBuilder;

struct DebugInfo {
    DIBuilder *TheCU;
    DIBuilder *DblTy;

    DIBuilder *getDoubleTy();
} KSDbgInfo;

DIBuilder *DebugInfo::getDoubleTy() {
    if (DblTy)
        return DblTy;

    DblTy = DBuilder->createBasicType("double", 64, dwarf::DW_ATE_float);
    return DblTy;
}
```

And then later on in main when we're constructing our module:

```
DBuilder = new DIBuilder(*TheModule);

KSDbgInfo.TheCU = DBuilder->createCompileUnit(
    dwarf::DW_LANG_C, DBuilder->createFile("fib.ks", "."),
    "Kaleidoscope Compiler", 0, "", 0);
```

There are a couple of things to note here. First, while we're producing a compile unit for a language called Kaleidoscope we used the language constant for C. This is because a debugger wouldn't necessarily understand the calling conventions or default ABI for a language it doesn't recognize and we follow the C ABI in our LLVM code generation so it's the closest thing to accurate. This ensures we can actually call functions from the debugger and have them execute. Secondly, you'll see the "fib.ks" in the call to `createCompileUnit`. This is a default hard coded value since we're using shell redirection to put our source into the Kaleidoscope compiler. In a usual front end you'd have an input file name and it would go there.

One last thing as part of emitting debug information via DIBuilder is that we need to "finalize" the debug information. The reasons are part of the underlying API for DIBuilder, but make sure you do this near the end of main:

```
DBuilder->finalize();
```

before you dump out the module.

Functions

Now that we have our `Compile Unit` and our source locations, we can add function definitions to the debug info. So in `PrototypeAST::codegen()` we add a few lines of code to describe a context for our subprogram, in this case the "File", and the actual definition of the function itself.

So the context:

```
DIFile *Unit = DBuilder->createFile(KSDBGInfo.TheCU.getFilename(),
                                   KSDBGInfo.TheCU.getDirectory());
```

giving us an `DIFile` and asking the `Compile Unit` we created above for the directory and filename where we are currently. Then, for now, we use some source locations of 0 (since our AST doesn't currently have source location information) and construct our function definition:

```
DIScope *FContext = Unit;
unsigned LineNo = 0;
unsigned ScopeLine = 0;
DISubprogram *SP = DBuilder->createFunction(
    FContext, P.getName(), StringRef(), Unit, LineNo,
    CreateFunctionType(TheFunction->arg_size(), Unit),
    false /* internal linkage */, true /* definition */, ScopeLine,
    DINode::FlagPrototyped, false);
TheFunction->setSubprogram(SP);
```

and we now have an `DISubprogram` that contains a reference to all of our metadata for the function.

Source Locations

The most important thing for debug information is accurate source location - this makes it possible to map your source code back. We have a problem though, Kaleidoscope really doesn't have any source location information in the lexer or parser so we'll need to add it.

```
struct SourceLocation {
    int Line;
    int Col;
};
static SourceLocation CurLoc;
static SourceLocation LexLoc = {1, 0};

static int advance() {
    int LastChar = getchar();

    if (LastChar == '\n' || LastChar == '\r') {
        LexLoc.Line++;
        LexLoc.Col = 0;
    } else
        LexLoc.Col++;
}
```

(continues on next page)

(continued from previous page)

```

return LastChar;
}

```

In this set of code we've added some functionality on how to keep track of the line and column of the "source file". As we lex every token we set our current "lexical location" to the assorted line and column for the beginning of the token. We do this by overriding all of the previous calls to `getchar()` with our new `advance()` that keeps track of the information and then we have added to all of our AST classes a source location:

```

class ExprAST {
    SourceLocation Loc;

public:
    ExprAST(SourceLocation Loc = CurLoc) : Loc(Loc) {}
    virtual ~ExprAST() {}
    virtual Value* codegen() = 0;
    int getLine() const { return Loc.Line; }
    int getCol() const { return Loc.Col; }
    virtual raw_ostream &dump(raw_ostream &out, int ind) {
        return out << ':' << getLine() << ':' << getCol() << '\n';
    }
}

```

that we pass down through when we create a new expression:

```

LHS = llvm::make_unique<BinaryExprAST>(BinLoc, BinOp, std::move(LHS),
                                       std::move(RHS));

```

giving us locations for each of our expressions and variables.

To make sure that every instruction gets proper source location information, we have to tell `Builder` whenever we're at a new source location. We use a small helper function for this:

```

void DebugInfo::emitLocation(ExprAST *AST) {
    DIScope *Scope;
    if (LexicalBlocks.empty())
        Scope = TheCU;
    else
        Scope = LexicalBlocks.back();
    Builder.SetCurrentDebugLocation(
        DebugLoc::get(AST->getLine(), AST->getCol(), Scope));
}

```

This both tells the main `IRBuilder` where we are, but also what scope we're in. The scope can either be on compile-unit level or be the nearest enclosing lexical block like the current function. To represent this we create a stack of scopes:

```

std::vector<DIScope *> LexicalBlocks;

```

and push the scope (function) to the top of the stack when we start generating the code for each function:

```

KSDbgInfo.LexicalBlocks.push_back(SP);

```

Also, we may not forget to pop the scope back off of the scope stack at the end of the code generation for the function:

```

// Pop off the lexical block for the function since we added it
// unconditionally.
KSDbgInfo.LexicalBlocks.pop_back();

```

Then we make sure to emit the location every time we start to generate code for a new AST object:

```
KSDBGInfo.emitLocation(this);
```

Variables

Now that we have functions, we need to be able to print out the variables we have in scope. Let's get our function arguments set up so we can get decent backtraces and see how our functions are being called. It isn't a lot of code, and we generally handle it when we're creating the argument allocas in `FunctionAST::codegen`.

```
// Record the function arguments in the NamedValues map.
NamedValues.clear();
unsigned ArgIdx = 0;
for (auto &Arg : TheFunction->args()) {
    // Create an alloca for this variable.
    AllocaInst *Alloca = CreateEntryBlockAlloca(TheFunction, Arg.getName());

    // Create a debug descriptor for the variable.
    DILocalVariable *D = DBuilder->createParameterVariable(
        SP, Arg.getName(), ++ArgIdx, Unit, LineNo, KSDBGInfo.getDoubleTy(),
        true);

    DBuilder->insertDeclare(Alloca, D, DBuilder->createExpression(),
        DebugLoc::get(LineNo, 0, SP),
        Builder.GetInsertBlock());

    // Store the initial value into the alloca.
    Builder.CreateStore(&Arg, Alloca);

    // Add arguments to variable symbol table.
    NamedValues[Arg.getName()] = Alloca;
}
```

Here we're first creating the variable, giving it the scope (SP), the name, source location, type, and since it's an argument, the argument index. Next, we create an `lvm.dbg.declare` call to indicate at the IR level that we've got a variable in an alloca (and it gives a starting location for the variable), and setting a source location for the beginning of the scope on the declare.

One interesting thing to note at this point is that various debuggers have assumptions based on how code and debug information was generated for them in the past. In this case we need to do a little bit of a hack to avoid generating line information for the function prologue so that the debugger knows to skip over those instructions when setting a breakpoint. So in `FunctionAST::CodeGen` we add some more lines:

```
// Unset the location for the prologue emission (leading instructions with no
// location in a function are considered part of the prologue and the debugger
// will run past them when breaking on a function)
KSDBGInfo.emitLocation(nullptr);
```

and then emit a new location when we actually start generating code for the body of the function:

```
KSDBGInfo.emitLocation(Body.get());
```

With this we have enough debug information to set breakpoints in functions, print out argument variables, and call functions. Not too bad for just a few simple lines of code!

Full Code Listing

Here is the complete code listing for our running example, enhanced with debug information. To build this example, use:

```
# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core mcjit_
↪native` -O3 -o toy
# Run
./toy
```

Here is the code:

```
#include "llvm/ADT/STLExtras.h"

Tutorial Conclusion

Welcome to the final chapter of the "Implementing a language with LLVM" tutorial. In the course of this tutorial, we have grown our little Kaleidoscope language from being a useless toy, to being a semi-interesting (but probably still useless) toy. :)

It is interesting to see how far we've come, and how little code it has taken. We built the entire lexer, parser, AST, code generator, an interactive run-loop (with a JIT!), and emitted debug information in standalone executables - all in under 1000 lines of (non-comment/non-blank) code.

Our little language supports a couple of interesting features: it supports user defined binary and unary operators, it uses JIT compilation for immediate evaluation, and it supports a few control flow constructs with SSA construction.

Part of the idea of this tutorial was to show you how easy and fun it can be to define, build, and play with languages. Building a compiler need not be a scary or mystical process! Now that you've seen some of the basics, I strongly encourage you to take the code and hack on it. For example, try adding:

- **global variables** - While global variables have questional value in modern software engineering, they are often useful when putting together quick little hacks like the Kaleidoscope compiler itself. Fortunately, our current setup makes it very easy to add global variables: just have value lookup check to see if an unresolved variable is in the global variable symbol table before rejecting it. To create a new global variable, make an instance of the LLVM `GlobalVariable` class.
- **typed variables** - Kaleidoscope currently only supports variables of type double. This gives the language a very nice elegance, because only supporting one type means that you never have to specify types. Different languages have different ways of handling this. The easiest way is to require the user to specify types for every variable definition, and record the type of the variable in the symbol table along with its `Value*`.
- **arrays, structs, vectors, etc** - Once you add types, you can start extending the type system in all sorts of interesting ways. Simple arrays are very easy and are quite useful for many different applications. Adding them is mostly an exercise in learning how the LLVM `getelementptr` instruction works: it is so nifty/unconventional, it has its own FAQ!
- **standard runtime** - Our current language allows the user to access arbitrary external functions, and we use it for things like "printf" and "putchar". As you extend the language to add higher-level constructs, often these constructs make the most sense if they are lowered to calls into a language-supplied runtime. For example, if you add hash tables to the language, it would probably make sense to add the routines to a runtime, instead of inlining them all the way.
- **memory management** - Currently we can only access the stack in Kaleidoscope. It would also be useful to be able to allocate heap memory, either with calls to the standard libc malloc/free interface or with a garbage collector. If you would like to use garbage collection, note that LLVM fully supports [Accurate Garbage Collection](#) including algorithms that move objects and need to scan/update the stack.
- **exception handling support** - LLVM supports generation of [zero cost exceptions](#) which interoperate with code compiled in other languages. You could also generate code by implicitly making every function return an error value and checking it. You could also make explicit use of `setjmp/longjmp`. There are many different ways to go here.
- **object orientation, generics, database access, complex numbers, geometric programming, ...** - Really, there is no end of crazy features that you can add to the language.
- **unusual domains** - We've been talking about applying LLVM to a domain that many people are interested in: building a compiler for a specific language. However, there are many other domains that can use compiler

technology that are not typically considered. For example, LLVM has been used to implement OpenGL graphics acceleration, translate C++ code to ActionScript, and many other cute and clever things. Maybe you will be the first to JIT compile a regular expression interpreter into native code with LLVM?

Have fun - try doing something crazy and unusual. Building a language like everyone else always has, is much less fun than trying something a little crazy or off the wall and seeing how it turns out. If you get stuck or want to talk about it, feel free to email the [llvm-dev mailing list](#): it has lots of people who are interested in languages and are often willing to help out.

Before we end this tutorial, I want to talk about some "tips and tricks" for generating LLVM IR. These are some of the more subtle things that may not be obvious, but are very useful if you want to take advantage of LLVM's capabilities.

Properties of the LLVM IR

We have a couple of common questions about code in the LLVM IR form - let's just get these out of the way right now, shall we?

Target Independence

Kaleidoscope is an example of a "portable language": any program written in Kaleidoscope will work the same way on any target that it runs on. Many other languages have this property, e.g. lisp, java, haskell, javascript, python, etc (note that while these languages are portable, not all their libraries are).

One nice aspect of LLVM is that it is often capable of preserving target independence in the IR: you can take the LLVM IR for a Kaleidoscope-compiled program and run it on any target that LLVM supports, even emitting C code and compiling that on targets that LLVM doesn't support natively. You can trivially tell that the Kaleidoscope compiler generates target-independent code because it never queries for any target-specific information when generating code.

The fact that LLVM provides a compact, target-independent, representation for code gets a lot of people excited. Unfortunately, these people are usually thinking about C or a language from the C family when they are asking questions about language portability. I say "unfortunately", because there is really no way to make (fully general) C code portable, other than shipping the source code around (and of course, C source code is not actually portable in general either - ever port a really old application from 32- to 64-bits?).

The problem with C (again, in its full generality) is that it is heavily laden with target specific assumptions. As one simple example, the preprocessor often destructively removes target-independence from the code when it processes the input text:

```
#ifdef __i386__
    int X = 1;
#else
    int X = 42;
#endif
```

While it is possible to engineer more and more complex solutions to problems like this, it cannot be solved in full generality in a way that is better than shipping the actual source code.

That said, there are interesting subsets of C that can be made portable. If you are willing to fix primitive types to a fixed size (say int = 32-bits, and long = 64-bits), don't care about ABI compatibility with existing binaries, and are willing to give up some other minor features, you can have portable code. This can make sense for specialized domains such as an in-kernel language.

Safety Guarantees

Many of the languages above are also "safe" languages: it is impossible for a program written in Java to corrupt its address space and crash the process (assuming the JVM has no bugs). Safety is an interesting property that requires a combination of language design, runtime support, and often operating system support.

It is certainly possible to implement a safe language in LLVM, but LLVM IR does not itself guarantee safety. The LLVM IR allows unsafe pointer casts, use after free bugs, buffer over-runs, and a variety of other problems. Safety needs to be implemented as a layer on top of LLVM and, conveniently, several groups have investigated this. Ask on the [llvm-dev mailing list](#) if you are interested in more details.

Language-Specific Optimizations

One thing about LLVM that turns off many people is that it does not solve all the world's problems in one system. One specific complaint is that people perceive LLVM as being incapable of performing high-level language-specific optimization: LLVM "loses too much information". Here are a few observations about this:

First, you're right that LLVM does lose information. For example, as of this writing, there is no way to distinguish in the LLVM IR whether an SSA-value came from a C "int" or a C "long" on an ILP32 machine (other than debug info). Both get compiled down to an 'i32' value and the information about what it came from is lost. The more general issue here, is that the LLVM type system uses "structural equivalence" instead of "name equivalence". Another place this surprises people is if you have two types in a high-level language that have the same structure (e.g. two different structs that have a single int field): these types will compile down into a single LLVM type and it will be impossible to tell what it came from.

Second, while LLVM does lose information, LLVM is not a fixed target: we continue to enhance and improve it in many different ways. In addition to adding new features (LLVM did not always support exceptions or debug info), we also extend the IR to capture important information for optimization (e.g. whether an argument is sign or zero extended, information about pointers aliasing, etc). Many of the enhancements are user-driven: people want LLVM to include some specific feature, so they go ahead and extend it.

Third, it is *possible and easy* to add language-specific optimizations, and you have a number of choices in how to do it. As one trivial example, it is easy to add language-specific optimization passes that "know" things about code compiled for a language. In the case of the C family, there is an optimization pass that "knows" about the standard C library functions. If you call "exit(0)" in main(), it knows that it is safe to optimize that into "return 0;" because C specifies what the 'exit' function does.

In addition to simple library knowledge, it is possible to embed a variety of other language-specific information into the LLVM IR. If you have a specific need and run into a wall, please bring the topic up on the [llvm-dev list](#). At the very worst, you can always treat LLVM as if it were a "dumb code generator" and implement the high-level optimizations you desire in your front-end, on the language-specific AST.

Tips and Tricks

There is a variety of useful tips and tricks that you come to know after working on/with LLVM that aren't obvious at first glance. Instead of letting everyone rediscover them, this section talks about some of these issues.

Implementing portable offsetof/sizeof

One interesting thing that comes up, if you are trying to keep the code generated by your compiler "target independent", is that you often need to know the size of some LLVM type or the offset of some field in an LLVM structure. For example, you might need to pass the size of a type into a function that allocates memory.

Unfortunately, this can vary widely across targets: for example the width of a pointer is trivially target-specific. However, there is a [clever way to use the `getelementptr` instruction](#) that allows you to compute this in a portable way.

Garbage Collected Stack Frames

Some languages want to explicitly manage their stack frames, often so that they are garbage collected or to allow easy implementation of closures. There are often better ways to implement these features than explicit stack frames, but [LLVM does support them](#), if you want. It requires your front-end to convert the code into [Continuation Passing Style](#) and the use of tail calls (which LLVM also supports).

2.20.2 Kaleidoscope: Implementing a Language with LLVM in Objective Caml

Kaleidoscope: Tutorial Introduction and the Lexer

- [Tutorial Introduction](#)
- [The Basic Language](#)
- [The Lexer](#)

Tutorial Introduction

Welcome to the "Implementing a language with LLVM" tutorial. This tutorial runs through the implementation of a simple language, showing how fun and easy it can be. This tutorial will get you up and started as well as help to build a framework you can extend to other languages. The code in this tutorial can also be used as a playground to hack on other LLVM specific things.

The goal of this tutorial is to progressively unveil our language, describing how it is built up over time. This will let us cover a fairly broad range of language design and LLVM-specific usage issues, showing and explaining the code for it all along the way, without overwhelming you with tons of details up front.

It is useful to point out ahead of time that this tutorial is really about teaching compiler techniques and LLVM specifically, *not* about teaching modern and sane software engineering principles. In practice, this means that we'll take a number of shortcuts to simplify the exposition. For example, the code leaks memory, uses global variables all over the place, doesn't use nice design patterns like [visitors](#), etc... but it is very simple. If you dig in and use the code as a basis for future projects, fixing these deficiencies shouldn't be hard.

I've tried to put this tutorial together in a way that makes chapters easy to skip over if you are already familiar with or are uninterested in the various pieces. The structure of the tutorial is:

- *Chapter #1*: Introduction to the Kaleidoscope language, and the definition of its Lexer - This shows where we are going and the basic functionality that we want it to do. In order to make this tutorial maximally understandable and hackable, we choose to implement everything in Objective Caml instead of using lexer and parser generators. LLVM obviously works just fine with such tools, feel free to use one if you prefer.

- [Chapter #2](#): Implementing a Parser and AST - With the lexer in place, we can talk about parsing techniques and basic AST construction. This tutorial describes recursive descent parsing and operator precedence parsing. Nothing in Chapters 1 or 2 is LLVM-specific, the code doesn't even link in LLVM at this point. :)
- [Chapter #3](#): Code generation to LLVM IR - With the AST ready, we can show off how easy generation of LLVM IR really is.
- [Chapter #4](#): Adding JIT and Optimizer Support - Because a lot of people are interested in using LLVM as a JIT, we'll dive right into it and show you the 3 lines it takes to add JIT support. LLVM is also useful in many other ways, but this is one simple and "sexy" way to show off its power. :)
- [Chapter #5](#): Extending the Language: Control Flow - With the language up and running, we show how to extend it with control flow operations (if/then/else and a 'for' loop). This gives us a chance to talk about simple SSA construction and control flow.
- [Chapter #6](#): Extending the Language: User-defined Operators - This is a silly but fun chapter that talks about extending the language to let the user program define their own arbitrary unary and binary operators (with assignable precedence!). This lets us build a significant piece of the "language" as library routines.
- [Chapter #7](#): Extending the Language: Mutable Variables - This chapter talks about adding user-defined local variables along with an assignment operator. The interesting part about this is how easy and trivial it is to construct SSA form in LLVM: no, LLVM does *not* require your front-end to construct SSA form!
- [Chapter #8](#): Conclusion and other useful LLVM tidbits - This chapter wraps up the series by talking about potential ways to extend the language, but also includes a bunch of pointers to info about "special topics" like adding garbage collection support, exceptions, debugging, support for "spaghetti stacks", and a bunch of other tips and tricks.

By the end of the tutorial, we'll have written a bit less than 700 lines of non-comment, non-blank, lines of code. With this small amount of code, we'll have built up a very reasonable compiler for a non-trivial language including a hand-written lexer, parser, AST, as well as code generation support with a JIT compiler. While other systems may have interesting "hello world" tutorials, I think the breadth of this tutorial is a great testament to the strengths of LLVM and why you should consider it if you're interested in language or compiler design.

A note about this tutorial: we expect you to extend the language and play with it on your own. Take the code and go crazy hacking away at it, compilers don't need to be scary creatures - it can be a lot of fun to play with languages!

The Basic Language

This tutorial will be illustrated with a toy language that we'll call "[Kaleidoscope](#)" (derived from "meaning beautiful, form, and view"). Kaleidoscope is a procedural language that allows you to define functions, use conditionals, math, etc. Over the course of the tutorial, we'll extend Kaleidoscope to support the if/then/else construct, a for loop, user defined operators, JIT compilation with a simple command line interface, etc.

Because we want to keep things simple, the only datatype in Kaleidoscope is a 64-bit floating point type (aka 'float' in OCaml parlance). As such, all values are implicitly double precision and the language doesn't require type declarations. This gives the language a very nice and simple syntax. For example, the following simple example computes [Fibonacci numbers](#):

```
# Compute the x'th fibonacci number.
def fib(x)
  if x < 3 then
    1
  else
    fib(x-1)+fib(x-2)

# This expression will compute the 40th number.
fib(40)
```

We also allow Kaleidoscope to call into standard library functions (the LLVM JIT makes this completely trivial). This means that you can use the 'extern' keyword to define a function before you use it (this is also useful for mutually recursive functions). For example:

```
extern sin(arg);
extern cos(arg);
extern atan2(arg1 arg2);

atan2(sin(.4), cos(42))
```

A more interesting example is included in Chapter 6 where we write a little Kaleidoscope application that [displays a Mandelbrot Set](#) at various levels of magnification.

Lets dive into the implementation of this language!

The Lexer

When it comes to implementing a language, the first thing needed is the ability to process a text file and recognize what it says. The traditional way to do this is to use a "lexer" (aka 'scanner') to break the input up into "tokens". Each token returned by the lexer includes a token code and potentially some metadata (e.g. the numeric value of a number). First, we define the possibilities:

```
(* The lexer returns these 'Kwd' if it is an unknown character, otherwise one of
 * these others for known things. *)
type token =
  (* commands *)
  | Def | Extern

  (* primary *)
  | Ident of string | Number of float

  (* unknown *)
  | Kwd of char
```

Each token returned by our lexer will be one of the token variant values. An unknown character like '+' will be returned as `Token.Kwd '+'`. If the curr token is an identifier, the value will be `Token.Ident s`. If the current token is a numeric literal (like 1.0), the value will be `Token.Number 1.0`.

The actual implementation of the lexer is a collection of functions driven by a function named `Lexer.lex`. The `Lexer.lex` function is called to return the next token from standard input. We will use [Camlp4](#) to simplify the tokenization of the standard input. Its definition starts as:

```
(=====)
* Lexer
(=====*)

let rec lex = parser
  (* Skip any whitespace. *)
  | [< ' (' | '\n' | '\r' | '\t'); stream >] -> lex stream
```

`Lexer.lex` works by recursing over a `char Stream.t` to read characters one at a time from the standard input. It eats them as it recognizes them and stores them in a `Token.token` variant. The first thing that it has to do is ignore whitespace between tokens. This is accomplished with the recursive call above.

The next thing `Lexer.lex` needs to do is recognize identifiers and specific keywords like "def". Kaleidoscope does this with a pattern match and a helper function.

```

(* identifier: [a-zA-Z][a-zA-Z0-9] *)
| [< ' ('A' .. 'Z' | 'a' .. 'z' as c); stream >] ->
    let buffer = Buffer.create 1 in
    Buffer.add_char buffer c;
    lex_ident buffer stream

...

and lex_ident buffer = parser
| [< ' ('A' .. 'Z' | 'a' .. 'z' | '0' .. '9' as c); stream >] ->
    Buffer.add_char buffer c;
    lex_ident buffer stream
| [< stream=lex >] ->
    match Buffer.contents buffer with
    | "def" -> [< 'Token.Def; stream >]
    | "extern" -> [< 'Token.Extern; stream >]
    | id -> [< 'Token.Ident id; stream >]

```

Numeric values are similar:

```

(* number: [0-9.]+ *)
| [< ' ('0' .. '9' as c); stream >] ->
    let buffer = Buffer.create 1 in
    Buffer.add_char buffer c;
    lex_number buffer stream

...

and lex_number buffer = parser
| [< ' ('0' .. '9' | '.' as c); stream >] ->
    Buffer.add_char buffer c;
    lex_number buffer stream
| [< stream=lex >] ->
    [< 'Token.Number (float_of_string (Buffer.contents buffer)); stream >]

```

This is all pretty straight-forward code for processing input. When reading a numeric value from input, we use the ocaml `float_of_string` function to convert it to a numeric value that we store in `Token.Number`. Note that this isn't doing sufficient error checking: it will raise `Failure` if the string `"1.23.45.67"`. Feel free to extend it :). Next we handle comments:

```

(* Comment until end of line. *)
| [< ' ('#'); stream >] ->
    lex_comment stream

...

and lex_comment = parser
| [< ' ('\n'); stream=lex >] -> stream
| [< 'c; e=lex_comment >] -> e
| [< >] -> [< >]

```

We handle comments by skipping to the end of the line and then return the next token. Finally, if the input doesn't match one of the above cases, it is either an operator character like `'+'` or the end of the file. These are handled with this code:

```

(* Otherwise, just return the character as its ascii value. *)
| [< 'c; stream >] ->

```

(continues on next page)

(continued from previous page)

```
[< 'Token.Kwd c; lex stream >]

(* end of stream. *)
| [< >] -> [< >]
```

With this, we have the complete lexer for the basic Kaleidoscope language (the [full code listing](#) for the Lexer is available in the [next chapter](#) of the tutorial). Next we'll [build a simple parser that uses this to build an Abstract Syntax Tree](#). When we have that, we'll include a driver so that you can use the lexer and parser together.

Next: [Implementing a Parser and AST](#)

Kaleidoscope: Implementing a Parser and AST

- *Chapter 2 Introduction*
- *The Abstract Syntax Tree (AST)*
- *Parser Basics*
- *Basic Expression Parsing*
- *Binary Expression Parsing*
- *Parsing the Rest*
- *The Driver*
- *Conclusions*
- *Full Code Listing*

Chapter 2 Introduction

Welcome to Chapter 2 of the "Implementing a language with LLVM in Objective Caml" tutorial. This chapter shows you how to use the lexer, built in [Chapter 1](#), to build a full [parser](#) for our Kaleidoscope language. Once we have a parser, we'll define and build an [Abstract Syntax Tree \(AST\)](#).

The parser we will build uses a combination of [Recursive Descent Parsing](#) and [Operator-Precedence Parsing](#) to parse the Kaleidoscope language (the latter for binary expressions and the former for everything else). Before we get to parsing though, let's talk about the output of the parser: the Abstract Syntax Tree.

The Abstract Syntax Tree (AST)

The AST for a program captures its behavior in such a way that it is easy for later stages of the compiler (e.g. code generation) to interpret. We basically want one object for each construct in the language, and the AST should closely model the language. In Kaleidoscope, we have expressions, a prototype, and a function object. We'll start with expressions first:

```
(* expr - Base type for all expression nodes. *)
type expr =
  (* variant for numeric literals like "1.0". *)
  | Number of float
```

The code above shows the definition of the base ExprAST class and one subclass which we use for numeric literals. The important thing to note about this code is that the Number variant captures the numeric value of the literal as an instance variable. This allows later phases of the compiler to know what the stored numeric value is.

Right now we only create the AST, so there are no useful functions on them. It would be very easy to add a function to pretty print the code, for example. Here are the other expression AST node definitions that we'll use in the basic form of the Kaleidoscope language:

```
(* variant for referencing a variable, like "a". *)
| Variable of string

(* variant for a binary operator. *)
| Binary of char * expr * expr

(* variant for function calls. *)
| Call of string * expr array
```

This is all (intentionally) rather straight-forward: variables capture the variable name, binary operators capture their opcode (e.g. '+'), and calls capture a function name as well as a list of any argument expressions. One thing that is nice about our AST is that it captures the language features without talking about the syntax of the language. Note that there is no discussion about precedence of binary operators, lexical structure, etc.

For our basic language, these are all of the expression nodes we'll define. Because it doesn't have conditional control flow, it isn't Turing-complete; we'll fix that in a later installment. The two things we need next are a way to talk about the interface to a function, and a way to talk about functions themselves:

```
(* proto - This type represents the "prototype" for a function, which captures
 * its name, and its argument names (thus implicitly the number of arguments the
 * function takes). *)
type proto = Prototype of string * string array

(* func - This type represents a function definition itself. *)
type func = Function of proto * expr
```

In Kaleidoscope, functions are typed with just a count of their arguments. Since all values are double precision floating point, the type of each argument doesn't need to be stored anywhere. In a more aggressive and realistic language, the "expr" variants would probably have a type field.

With this scaffolding, we can now talk about parsing expressions and function bodies in Kaleidoscope.

Parser Basics

Now that we have an AST to build, we need to define the parser code to build it. The idea here is that we want to parse something like "x+y" (which is returned as three tokens by the lexer) into an AST that could be generated with calls like this:

```
let x = Variable "x" in
let y = Variable "y" in
let result = Binary ('+', x, y) in
...
```

The error handling routines make use of the builtin `Stream.Failure` and `Stream.Error``s. ``Stream.Failure` is raised when the parser is unable to find any matching token in the first position of a pattern. `Stream.Error` is raised when the first token matches, but the rest do not. The error recovery in our parser will not be the best and is not particularly user-friendly, but it will be enough for our tutorial. These exceptions make it easier to handle errors in routines that have various return types.

With these basic types and exceptions, we can implement the first piece of our grammar: numeric literals.

Basic Expression Parsing

We start with numeric literals, because they are the simplest to process. For each production in our grammar, we'll define a function which parses that production. We call this class of expressions "primary" expressions, for reasons that will become more clear [later in the tutorial](#). In order to parse an arbitrary primary expression, we need to determine what sort of expression it is. For numeric literals, we have:

```
(* primary
 * ::= identifier
 * ::= numberexpr
 * ::= parenexpr *)
parse_primary = parser
  (* numberexpr ::= number *)
  | [< 'Token.Number n >] -> Ast.Number n
```

This routine is very simple: it expects to be called when the current token is a `Token.Number` token. It takes the current number value, creates a `Ast.Number` node, advances the lexer to the next token, and finally returns.

There are some interesting aspects to this. The most important one is that this routine eats all of the tokens that correspond to the production and returns the lexer buffer with the next token (which is not part of the grammar production) ready to go. This is a fairly standard way to go for recursive descent parsers. For a better example, the parenthesis operator is defined like this:

```
(* parenexpr ::= '(' expression ')' *)
| [< 'Token.Kwd '('; e=parse_expr; 'Token.Kwd ')' ?? "expected ')'" >] -> e
```

This function illustrates a number of interesting things about the parser:

- 1) It shows how we use the `Stream.Error` exception. When called, this function expects that the current token is a '(' token, but after parsing the subexpression, it is possible that there is no ')' waiting. For example, if the user types in "(4 x" instead of "(4)", the parser should emit an error. Because errors can occur, the parser needs a way to indicate that they happened. In our parser, we use the `camp4` shortcut syntax token `?? "parse error"`, where if the token before the `??` does not match, then `Stream.Error "parse error"` will be raised.
- 2) Another interesting aspect of this function is that it uses recursion by calling `Parser.parse_primary` (we will soon see that `Parser.parse_primary` can call `Parser.parse_primary`). This is powerful because it allows us to handle recursive grammars, and keeps each production very simple. Note that parentheses do not cause construction of AST nodes themselves. While we could do it this way, the most important role of parentheses are to guide the parser and provide grouping. Once the parser constructs the AST, parentheses are not needed.

The next simple production is for handling variable references and function calls:

```
(* identifierexpr
 * ::= identifier
 * ::= identifier '(' argumentexpr ')' *)
| [< 'Token.Ident id; stream >] ->
  let rec parse_args accumulator = parser
    | [< e=parse_expr; stream >] ->
      begin parser
        | [< 'Token.Kwd ','; e=parse_args (e :: accumulator) >] -> e
        | [< >] -> e :: accumulator
      end stream
    | [< >] -> accumulator
  in
  let rec parse_ident id = parser
```

(continues on next page)

(continued from previous page)

```

(* Call. *)
| [< 'Token.Kwd '(';
    args=parse_args [];
    'Token.Kwd ')' ?? "expected ')">] ->
    Ast.Call (id, Array.of_list (List.rev args))

(* Simple variable ref. *)
| [< >] -> Ast.Variable id
in
parse_ident id stream

```

This routine follows the same style as the other routines. (It expects to be called if the current token is a `Token.Ident` token). It also has recursion and error handling. One interesting aspect of this is that it uses *look-ahead* to determine if the current identifier is a stand alone variable reference or if it is a function call expression. It handles this by checking to see if the token after the identifier is a '(' token, constructing either a `Ast.Variable` or `Ast.Call` node as appropriate.

We finish up by raising an exception if we received a token we didn't expect:

```

| [< >] -> raise (Stream.Error "unknown token when expecting an expression.")

```

Now that basic expressions are handled, we need to handle binary expressions. They are a bit more complex.

Binary Expression Parsing

Binary expressions are significantly harder to parse because they are often ambiguous. For example, when given the string "x+y*z", the parser can choose to parse it as either "(x+y)*z" or "x+(y*z)". With common definitions from mathematics, we expect the later parse, because "*" (multiplication) has higher *precedence* than "+" (addition).

There are many ways to handle this, but an elegant and efficient way is to use [Operator-Precedence Parsing](#). This parsing technique uses the precedence of binary operators to guide recursion. To start with, we need a table of precedences:

```

(* binop_precedence - This holds the precedence for each binary operator that is
 * defined *)
let binop_precedence: (char, int) Hashtbl.t = Hashtbl.create 10

(* precedence - Get the precedence of the pending binary operator token. *)
let precedence c = try Hashtbl.find binop_precedence c with Not_found -> -1

...

let main () =
  (* Install standard binary operators.
   * 1 is the lowest precedence. *)
  Hashtbl.add Parser.binop_precedence '<' 10;
  Hashtbl.add Parser.binop_precedence '+' 20;
  Hashtbl.add Parser.binop_precedence '-' 20;
  Hashtbl.add Parser.binop_precedence '*' 40;      (* highest. *)
  ...

```

For the basic form of Kaleidoscope, we will only support 4 binary operators (this can obviously be extended by you, our brave and intrepid reader). The `Parser.precedence` function returns the precedence for the current token, or -1 if the token is not a binary operator. Having a `Hashtbl.t` makes it easy to add new operators and makes it clear that the algorithm doesn't depend on the specific operators involved, but it would be easy enough to eliminate the `Hashtbl.t` and do the comparisons in the `Parser.precedence` function. (Or just use a fixed-size array).

With the helper above defined, we can now start parsing binary expressions. The basic idea of operator precedence parsing is to break down an expression with potentially ambiguous binary operators into pieces. Consider, for example, the expression "a+b+(c+d)*e*f+g". Operator precedence parsing considers this as a stream of primary expressions separated by binary operators. As such, it will first parse the leading primary expression "a", then it will see the pairs [+ , b] [+ , (c+d)] [* , e] [* , f] and [+ , g]. Note that because parentheses are primary expressions, the binary expression parser doesn't need to worry about nested subexpressions like (c+d) at all.

To start, an expression is a primary expression potentially followed by a sequence of [binop,primaryexpr] pairs:

```
(* expression
 *   ::= primary binoprhs *)
and parse_expr = parser
| [< lhs=parse_primary; stream >] -> parse_bin_rhs 0 lhs stream
```

Parser.parse_bin_rhs is the function that parses the sequence of pairs for us. It takes a precedence and a pointer to an expression for the part that has been parsed so far. Note that "x" is a perfectly valid expression: As such, "binoprhs" is allowed to be empty, in which case it returns the expression that is passed into it. In our example above, the code passes the expression for "a" into Parser.parse_bin_rhs and the current token is "+".

The precedence value passed into Parser.parse_bin_rhs indicates the *minimal operator precedence* that the function is allowed to eat. For example, if the current pair stream is [+ , x] and Parser.parse_bin_rhs is passed in a precedence of 40, it will not consume any tokens (because the precedence of '+' is only 20). With this in mind, Parser.parse_bin_rhs starts with:

```
(* binoprhs
 *   ::= ('+' primary)* *)
and parse_bin_rhs expr_prec lhs stream =
  match Stream.peek stream with
  (* If this is a binop, find its precedence. *)
  | Some (Token.Kwd c) when Hashtbl.mem binop_precedence c ->
    let token_prec = precedence c in

    (* If this is a binop that binds at least as tightly as the current binop,
     * consume it, otherwise we are done. *)
    if token_prec < expr_prec then lhs else begin
```

This code gets the precedence of the current token and checks to see if it is too low. Because we defined invalid tokens to have a precedence of -1, this check implicitly knows that the pair-stream ends when the token stream runs out of binary operators. If this check succeeds, we know that the token is a binary operator and that it will be included in this expression:

```
(* Eat the binop. *)
Stream.junk stream;

(* Parse the primary expression after the binary operator *)
let rhs = parse_primary stream in

(* Okay, we know this is a binop. *)
let rhs =
  match Stream.peek stream with
  | Some (Token.Kwd c2) ->
```

As such, this code eats (and remembers) the binary operator and then parses the primary expression that follows. This builds up the whole pair, the first of which is [+ , b] for the running example.

Now that we parsed the left-hand side of an expression and one pair of the RHS sequence, we have to decide which way the expression associates. In particular, we could have "(a+b) binop unparsed" or "a + (b binop unparsed)". To determine this, we look ahead at "binop" to determine its precedence and compare it to BinOp's precedence (which is

'+' in this case):

```
(* If BinOp binds less tightly with rhs than the operator after
 * rhs, let the pending operator take rhs as its lhs. *)
let next_prec = precedence c2 in
if token_prec < next_prec
```

If the precedence of the binop to the right of "RHS" is lower or equal to the precedence of our current operator, then we know that the parentheses associate as "(a+b) binop ...". In our example, the current operator is "+" and the next operator is "+", we know that they have the same precedence. In this case we'll create the AST node for "a+b", and then continue parsing:

```
... if body omitted ...
in

(* Merge lhs/rhs. *)
let lhs = Ast.Binary (c, lhs, rhs) in
parse_bin_rhs expr_prec lhs stream
end
```

In our example above, this will turn "a+b+" into "(a+b)" and execute the next iteration of the loop, with "+" as the current token. The code above will eat, remember, and parse "(c+d)" as the primary expression, which makes the current pair equal to [+, (c+d)]. It will then evaluate the 'if' conditional above with "*" as the binop to the right of the primary. In this case, the precedence of "*" is higher than the precedence of "+" so the if condition will be entered.

The critical question left here is "how can the if condition parse the right hand side in full"? In particular, to build the AST correctly for our example, it needs to get all of "(c+d)*e*f" as the RHS expression variable. The code to do this is surprisingly simple (code from the above two blocks duplicated for context):

```
match Stream.peek stream with
| Some (Token.Kwd c2) ->
    (* If BinOp binds less tightly with rhs than the operator after
    * rhs, let the pending operator take rhs as its lhs. *)
    if token_prec < precedence c2
    then parse_bin_rhs (token_prec + 1) rhs stream
    else rhs
| _ -> rhs
in

(* Merge lhs/rhs. *)
let lhs = Ast.Binary (c, lhs, rhs) in
parse_bin_rhs expr_prec lhs stream
end
```

At this point, we know that the binary operator to the RHS of our primary has higher precedence than the binop we are currently parsing. As such, we know that any sequence of pairs whose operators are all higher precedence than "+" should be parsed together and returned as "RHS". To do this, we recursively invoke the `Parser.parse_bin_rhs` function specifying "token_prec+1" as the minimum precedence required for it to continue. In our example above, this will cause it to return the AST node for "(c+d)*e*f" as RHS, which is then set as the RHS of the '+' expression.

Finally, on the next iteration of the while loop, the "+g" piece is parsed and added to the AST. With this little bit of code (14 non-trivial lines), we correctly handle fully general binary expression parsing in a very elegant way. This was a whirlwind tour of this code, and it is somewhat subtle. I recommend running through it with a few tough examples to see how it works.

This wraps up handling of expressions. At this point, we can point the parser at an arbitrary token stream and build an expression from it, stopping at the first token that is not part of the expression. Next up we need to handle function definitions, etc.

Parsing the Rest

The next thing missing is handling of function prototypes. In Kaleidoscope, these are used both for 'extern' function declarations as well as function body definitions. The code to do this is straight-forward and not very interesting (once you've survived expressions):

```
(* prototype
 * ::= id '(' id* ')' *)
let parse_prototype =
  let rec parse_args accumulator = parser
    | [< 'Token.Ident' id; e=parse_args (id::accumulator) >] -> e
    | [< >] -> accumulator
  in

  parser
  | [< 'Token.Ident' id;
    'Token.Kwd' '(' ?? "expected '(' in prototype";
    args=parse_args [];
    'Token.Kwd ')' ?? "expected ')' in prototype" >] ->
    (* success. *)
    Ast.Prototype (id, Array.of_list (List.rev args))

  | [< >] ->
    raise (Stream.Error "expected function name in prototype")
```

Given this, a function definition is very simple, just a prototype plus an expression to implement the body:

```
(* definition ::= 'def' prototype expression *)
let parse_definition = parser
  | [< 'Token.Def'; p=parse_prototype; e=parse_expr >] ->
    Ast.Function (p, e)
```

In addition, we support 'extern' to declare functions like 'sin' and 'cos' as well as to support forward declaration of user functions. These 'extern's are just prototypes with no body:

```
(* external ::= 'extern' prototype *)
let parse_extern = parser
  | [< 'Token.Extern'; e=parse_prototype >] -> e
```

Finally, we'll also let the user type in arbitrary top-level expressions and evaluate them on the fly. We will handle this by defining anonymous nullary (zero argument) functions for them:

```
(* toplevelexpr ::= expression *)
let parse_toplevel = parser
  | [< e=parse_expr >] ->
    (* Make an anonymous proto. *)
    Ast.Function (Ast.Prototype ("", []), e)
```

Now that we have all the pieces, let's build a little driver that will let us actually *execute* this code we've built!

The Driver

The driver for this simply invokes all of the parsing pieces with a top-level dispatch loop. There isn't much interesting here, so I'll just include the top-level loop. See [below](#) for full code in the "Top-Level Parsing" section.

```
(* top ::= definition | external | expression | ';' *)
let rec main_loop stream =
  match Stream.peek stream with
  | None -> ()

  (* ignore top-level semicolons. *)
  | Some (Token.Kwd ';') ->
    Stream.junk stream;
    main_loop stream

  | Some token ->
    begin
      try match token with
      | Token.Def ->
        ignore(Parser.parse_definition stream);
        print_endline "parsed a function definition.";
      | Token.Extern ->
        ignore(Parser.parse_extern stream);
        print_endline "parsed an extern.";
      | _ ->
        (* Evaluate a top-level expression into an anonymous function. *)
        ignore(Parser.parse_toplevel stream);
        print_endline "parsed a top-level expr";
      with Stream.Error s ->
        (* Skip token for error recovery. *)
        Stream.junk stream;
        print_endline s;
    end;
    print_string "ready> "; flush stdout;
    main_loop stream
```

The most interesting part of this is that we ignore top-level semicolons. Why is this, you ask? The basic reason is that if you type "4 + 5" at the command line, the parser doesn't know whether that is the end of what you will type or not. For example, on the next line you could type "def foo..." in which case 4+5 is the end of a top-level expression. Alternatively you could type "* 6", which would continue the expression. Having top-level semicolons allows you to type "4+5;", and the parser will know you are done.

Conclusions

With just under 300 lines of commented code (240 lines of non-comment, non-blank code), we fully defined our minimal language, including a lexer, parser, and AST builder. With this done, the executable will validate Kaleidoscope code and tell us if it is grammatically invalid. For example, here is a sample interaction:

```
$ ./toy.byte
ready> def foo(x y) x+foo(y, 4.0);
Parsed a function definition.
ready> def foo(x y) x+y y;
Parsed a function definition.
Parsed a top-level expr
ready> def foo(x y) x+y );
```

(continues on next page)

(continued from previous page)

```
Parsed a function definition.
Error: unknown token when expecting an expression
ready> extern sin(a);
ready> Parsed an extern
ready> ^D
$
```

There is a lot of room for extension here. You can define new AST nodes, extend the language in many ways, etc. In the [next installment](#), we will describe how to generate LLVM Intermediate Representation (IR) from the AST.

Full Code Listing

Here is the complete code listing for this and the previous chapter. Note that it is fully self-contained: you don't need LLVM or any external libraries at all for this. (Besides the ocaml standard libraries, of course.) To build this, just compile with:

```
# Compile
ocamlbuild toy.byte
# Run
./toy.byte
```

Here is the code:

- *Full Code Listing*

Chapter 3 Introduction

Welcome to Chapter 3 of the "Implementing a language with LLVM" tutorial. This chapter shows you how to transform the [Abstract Syntax Tree](#), built in Chapter 2, into LLVM IR. This will teach you a little bit about how LLVM does things, as well as demonstrate how easy it is to use. It's much more work to build a lexer and parser than it is to generate LLVM IR code. :)

Please note: the code in this chapter and later require LLVM 2.3 or LLVM SVN to work. LLVM 2.2 and before will not work with it.

Code Generation Setup

In order to generate LLVM IR, we want some simple setup to get started. First we define virtual code generation (codegen) methods in each AST class:

```
let rec codegen_expr = function
| Ast.Number n -> ...
| Ast.Variable name -> ...
```

The `Codgen.codegen_expr` function says to emit IR for that AST node along with all the things it depends on, and they all return an LLVM Value object. "Value" is the class used to represent a "Static Single Assignment (SSA) register" or "SSA value" in LLVM. The most distinct aspect of SSA values is that their value is computed as the related instruction executes, and it does not get a new value until (and if) the instruction re-executes. In other words, there is no way to "change" an SSA value. For more information, please read up on [Static Single Assignment](#) - the concepts are really quite natural once you grok them.

The second thing we want is an "Error" exception like we used for the parser, which will be used to report errors found during code generation (for example, use of an undeclared parameter):

```
exception Error of string

let context = global_context ()
let the_module = create_module context "my cool jit"
let builder = builder context
let named_values:(string, llvalue) Hashtbl.t = Hashtbl.create 10
let double_type = double_type context
```

The static variables will be used during code generation. `Codgen.the_module` is the LLVM construct that contains all of the functions and global variables in a chunk of code. In many ways, it is the top-level structure that the LLVM IR uses to contain code.

The `Codgen.builder` object is a helper object that makes it easy to generate LLVM instructions. Instances of the [IRBuilder](#) class keep track of the current place to insert instructions and has methods to create new instructions.

The `Codgen.named_values` map keeps track of which values are defined in the current scope and what their LLVM representation is. (In other words, it is a symbol table for the code). In this form of Kaleidoscope, the only things that can be referenced are function parameters. As such, function parameters will be in this map when generating code for their function body.

With these basics in place, we can start talking about how to generate code for each expression. Note that this assumes that the `Codgen.builder` has been set up to generate code *into* something. For now, we'll assume that this has already been done, and we'll just use it to emit code.

Expression Code Generation

Generating LLVM code for expression nodes is very straightforward: less than 30 lines of commented code for all four of our expression nodes. First we'll do numeric literals:

```
| Ast.Number n -> const_float double_type n
```

In the LLVM IR, numeric constants are represented with the `ConstantFP` class, which holds the numeric value in an `APFloat` internally (`APFloat` has the capability of holding floating point constants of Arbitrary Precision). This code basically just creates and returns a `ConstantFP`. Note that in the LLVM IR that constants are all uniqued together and shared. For this reason, the API uses "the `foo::get(..)`" idiom instead of "new `foo(..)`" or "`foo::Create(..)`".

```
| Ast.Variable name ->
  (try Hashtbl.find named_values name with
   | Not_found -> raise (Error "unknown variable name"))
```

References to variables are also quite simple using LLVM. In the simple version of Kaleidoscope, we assume that the variable has already been emitted somewhere and its value is available. In practice, the only values that can be in the `Codegen.named_values` map are function arguments. This code simply checks to see that the specified name is in the map (if not, an unknown variable is being referenced) and returns the value for it. In future chapters, we'll add support for [loop induction variables](#) in the symbol table, and for [local variables](#).

```
| Ast.Binary (op, lhs, rhs) ->
  let lhs_val = codegen_expr lhs in
  let rhs_val = codegen_expr rhs in
  begin
    match op with
    | '+' -> build_fadd lhs_val rhs_val "addtmp" builder
    | '-' -> build_fsub lhs_val rhs_val "subtmp" builder
    | '*' -> build_fmull lhs_val rhs_val "multtmp" builder
    | '<' ->
      (* Convert bool 0/1 to double 0.0 or 1.0 *)
      let i = build_fcmp Fcmp.Ult lhs_val rhs_val "cmptmp" builder in
      build_uitofp i double_type "booltmp" builder
    | _ -> raise (Error "invalid binary operator")
  end
```

Binary operators start to get more interesting. The basic idea here is that we recursively emit code for the left-hand side of the expression, then the right-hand side, then we compute the result of the binary expression. In this code, we do a simple switch on the opcode to create the right LLVM instruction.

In the example above, the LLVM builder class is starting to show its value. `IRBuilder` knows where to insert the newly created instruction, all you have to do is specify what instruction to create (e.g. with `Llvm.create_add`), which operands to use (`lhs` and `rhs` here) and optionally provide a name for the generated instruction.

One nice thing about LLVM is that the name is just a hint. For instance, if the code above emits multiple "addtmp" variables, LLVM will automatically provide each one with an increasing, unique numeric suffix. Local value names for instructions are purely optional, but it makes it much easier to read the IR dumps.

[LLVM instructions](#) are constrained by strict rules: for example, the Left and Right operators of an [add instruction](#) must have the same type, and the result type of the add must match the operand types. Because all values in Kaleidoscope are doubles, this makes for very simple code for add, sub and mul.

On the other hand, LLVM specifies that the [fcmp instruction](#) always returns an 'i1' value (a one bit integer). The problem with this is that Kaleidoscope wants the value to be a 0.0 or 1.0 value. In order to get these semantics, we combine the `fcmp` instruction with a [uitofp instruction](#). This instruction converts its input integer into a floating point value by treating the input as an unsigned value. In contrast, if we used the [sitofp instruction](#), the Kaleidoscope '<' operator would return 0.0 and -1.0, depending on the input value.

```
| Ast.Call (callee, args) ->
  (* Look up the name in the module table. *)
  let callee =
    match lookup_function callee the_module with
    | Some callee -> callee
    | None -> raise (Error "unknown function referenced")
  in
  let params = params callee in

  (* If argument mismatch error. *)
  if Array.length params == Array.length args then () else
    raise (Error "incorrect # arguments passed");
  let args = Array.map codegen_expr args in
  build_call callee args "calltmp" builder
```

Code generation for function calls is quite straightforward with LLVM. The code above initially does a function name lookup in the LLVM Module's symbol table. Recall that the LLVM Module is the container that holds all of the functions we are JIT'ing. By giving each function the same name as what the user specifies, we can use the LLVM symbol table to resolve function names for us.

Once we have the function to call, we recursively codegen each argument that is to be passed in, and create an LLVM [call instruction](#). Note that LLVM uses the native C calling conventions by default, allowing these calls to also call into standard library functions like "sin" and "cos", with no additional effort.

This wraps up our handling of the four basic expressions that we have so far in Kaleidoscope. Feel free to go in and add some more. For example, by browsing the [LLVM language reference](#) you'll find several other interesting instructions that are really easy to plug into our basic framework.

Function Code Generation

Code generation for prototypes and functions must handle a number of details, which make their code less beautiful than expression code generation, but allows us to illustrate some important points. First, let's talk about code generation for prototypes: they are used both for function bodies and external function declarations. The code starts with:

```
let codegen_proto = function
| Ast.Prototype (name, args) ->
  (* Make the function type: double(double,double) etc. *)
  let doubles = Array.make (Array.length args) double_type in
  let ft = function_type double_type doubles in
  let f =
    match lookup_function name the_module with
```

This code packs a lot of power into a few lines. Note first that this function returns a "Function*" instead of a "Value*" (although at the moment they both are modeled by `llvalue` in `ocaml`). Because a "prototype" really talks about the external interface for a function (not the value computed by an expression), it makes sense for it to return the LLVM Function it corresponds to when codegen'd.

The call to `Llvm.function_type` creates the `Llvm.llvalue` that should be used for a given Prototype. Since all function arguments in Kaleidoscope are of type `double`, the first line creates a vector of "N" LLVM double types. It then uses the `Llvm.function_type` method to create a function type that takes "N" doubles as arguments, returns one double as a result, and that is not `vararg` (that uses the function `Llvm.var_arg_function_type`). Note that Types in LLVM are unique just like Constants are, so you don't "new" a type, you "get" it.

The final line above checks if the function has already been defined in `Codegen.the_module`. If not, we will create it.

```
| None -> declare_function name ft the_module
```

This indicates the type and name to use, as well as which module to insert into. By default we assume a function has `Llvm.Linkage.ExternalLinkage`. "external linkage" means that the function may be defined outside the current module and/or that it is callable by functions outside the module. The "name" passed in is the name the user specified: this name is registered in `Codegen.the_module`'s symbol table, which is used by the function call code above.

In Kaleidoscope, I choose to allow redefinitions of functions in two cases: first, we want to allow 'extern'ing a function more than once, as long as the prototypes for the externs match (since all arguments have the same type, we just have to check that the number of arguments match). Second, we want to allow 'extern'ing a function and then defining a body for it. This is useful when defining mutually recursive functions.

```
(* If 'f' conflicted, there was already something named 'name'. If it
 * has a body, don't allow redefinition or reextern. *)
| Some f ->
    (* If 'f' already has a body, reject this. *)
    if Array.length (basic_blocks f) == 0 then () else
        raise (Error "redefinition of function");

    (* If 'f' took a different number of arguments, reject. *)
    if Array.length (params f) == Array.length args then () else
        raise (Error "redefinition of function with different # args");
    f
in
```

In order to verify the logic above, we first check to see if the pre-existing function is "empty". In this case, empty means that it has no basic blocks in it, which means it has no body. If it has no body, it is a forward declaration. Since we don't allow anything after a full definition of the function, the code rejects this case. If the previous reference to a function was an 'extern', we simply verify that the number of arguments for that definition and this one match up. If not, we emit an error.

```
(* Set names for all arguments. *)
Array.iteri (fun i a ->
    let n = args.(i) in
    set_value_name n a;
    Hashtbl.add named_values n a;
) (params f);
f
```

The last bit of code for prototypes loops over all of the arguments in the function, setting the name of the LLVM Argument objects to match, and registering the arguments in the `Codegen.named_values` map for future use by the `Ast.Variable` variant. Once this is set up, it returns the Function object to the caller. Note that we don't check for conflicting argument names here (e.g. "extern foo(a b a)"). Doing so would be very straight-forward with the mechanics we have already used above.

```
let codegen_func = function
| Ast.Function (proto, body) ->
    Hashtbl.clear named_values;
    let the_function = codegen_proto proto in
```

Code generation for function definitions starts out simply enough: we just codegen the prototype (Proto) and verify that it is ok. We then clear out the `Codegen.named_values` map to make sure that there isn't anything in it from the last function we compiled. Code generation of the prototype ensures that there is an LLVM Function object that is ready to go for us.

```
(* Create a new basic block to start insertion into. *)
let bb = append_block context "entry" the_function in
position_at_end bb builder;

try
  let ret_val = codegen_expr body in
```

Now we get to the point where the `Codegen.builder` is set up. The first line creates a new `basic block` (named "entry"), which is inserted into `the_function`. The second line then tells the builder that new instructions should be inserted into the end of the new basic block. Basic blocks in LLVM are an important part of functions that define the `Control Flow Graph`. Since we don't have any control flow, our functions will only contain one block at this point. We'll fix this in [Chapter 5](#) :).

```
let ret_val = codegen_expr body in

(* Finish off the function. *)
let _ = build_ret ret_val builder in

(* Validate the generated code, checking for consistency. *)
Llvm_analysis.assert_valid_function the_function;

the_function
```

Once the insertion point is set up, we call the `Codegen.codegen_func` method for the root expression of the function. If no error happens, this emits code to compute the expression into the entry block and returns the value that was computed. Assuming no error, we then create an LLVM `ret instruction`, which completes the function. Once the function is built, we call `Llvm_analysis.assert_valid_function`, which is provided by LLVM. This function does a variety of consistency checks on the generated code, to determine if our compiler is doing everything right. Using this is important: it can catch a lot of bugs. Once the function is finished and validated, we return it.

```
with e ->
  delete_function the_function;
  raise e
```

The only piece left here is handling of the error case. For simplicity, we handle this by merely deleting the function we produced with the `Llvm.delete_function` method. This allows the user to redefine a function that they incorrectly typed in before: if we didn't delete it, it would live in the symbol table, with a body, preventing future redefinition.

This code does have a bug, though. Since the `Codegen.codegen_proto` can return a previously defined forward declaration, our code can actually delete a forward declaration. There are a number of ways to fix this bug, see what you can come up with! Here is a testcase:

```
extern foo(a b);      # ok, defines foo.
def foo(a b) c;       # error, 'c' is invalid.
def bar() foo(1, 2);  # error, unknown function "foo"
```

Driver Changes and Closing Thoughts

For now, code generation to LLVM doesn't really get us much, except that we can look at the pretty IR calls. The sample code inserts calls to Codegen into the "Toplevel.main_loop", and then dumps out the LLVM IR. This gives a nice way to look at the LLVM IR for simple functions. For example:

```
ready> 4+5;
Read top-level expression:
define double @"()" {
entry:
    %addtmp = fadd double 4.000000e+00, 5.000000e+00
    ret double %addtmp
}
```

Note how the parser turns the top-level expression into anonymous functions for us. This will be handy when we add [JIT support](#) in the next chapter. Also note that the code is very literally transcribed, no optimizations are being performed. We will [add optimizations](#) explicitly in the next chapter.

```
ready> def foo(a b) a*a + 2*a*b + b*b;
Read function definition:
define double @foo(double %a, double %b) {
entry:
    %multmp = fmul double %a, %a
    %multmp1 = fmul double 2.000000e+00, %a
    %multmp2 = fmul double %multmp1, %b
    %addtmp = fadd double %multmp, %multmp2
    %multmp3 = fmul double %b, %b
    %addtmp4 = fadd double %addtmp, %multmp3
    ret double %addtmp4
}
```

This shows some simple arithmetic. Notice the striking similarity to the LLVM builder calls that we use to create the instructions.

```
ready> def bar(a) foo(a, 4.0) + bar(31337);
Read function definition:
define double @bar(double %a) {
entry:
    %calltmp = call double @foo(double %a, double 4.000000e+00)
    %calltmp1 = call double @bar(double 3.133700e+04)
    %addtmp = fadd double %calltmp, %calltmp1
    ret double %addtmp
}
```

This shows some function calls. Note that this function will take a long time to execute if you call it. In the future we'll add conditional control flow to actually make recursion useful :).

```
ready> extern cos(x);
Read extern:
declare double @cos(double)

ready> cos(1.234);
Read top-level expression:
define double @"()" {
entry:
    %calltmp = call double @cos(double 1.234000e+00)
```

(continues on next page)

(continued from previous page)

```
    ret double %calltmp
}
```

This shows an extern for the libm "cos" function, and a call to it.

```
ready> ^D
; ModuleID = 'my cool jit'

define double @"()" {
entry:
    %addtmp = fadd double 4.000000e+00, 5.000000e+00
    ret double %addtmp
}

define double @foo(double %a, double %b) {
entry:
    %multmp = fmul double %a, %a
    %multmp1 = fmul double 2.000000e+00, %a
    %multmp2 = fmul double %multmp1, %b
    %addtmp = fadd double %multmp, %multmp2
    %multmp3 = fmul double %b, %b
    %addtmp4 = fadd double %addtmp, %multmp3
    ret double %addtmp4
}

define double @bar(double %a) {
entry:
    %calltmp = call double @foo(double %a, double 4.000000e+00)
    %calltmp1 = call double @bar(double 3.133700e+04)
    %addtmp = fadd double %calltmp, %calltmp1
    ret double %addtmp
}

declare double @cos(double)

define double @"()" {
entry:
    %calltmp = call double @cos(double 1.234000e+00)
    ret double %calltmp
}
```

When you quit the current demo, it dumps out the IR for the entire module generated. Here you can see the big picture with all the functions referencing each other.

This wraps up the third chapter of the Kaleidoscope tutorial. Up next, we'll describe how to [add JIT codegen and optimizer support](#) to this so we can actually start running code!

Full Code Listing

Here is the complete code listing for our running example, enhanced with the LLVM code generator. Because this uses the LLVM libraries, we need to link them in. To do this, we use the `llvm-config` tool to inform our makefile/command line about which options to use:

```
# Compile
ocamlbuild toy.byte
# Run
./toy.byte
```

Here is the code:

_tags:

```
<{lexer,parser}.ml>: use_camlp4, pp(camlp4of)
<*. {byte,native}>: g++, use_llvm, use_llvm_analysis
```

myocamlbuild.ml:

```
open Ocamlbuild_plugin;;

ocaml_lib ~extern:true "llvm";;
ocaml_lib ~extern:true "llvm_analysis";;

flag ["link"; "ocaml"; "g++"] (S[A"-cc"; A"g++"]);;
```

token.ml:

```
(=====
 * Lexer Tokens
 *=====)

(* The lexer returns these 'Kwd' if it is an unknown character, otherwise one of
 * these others for known things. *)
type token =

- *LLVM Optimization Passes*
- *Adding a JIT Compiler*
- *Full Code Listing*

Chapter 4 Introduction

Welcome to Chapter 4 of the "Implementing a language with LLVM" tutorial. Chapters 1-3 described the implementation of a simple language and added support for generating LLVM IR. This chapter describes two new techniques: adding optimizer support to your language, and adding JIT compiler support. These additions will demonstrate how to get nice, efficient code for the Kaleidoscope language.

Trivial Constant Folding

Note: the default `IRBuilder` now always includes the constant folding optimisations below.

Our demonstration for Chapter 3 is elegant and easy to extend. Unfortunately, it does not produce wonderful code. For example, when compiling simple code, we don't get obvious optimizations:

```
ready> def test(x) 1+2+x;
Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double 1.000000e+00, 2.000000e+00
    %addtmp1 = fadd double %addtmp, %x
    ret double %addtmp1
}
```

This code is a very, very literal transcription of the AST built by parsing the input. As such, this transcription lacks optimizations like constant folding (we'd like to get "add x, 3.0" in the example above) as well as other more important optimizations. Constant folding, in particular, is a very common and very important optimization: so much so that many language implementors implement constant folding support in their AST representation.

With LLVM, you don't need this support in the AST. Since all calls to build LLVM IR go through the LLVM builder, it would be nice if the builder itself checked to see if there was a constant folding opportunity when you call it. If so, it could just do the constant fold and return the constant instead of creating an instruction. This is exactly what the `LLVMFoldingBuilder` class does.

All we did was switch from `LLVMBuilder` to `LLVMFoldingBuilder`. Though we change no other code, we now have all of our instructions implicitly constant folded without us having to do anything about it. For example, the input above now compiles to:

```
ready> def test(x) 1+2+x;
Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double 3.000000e+00, %x
    ret double %addtmp
}
```

Well, that was easy :). In practice, we recommend always using `LLVMFoldingBuilder` when generating code like this. It has no "syntactic overhead" for its use (you don't have to uglify your compiler with constant checks everywhere) and it can dramatically reduce the amount of LLVM IR that is generated in some cases (particular for languages with a macro preprocessor or that use a lot of constants).

On the other hand, the `LLVMFoldingBuilder` is limited by the fact that it does all of its analysis inline with the code as it is built. If you take a slightly more complex example:

```
ready> def test(x) (1+2+x) * (x+(1+2));
ready> Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double 3.000000e+00, %x
    %addtmp1 = fadd double %x, 3.000000e+00
    %multtmp = fmul double %addtmp, %addtmp1
    ret double %multtmp
}
```

In this case, the LHS and RHS of the multiplication are the same value. We'd really like to see this generate "tmp = x+3; result = tmp*tmp;" instead of computing "x*3" twice.

Unfortunately, no amount of local analysis will be able to detect and correct this. This requires two transformations: reassociation of expressions (to make the add's lexically identical) and Common Subexpression Elimination (CSE) to delete the redundant add instruction. Fortunately, LLVM provides a broad range of optimizations that you can use, in the form of "passes".

LLVM Optimization Passes

LLVM provides many optimization passes, which do many different sorts of things and have different tradeoffs. Unlike other systems, LLVM doesn't hold to the mistaken notion that one set of optimizations is right for all languages and for all situations. LLVM allows a compiler implementor to make complete decisions about what optimizations to use, in which order, and in what situation.

As a concrete example, LLVM supports both "whole module" passes, which look across as large of body of code as they can (often a whole file, but if run at link time, this can be a substantial portion of the whole program). It also supports and includes "per-function" passes which just operate on a single function at a time, without looking at other functions. For more information on passes and how they are run, see the [How to Write a Pass](#) document and the [List of LLVM Passes](#).

For Kaleidoscope, we are currently generating functions on the fly, one at a time, as the user types them in. We aren't shooting for the ultimate optimization experience in this setting, but we also want to catch the easy and quick stuff where possible. As such, we will choose to run a few per-function optimizations as the user types the function in. If we wanted to make a "static Kaleidoscope compiler", we would use exactly the code we have now, except that we would defer running the optimizer until the entire file has been parsed.

In order to get per-function optimizations going, we need to set up a `Llvm.PassManager` to hold and organize the LLVM optimizations that we want to run. Once we have that, we can add a set of optimizations to run. The code looks like this:

```
(* Create the JIT. *)
let the_execution_engine = ExecutionEngine.create Codegen.the_module in
let the_fpm = PassManager.create_function Codegen.the_module in

(* Set up the optimizer pipeline. Start with registering info about how the
 * target lays out data structures. *)
DataLayout.add (ExecutionEngine.target_data the_execution_engine) the_fpm;

(* Do simple "peephole" optimizations and bit-twiddling optzn. *)
add_instruction_combining the_fpm;

(* reassociate expressions. *)
add_reassociation the_fpm;

(* Eliminate Common SubExpressions. *)
add_gvn the_fpm;

(* Simplify the control flow graph (deleting unreachable blocks, etc). *)
add_cfg_simplification the_fpm;

ignore (PassManager.initialize the_fpm);

(* Run the main "interpreter loop" now. *)
Toplevel.main_loop the_fpm the_execution_engine stream;
```

The meat of the matter here, is the definition of "the_fpm". It requires a pointer to the the_module to construct itself. Once it is set up, we use a series of "add" calls to add a bunch of LLVM passes. The first pass is basically boilerplate, it adds a pass so that later optimizations know how the data structures in the program are laid out. The "the_execution_engine" variable is related to the JIT, which we will get to in the next section.

In this case, we choose to add 4 optimization passes. The passes we chose here are a pretty standard set of "cleanup" optimizations that are useful for a wide variety of code. I won't delve into what they do but, believe me, they are a good starting place :).

Once the `Llvm.PassManager` is set up, we need to make use of it. We do this by running it after our newly created function is constructed (in `Codegen.codegen_func`), but before it is returned to the client:

```
let codegen_func the_fpm = function
  ...
  try
    let ret_val = codegen_expr body in

    (* Finish off the function. *)
    let _ = build_ret ret_val builder in

    (* Validate the generated code, checking for consistency. *)
    Llvm_analysis.assert_valid_function the_function;

    (* Optimize the function. *)
    let _ = PassManager.run_function the_function the_fpm in

    the_function
```

As you can see, this is pretty straightforward. The `the_fpm` optimizes and updates the LLVM `Function*` in place, improving (hopefully) its body. With this in place, we can try our test above again:

```
ready> def test(x) (1+2+x)*(x+(1+2));
ready> Read function definition:
define double @test(double %x) {
entry:
    %addtmp = fadd double %x, 3.000000e+00
    %multmp = fmul double %addtmp, %addtmp
    ret double %multmp
}
```

As expected, we now get our nicely optimized code, saving a floating point add instruction from every execution of this function.

LLVM provides a wide variety of optimizations that can be used in certain circumstances. Some [documentation about the various passes](#) is available, but it isn't very complete. Another good source of ideas can come from looking at the passes that Clang runs to get started. The "opt" tool allows you to experiment with passes from the command line, so you can see if they do anything.

Now that we have reasonable code coming out of our front-end, lets talk about executing it!

Adding a JIT Compiler

Code that is available in LLVM IR can have a wide variety of tools applied to it. For example, you can run optimizations on it (as we did above), you can dump it out in textual or binary forms, you can compile the code to an assembly file (.s) for some target, or you can JIT compile it. The nice thing about the LLVM IR representation is that it is the "common currency" between many different parts of the compiler.

In this section, we'll add JIT compiler support to our interpreter. The basic idea that we want for Kaleidoscope is to have the user enter function bodies as they do now, but immediately evaluate the top-level expressions they type in. For example, if they type in "1 + 2;", we should evaluate and print out 3. If they define a function, they should be able to call it from the command line.

In order to do this, we first declare and initialize the JIT. This is done by adding a global variable and a call in `main`:

```
...
let main () =
  ...
  (* Create the JIT. *)
  let the_execution_engine = ExecutionEngine.create Codegen.the_module in
  ...
```

This creates an abstract "Execution Engine" which can be either a JIT compiler or the LLVM interpreter. LLVM will automatically pick a JIT compiler for you if one is available for your platform, otherwise it will fall back to the interpreter.

Once the `Llvm_executionengine.ExecutionEngine.t` is created, the JIT is ready to be used. There are a variety of APIs that are useful, but the simplest one is the `"Llvm_executionengine.ExecutionEngine.run_function"` function. This method JIT compiles the specified LLVM Function and returns a function pointer to the generated machine code. In our case, this means that we can change the code that parses a top-level expression to look like this:

```
(* Evaluate a top-level expression into an anonymous function. *)
let e = Parser.parse_toplevel stream in
print_endline "parsed a top-level expr";
let the_function = Codegen.codegen_func the_fpm e in
dump_value the_function;

(* JIT the function, returning a function pointer. *)
let result = ExecutionEngine.run_function the_function [||]
  the_execution_engine in

print_string "Evaluated to ";
print_float (GenericValue.as_float Codegen.double_type result);
print_newline ();
```

Recall that we compile top-level expressions into a self-contained LLVM function that takes no arguments and returns the computed double. Because the LLVM JIT compiler matches the native platform ABI, this means that you can just cast the result pointer to a function pointer of that type and call it directly. This means, there is no difference between JIT compiled code and native machine code that is statically linked into your application.

With just these two changes, lets see how Kaleidoscope works now!

```
ready> 4+5;
define double @"()" {
entry:
    ret double 9.000000e+00
}

Evaluated to 9.000000
```

Well this looks like it is basically working. The dump of the function shows the "no argument function that always returns double" that we synthesize for each top level expression that is typed in. This demonstrates very basic functionality, but can we do more?

```
ready> def testfunc(x y) x + y*2;
Read function definition:
define double @testfunc(double %x, double %y) {
entry:
    %multmp = fmul double %y, 2.000000e+00
    %addtmp = fadd double %multmp, %x
    ret double %addtmp
```

(continues on next page)

(continued from previous page)

```

}

ready> testfunc(4, 10);
define double @"@"() {
entry:
    %calltmp = call double @testfunc(double 4.000000e+00, double 1.000000e+01)
    ret double %calltmp
}

Evaluated to 24.000000

```

This illustrates that we can now call user code, but there is something a bit subtle going on here. Note that we only invoke the JIT on the anonymous functions that *call* *testfunc*, but we never invoked it on *testfunc* itself. What actually happened here is that the JIT scanned for all non-JIT'd functions transitively called from the anonymous function and compiled all of them before returning from *run_function*.

The JIT provides a number of other more advanced interfaces for things like freeing allocated machine code, rejit'ing functions to update them, etc. However, even with this simple code, we get some surprisingly powerful capabilities - check this out (I removed the dump of the anonymous functions, you should get the idea by now :) :

```

ready> extern sin(x);
Read extern:
declare double @sin(double)

ready> extern cos(x);
Read extern:
declare double @cos(double)

ready> sin(1.0);
Evaluated to 0.841471

ready> def foo(x) sin(x)*sin(x) + cos(x)*cos(x);
Read function definition:
define double @foo(double %x) {
entry:
    %calltmp = call double @sin(double %x)
    %multmp = fmul double %calltmp, %calltmp
    %calltmp2 = call double @cos(double %x)
    %multmp4 = fmul double %calltmp2, %calltmp2
    %addtmp = fadd double %multmp, %multmp4
    ret double %addtmp
}

ready> foo(4.0);
Evaluated to 1.000000

```

Whoa, how does the JIT know about *sin* and *cos*? The answer is surprisingly simple: in this example, the JIT started execution of a function and got to a function call. It realized that the function was not yet JIT compiled and invoked the standard set of routines to resolve the function. In this case, there is no body defined for the function, so the JIT ended up calling "*dlsym*(\"sin\")" on the Kaleidoscope process itself. Since "*sin*" is defined within the JIT's address space, it simply patches up calls in the module to call the *libm* version of *sin* directly.

The LLVM JIT provides a number of interfaces (look in the *llvm_executionengine.mli* file) for controlling how unknown functions get resolved. It allows you to establish explicit mappings between IR objects and addresses (useful for LLVM global variables that you want to map to static tables, for example), allows you to dynamically decide on the fly based on the function name, and even allows you to have the JIT compile functions lazily the first time they're called.

One interesting application of this is that we can now extend the language by writing arbitrary C code to implement operations. For example, if we add:

```
/* putchar - putchar that takes a double and returns 0. */
extern "C"
double putchar(double X) {
    putchar((char)X);
    return 0;
}
```

Now we can produce simple output to the console by using things like: "extern putchar(x); putchar(120);", which prints a lowercase 'x' on the console (120 is the ASCII code for 'x'). Similar code could be used to implement file I/O, console input, and many other capabilities in Kaleidoscope.

This completes the JIT and optimizer chapter of the Kaleidoscope tutorial. At this point, we can compile a non-Turing-complete programming language, optimize and JIT compile it in a user-driven way. Next up we'll look into [extending the language with control flow constructs](#), tackling some interesting LLVM IR issues along the way.

Full Code Listing

Here is the complete code listing for our running example, enhanced with the LLVM JIT and optimizer. To build this example, use:

```
# Compile
ocamlbuild toy.byte
# Run
./toy.byte
```

Here is the code:

Chapter 5 Introduction

Welcome to Chapter 5 of the "[Implementing a language with LLVM](#)" tutorial. Parts 1-4 described the implementation of the simple Kaleidoscope language and included support for generating LLVM IR, followed by optimizations and a JIT compiler. Unfortunately, as presented, Kaleidoscope is mostly useless: it has no control flow other than call and return. This means that you can't have conditional branches in the code, significantly limiting its power. In this episode of "build that compiler", we'll extend Kaleidoscope to have an if/then/else expression plus a simple 'for' loop.

If/Then/Else

Extending Kaleidoscope to support if/then/else is quite straightforward. It basically requires adding lexer support for this "new" concept to the lexer, parser, AST, and LLVM code emitter. This example is nice, because it shows how easy it is to "grow" a language over time, incrementally extending it as new ideas are discovered.

Before we get going on "how" we add this extension, let's talk about "what" we want. The basic idea is that we want to be able to write this sort of thing:

```
def fib(x)
  if x < 3 then
    1
  else
    fib(x-1)+fib(x-2);
```

In Kaleidoscope, every construct is an expression: there are no statements. As such, the if/then/else expression needs to return a value like any other. Since we're using a mostly functional form, we'll have it evaluate its conditional, then return the 'then' or 'else' value based on how the condition was resolved. This is very similar to the C "?:" expression.

The semantics of the if/then/else expression is that it evaluates the condition to a boolean equality value: 0.0 is considered to be false and everything else is considered to be true. If the condition is true, the first subexpression is evaluated and returned, if the condition is false, the second subexpression is evaluated and returned. Since Kaleidoscope allows side-effects, this behavior is important to nail down.

Now that we know what we "want", let's break this down into its constituent pieces.

Lexer Extensions for If/Then/Else

The lexer extensions are straightforward. First we add new variants for the relevant tokens:

```
(* control *)
| If | Then | Else | For | In
```

Once we have that, we recognize the new keywords in the lexer. This is pretty simple stuff:

```
...
match Buffer.contents buffer with
| "def" -> [< 'Token.Def; stream >]
| "extern" -> [< 'Token.Extern; stream >]
| "if" -> [< 'Token.If; stream >]
| "then" -> [< 'Token.Then; stream >]
| "else" -> [< 'Token.Else; stream >]
| "for" -> [< 'Token.For; stream >]
| "in" -> [< 'Token.In; stream >]
| id -> [< 'Token.Ident id; stream >]
```

AST Extensions for If/Then/Else

To represent the new expression we add a new AST variant for it:

```
type expr =
...
(* variant for if/then/else. *)
| If of expr * expr * expr
```

The AST variant just has pointers to the various subexpressions.

Parser Extensions for If/Then/Else

Now that we have the relevant tokens coming from the lexer and we have the AST node to build, our parsing logic is relatively straightforward. Next we add a new case for parsing a if-expression as a primary expression:

```
let rec parse_primary = parser
...
(* ifexpr ::= 'if' expr 'then' expr 'else' expr *)
| [< 'Token.If; c=parse_expr;
   'Token.Then ?? "expected 'then'"; t=parse_expr;
   'Token.Else ?? "expected 'else'"; e=parse_expr >] ->
   Ast.If (c, t, e)
```

LLVM IR for If/Then/Else

Now that we have it parsing and building the AST, the final piece is adding LLVM code generation support. This is the most interesting part of the if/then/else example, because this is where it starts to introduce new concepts. All of the code above has been thoroughly described in previous chapters.

To motivate the code we want to produce, let's take a look at a simple example. Consider:

```
extern foo();
extern bar();
def baz(x) if x then foo() else bar();
```

If you disable optimizations, the code you'll (soon) get from Kaleidoscope looks like this:

```
declare double @foo()

declare double @bar()

define double @baz(double %x) {
entry:
    %ifcond = fcmp one double %x, 0.000000e+00
    br i1 %ifcond, label %then, label %else

then:    ; preds = %entry
    %calltmp = call double @foo()
    br label %ifcont

else:    ; preds = %entry
    %calltmp1 = call double @bar()
    br label %ifcont

ifcont:  ; preds = %else, %then
    %iftmp = phi double [ %calltmp, %then ], [ %calltmp1, %else ]
    ret double %iftmp
}
```

To visualize the control flow graph, you can use a nifty feature of the LLVM 'opt' tool. If you put this LLVM IR into "t.ll" and run "llvm-as < t.ll | opt -analyze -view-cfg", a window will pop up and you'll see this graph:

Another way to get this is to call "Llvm_analysis.view_function_cfg f" or "Llvm_analysis.view_function_cfg_only f" (where f is a "Function") either by inserting actual calls into the code and recompiling or by calling these in the debugger. LLVM has many nice features for visualizing various graphs.

Getting back to the generated code, it is fairly simple: the entry block evaluates the conditional expression ("x" in our case here) and compares the result to 0.0 with the "fcmp one" instruction ('one' is "Ordered and Not Equal"). Based on the result of this expression, the code jumps to either the "then" or "else" blocks, which contain the expressions for the true/false cases.

Once the then/else blocks are finished executing, they both branch back to the 'ifcont' block to execute the code that happens after the if/then/else. In this case the only thing left to do is to return to the caller of the function. The question then becomes: how does the code know which expression to return?

The answer to this question involves an important SSA operation: the [Phi operation](#). If you're not familiar with SSA, [the wikipedia article](#) is a good introduction and there are various other introductions to it available on your favorite search engine. The short version is that "execution" of the Phi operation requires "remembering" which block control came from. The Phi operation takes on the value corresponding to the input control block. In this case, if control comes in from the "then" block, it gets the value of "calltmp". If control comes from the "else" block, it gets the value of "calltmp1".

Fig. 2: Example CFG

At this point, you are probably starting to think "Oh no! This means my simple and elegant front-end will have to start generating SSA form in order to use LLVM!". Fortunately, this is not the case, and we strongly advise *not* implementing an SSA construction algorithm in your front-end unless there is an amazingly good reason to do so. In practice, there are two sorts of values that float around in code written for your average imperative programming language that might need Phi nodes:

1. Code that involves user variables: `x = 1; x = x + 1;`
2. Values that are implicit in the structure of your AST, such as the Phi node in this case.

In [Chapter 7](#) of this tutorial ("mutable variables"), we'll talk about #1 in depth. For now, just believe me that you don't need SSA construction to handle this case. For #2, you have the choice of using the techniques that we will describe for #1, or you can insert Phi nodes directly, if convenient. In this case, it is really really easy to generate the Phi node, so we choose to do it directly.

Okay, enough of the motivation and overview, lets generate code!

Code Generation for If/Then/Else

In order to generate code for this, we implement the Codegen method for `IfExprAST`:

```
let rec codegen_expr = function
...
| Ast.If (cond, then_, else_) ->
    let cond = codegen_expr cond in

    (* Convert condition to a bool by comparing equal to 0.0 *)
    let zero = const_float double_type 0.0 in
    let cond_val = build_fcmp Fcmp.One cond zero "ifcond" builder in
```

This code is straightforward and similar to what we saw before. We emit the expression for the condition, then compare that value to zero to get a truth value as a 1-bit (bool) value.

```
(* Grab the first block so that we might later add the conditional branch
 * to it at the end of the function. *)
let start_bb = insertion_block builder in
let the_function = block_parent start_bb in

let then_bb = append_block context "then" the_function in
position_at_end then_bb builder;
```

As opposed to the [C++ tutorial](#), we have to build our basic blocks bottom up since we can't have dangling BasicBlocks. We start off by saving a pointer to the first block (which might not be the entry block), which we'll need to build a conditional branch later. We do this by asking the builder for the current BasicBlock. The fourth line gets the current Function object that is being built. It gets this by the `start_bb` for its "parent" (the function it is currently embedded into).

Once it has that, it creates one block. It is automatically appended into the function's list of blocks.

```
(* Emit 'then' value. *)
position_at_end then_bb builder;
let then_val = codegen_expr then_ in

(* Codegen of 'then' can change the current block, update then_bb for the
 * phi. We create a new name because one is used for the phi node, and the
 * other is used for the conditional branch. *)
let new_then_bb = insertion_block builder in
```

We move the builder to start inserting into the "then" block. Strictly speaking, this call moves the insertion point to be at the end of the specified block. However, since the "then" block is empty, it also starts out by inserting at the beginning of the block. :)

Once the insertion point is set, we recursively codegen the "then" expression from the AST.

The final line here is quite subtle, but is very important. The basic issue is that when we create the Phi node in the merge block, we need to set up the block/value pairs that indicate how the Phi will work. Importantly, the Phi node expects to have an entry for each predecessor of the block in the CFG. Why then, are we getting the current block when we just set it to ThenBB 5 lines above? The problem is that the "Then" expression may actually itself change the block that the Builder is emitting into if, for example, it contains a nested "if/then/else" expression. Because calling Codegen recursively could arbitrarily change the notion of the current block, we are required to get an up-to-date value for code that will set up the Phi node.

```
(* Emit 'else' value. *)
let else_bb = append_block context "else" the_function in
position_at_end else_bb builder;
let else_val = codegen_expr else_ in

(* Codegen of 'else' can change the current block, update else_bb for the
 * phi. *)
let new_else_bb = insertion_block builder in
```

Code generation for the 'else' block is basically identical to codegen for the 'then' block.

```
(* Emit merge block. *)
let merge_bb = append_block context "ifcont" the_function in
position_at_end merge_bb builder;
let incoming = [(then_val, new_then_bb); (else_val, new_else_bb)] in
let phi = build_phi incoming "iftmp" builder in
```

The first two lines here are now familiar: the first adds the "merge" block to the Function object. The second changes the insertion point so that newly created code will go into the "merge" block. Once that is done, we need to create the PHI node and set up the block/value pairs for the PHI.

```
(* Return to the start block to add the conditional branch. *)
position_at_end start_bb builder;
ignore (build_cond_br cond_val then_bb else_bb builder);
```

Once the blocks are created, we can emit the conditional branch that chooses between them. Note that creating new blocks does not implicitly affect the IRBuilder, so it is still inserting into the block that the condition went into. This is why we needed to save the "start" block.

```
(* Set a unconditional branch at the end of the 'then' block and the
 * 'else' block to the 'merge' block. *)
position_at_end new_then_bb builder; ignore (build_br merge_bb builder);
position_at_end new_else_bb builder; ignore (build_br merge_bb builder);

(* Finally, set the builder to the end of the merge block. *)
position_at_end merge_bb builder;

phi
```

To finish off the blocks, we create an unconditional branch to the merge block. One interesting (and very important) aspect of the LLVM IR is that it **requires all basic blocks to be "terminated"** with a **control flow instruction** such as return or branch. This means that all control flow, *including fall throughs* must be made explicit in the LLVM IR. If you violate this rule, the verifier will emit an error.

Finally, the CodeGen function returns the phi node as the value computed by the if/then/else expression. In our example above, this returned value will feed into the code for the top-level function, which will create the return instruction.

Overall, we now have the ability to execute conditional code in Kaleidoscope. With this extension, Kaleidoscope is a fairly complete language that can calculate a wide variety of numeric functions. Next up we'll add another useful expression that is familiar from non-functional languages...

'for' Loop Expression

Now that we know how to add basic control flow constructs to the language, we have the tools to add more powerful things. Lets add something more aggressive, a 'for' expression:

```
extern putchar(char);
def printstar(n)
  for i = 1, i < n, 1.0 in
    putchar(42); # ascii 42 = '*'

# print 100 '*' characters
printstar(100);
```

This expression defines a new variable ("i" in this case) which iterates from a starting value, while the condition ("i < n" in this case) is true, incrementing by an optional step value ("1.0" in this case). If the step value is omitted, it defaults to 1.0. While the loop is true, it executes its body expression. Because we don't have anything better to return, we'll just define the loop as always returning 0.0. In the future when we have mutable variables, it will get more useful.

As before, lets talk about the changes that we need to Kaleidoscope to support this.

Lexer Extensions for the 'for' Loop

The lexer extensions are the same sort of thing as for if/then/else:

```
... in Token.token ...
(* control *)
| If | Then | Else
| For | In

... in Lexer.lex_ident...
match Buffer.contents buffer with
| "def" -> [< 'Token.Def; stream >]
| "extern" -> [< 'Token.Extern; stream >]
| "if" -> [< 'Token.If; stream >]
| "then" -> [< 'Token.Then; stream >]
| "else" -> [< 'Token.Else; stream >]
| "for" -> [< 'Token.For; stream >]
| "in" -> [< 'Token.In; stream >]
| id -> [< 'Token.Ident id; stream >]
```

AST Extensions for the 'for' Loop

The AST variant is just as simple. It basically boils down to capturing the variable name and the constituent expressions in the node.

```
type expr =
  ...
  (* variant for for/in. *)
  | For of string * expr * expr * expr option * expr
```

Parser Extensions for the 'for' Loop

The parser code is also fairly standard. The only interesting thing here is handling of the optional step value. The parser code handles it by checking to see if the second comma is present. If not, it sets the step value to null in the AST node:

```
let rec parse_primary = parser
  ...
  (* forexpr
    ::= 'for' identifier '=' expr ',' expr (',' expr)? 'in' expression *)
  | [< 'Token.For;
    'Token.Ident id ?? "expected identifier after for";
    'Token.Kwd '=' ?? "expected '=' after for";
    stream >] ->
    begin parser
      | [<
        start=parse_expr;
        'Token.Kwd ',' ?? "expected ',' after for";
        end_=parse_expr;
        stream >] ->
        let step =
          begin parser
            | [< 'Token.Kwd ','; step=parse_expr >] -> Some step
            | [< >] -> None
          end stream
        in
        begin parser
          | [< 'Token.In; body=parse_expr >] ->
            Ast.For (id, start, end_, step, body)
          | [< >] ->
            raise (Stream.Error "expected 'in' after for")
          end stream
        | [< >] ->
          raise (Stream.Error "expected '=' after for")
        end stream
```

LLVM IR for the 'for' Loop

Now we get to the good part: the LLVM IR we want to generate for this thing. With the simple example above, we get this LLVM IR (note that this dump is generated with optimizations disabled for clarity):

```
declare double @putchar(double)

define double @printstar(double %n) {
entry:
    ; initial value = 1.0 (inlined into phi)
    br label %loop

loop:    ; preds = %loop, %entry
    %i = phi double [ 1.000000e+00, %entry ], [ %nextvar, %loop ]
    ; body
    %calltmp = call double @putchar(double 4.200000e+01)
    ; increment
    %nextvar = fadd double %i, 1.000000e+00

    ; termination test
    %cmptmp = fcmp ult double %i, %n
    %booltmp = uitoffp i1 %cmptmp to double
    %loopcond = fcmp one double %booltmp, 0.000000e+00
    br i1 %loopcond, label %loop, label %afterloop

afterloop:    ; preds = %loop
    ; loop always returns 0.0
    ret double 0.000000e+00
}
```

This loop contains all the same constructs we saw before: a phi node, several expressions, and some basic blocks. Lets see how this fits together.

Code Generation for the 'for' Loop

The first part of Codegen is very simple: we just output the start expression for the loop value:

```
let rec codegen_expr = function
...
| Ast.For (var_name, start, end_, step, body) ->
    (* Emit the start code first, without 'variable' in scope. *)
    let start_val = codegen_expr start in
```

With this out of the way, the next step is to set up the LLVM basic block for the start of the loop body. In the case above, the whole loop body is one block, but remember that the body code itself could consist of multiple blocks (e.g. if it contains an if/then/else or a for/in expression).

```
(* Make the new basic block for the loop header, inserting after current
 * block. *)
let preheader_bb = insertion_block builder in
let the_function = block_parent preheader_bb in
let loop_bb = append_block context "loop" the_function in

(* Insert an explicit fall through from the current block to the
 * loop_bb. *)
ignore (build_br loop_bb builder);
```

This code is similar to what we saw for if/then/else. Because we will need it to create the Phi node, we remember the block that falls through into the loop. Once we have that, we create the actual block that starts the loop and create an unconditional branch for the fall-through between the two blocks.

```
(* Start insertion in loop_bb. *)
position_at_end loop_bb builder;

(* Start the PHI node with an entry for start. *)
let variable = build_phi [(start_val, preheader_bb)] var_name builder in
```

Now that the "preheader" for the loop is set up, we switch to emitting code for the loop body. To begin with, we move the insertion point and create the PHI node for the loop induction variable. Since we already know the incoming value for the starting value, we add it to the Phi node. Note that the Phi will eventually get a second value for the backedge, but we can't set it up yet (because it doesn't exist!).

```
(* Within the loop, the variable is defined equal to the PHI node. If it
 * shadows an existing variable, we have to restore it, so save it
 * now. *)
let old_val =
  try Some (Hashtbl.find named_values var_name) with Not_found -> None
in
Hashtbl.add named_values var_name variable;

(* Emit the body of the loop. This, like any other expr, can change the
 * current BB. Note that we ignore the value computed by the body, but
 * don't allow an error *)
ignore (codegen_expr body);
```

Now the code starts to get more interesting. Our 'for' loop introduces a new variable to the symbol table. This means that our symbol table can now contain either function arguments or loop variables. To handle this, before we codegen the body of the loop, we add the loop variable as the current value for its name. Note that it is possible that there is a variable of the same name in the outer scope. It would be easy to make this an error (emit an error and return null if there is already an entry for VarName) but we choose to allow shadowing of variables. In order to handle this correctly, we remember the Value that we are potentially shadowing in `old_val` (which will be None if there is no shadowed variable).

Once the loop variable is set into the symbol table, the code recursively codegen's the body. This allows the body to use the loop variable: any references to it will naturally find it in the symbol table.

```
(* Emit the step value. *)
let step_val =
  match step with
  | Some step -> codegen_expr step
  (* If not specified, use 1.0. *)
  | None -> const_float double_type 1.0
in

let next_var = build_add variable step_val "nextvar" builder in
```

Now that the body is emitted, we compute the next value of the iteration variable by adding the step value, or 1.0 if it isn't present. 'next_var' will be the value of the loop variable on the next iteration of the loop.

```
(* Compute the end condition. *)
let end_cond = codegen_expr end_ in

(* Convert condition to a bool by comparing equal to 0.0. *)
let zero = const_float double_type 0.0 in
let end_cond = build_fcmp Fcmp.One end_cond zero "loopcond" builder in
```

Finally, we evaluate the exit value of the loop, to determine whether the loop should exit. This mirrors the condition evaluation for the if/then/else statement.

```
(* Create the "after loop" block and insert it. *)
let loop_end_bb = insertion_block builder in
let after_bb = append_block context "afterloop" the_function in

(* Insert the conditional branch into the end of loop_end_bb. *)
ignore (build_cond_br end_cond loop_bb after_bb builder);

(* Any new code will be inserted in after_bb. *)
position_at_end after_bb builder;
```

With the code for the body of the loop complete, we just need to finish up the control flow for it. This code remembers the end block (for the phi node), then creates the block for the loop exit ("afterloop"). Based on the value of the exit condition, it creates a conditional branch that chooses between executing the loop again and exiting the loop. Any future code is emitted in the "afterloop" block, so it sets the insertion position to it.

```
(* Add a new entry to the PHI node for the backedge. *)
add_incoming (next_var, loop_end_bb) variable;

(* Restore the unshadowed variable. *)
begin match old_val with
| Some old_val -> Hashtbl.add named_values var_name old_val
| None -> ()
end;

(* for expr always returns 0.0. *)
const_null double_type
```

The final code handles various cleanups: now that we have the "next_var" value, we can add the incoming value to the loop PHI node. After that, we remove the loop variable from the symbol table, so that it isn't in scope after the for loop. Finally, code generation of the for loop always returns 0.0, so that is what we return from `Codegen.codegen_expr`.

With this, we conclude the "adding control flow to Kaleidoscope" chapter of the tutorial. In this chapter we added two control flow constructs, and used them to motivate a couple of aspects of the LLVM IR that are important for front-end implementors to know. In the next chapter of our saga, we will get a bit crazier and add [user-defined operators](#) to our poor innocent language.

Full Code Listing

Here is the complete code listing for our running example, enhanced with the if/then/else and for expressions.. To build this example, use:

```
# Compile
ocamlbuild toy.byte
# Run
./toy.byte
```

Here is the code:

Chapter 6 Introduction

Welcome to Chapter 6 of the "[Implementing a language with LLVM](#)" tutorial. At this point in our tutorial, we now have a fully functional language that is fairly minimal, but also useful. There is still one big problem with it, however. Our language doesn't have many useful operators (like division, logical negation, or even any comparisons besides less-than).

This chapter of the tutorial takes a wild digression into adding user-defined operators to the simple and beautiful Kaleidoscope language. This digression now gives us a simple and ugly language in some ways, but also a powerful one at the same time. One of the great things about creating your own language is that you get to decide what is good or bad. In this tutorial we'll assume that it is okay to use this as a way to show some interesting parsing techniques.

At the end of this tutorial, we'll run through an example Kaleidoscope application that *renders the Mandelbrot set*. This gives an example of what you can build with Kaleidoscope and its feature set.

User-defined Operators: the Idea

The "operator overloading" that we will add to Kaleidoscope is more general than languages like C++. In C++, you are only allowed to redefine existing operators: you can't programmatically change the grammar, introduce new operators, change precedence levels, etc. In this chapter, we will add this capability to Kaleidoscope, which will let the user round out the set of operators that are supported.

The point of going into user-defined operators in a tutorial like this is to show the power and flexibility of using a hand-written parser. Thus far, the parser we have been implementing uses recursive descent for most parts of the grammar and operator precedence parsing for the expressions. See [Chapter 2](#) for details. Without using operator precedence parsing, it would be very difficult to allow the programmer to introduce new operators into the grammar: the grammar is dynamically extensible as the JIT runs.

The two specific features we'll add are programmable unary operators (right now, Kaleidoscope has no unary operators at all) as well as binary operators. An example of this is:

```
# Logical unary not.
def unary!(v)
  if v then
    0
  else
    1;

# Define > with the same precedence as <.
def binary> 10 (LHS RHS)
  RHS < LHS;

# Binary "logical or", (note that it does not "short circuit")
def binary| 5 (LHS RHS)
  if LHS then
    1
  else if RHS then
    1
  else
    0;

# Define = with slightly lower precedence than relationals.
def binary= 9 (LHS RHS)
  !(LHS < RHS | LHS > RHS);
```

Many languages aspire to being able to implement their standard runtime library in the language itself. In Kaleidoscope, we can implement significant parts of the language in the library!

We will break down implementation of these features into two parts: implementing support for user-defined binary operators and adding unary operators.

User-defined Binary Operators

Adding support for user-defined binary operators is pretty simple with our current framework. We'll first add support for the unary/binary keywords:

```
type token =
...
(* operators *)
| Binary | Unary
```

(continues on next page)

(continued from previous page)

```
...
and lex_ident buffer = parser
  ...
  | "for" -> [< 'Token.For; stream >]
  | "in" -> [< 'Token.In; stream >]
  | "binary" -> [< 'Token.Binary; stream >]
  | "unary" -> [< 'Token.Unary; stream >]
```

This just adds lexer support for the unary and binary keywords, like we did in [previous chapters](#). One nice thing about our current AST, is that we represent binary operators with full generalisation by using their ASCII code as the opcode. For our extended operators, we'll use this same representation, so we don't need any new AST or parser support.

On the other hand, we have to be able to represent the definitions of these new operators, in the "def binary| 5" part of the function definition. In our grammar so far, the "name" for the function definition is parsed as the "prototype" production and into the `Ast.Prototype` AST node. To represent our new user-defined operators as prototypes, we have to extend the `Ast.Prototype` AST node like this:

```
(* proto - This type represents the "prototype" for a function, which captures
 * its name, and its argument names (thus implicitly the number of arguments the
 * function takes). *)
type proto =
  | Prototype of string * string array
  | BinOpPrototype of string * string array * int
```

Basically, in addition to knowing a name for the prototype, we now keep track of whether it was an operator, and if it was, what precedence level the operator is at. The precedence is only used for binary operators (as you'll see below, it just doesn't apply for unary operators). Now that we have a way to represent the prototype for a user-defined operator, we need to parse it:

```
(* prototype
 * ::= id '(' id* ')'
 * ::= binary LETTER number? (id, id)
 * ::= unary LETTER number? (id) *)
let parse_prototype =
  let rec parse_args accumulator = parser
    | [< 'Token.Ident id; e=parse_args (id::accumulator) >] -> e
    | [< >] -> accumulator
  in
  let parse_operator = parser
    | [< 'Token.Unary >] -> "unary", 1
    | [< 'Token.Binary >] -> "binary", 2
  in
  let parse_binary_precedence = parser
    | [< 'Token.Number n >] -> int_of_float n
    | [< >] -> 30
  in
  parser
  | [< 'Token.Ident id;
    'Token.Kwd '(' ?? "expected '(' in prototype";
    args=parse_args [];
    'Token.Kwd ')' ?? "expected ')' in prototype" >] ->
    (* success. *)
    Ast.Prototype (id, Array.of_list (List.rev args))
  | [< (prefix, kind)=parse_operator;
    'Token.Kwd op ?? "expected an operator";
```

(continues on next page)

(continued from previous page)

```

    (* Read the precedence if present. *)
    binary_precedence=parse_binary_precedence;
    'Token.Kwd '(' ?? "expected '(' in prototype";
    args=parse_args [];
    'Token.Kwd ')' ?? "expected ')' in prototype" >] ->
    let name = prefix ^ (String.make 1 op) in
    let args = Array.of_list (List.rev args) in

    (* Verify right number of arguments for operator. *)
    if Array.length args != kind
    then raise (Stream.Error "invalid number of operands for operator")
    else
        if kind == 1 then
            Ast.Prototype (name, args)
        else
            Ast.BinOpPrototype (name, args, binary_precedence)
| [< >] ->
    raise (Stream.Error "expected function name in prototype")

```

This is all fairly straightforward parsing code, and we have already seen a lot of similar code in the past. One interesting part about the code above is the couple lines that set up name for binary operators. This builds names like "binary@" for a newly defined "@" operator. This then takes advantage of the fact that symbol names in the LLVM symbol table are allowed to have any character in them, including embedded nul characters.

The next interesting thing to add, is codegen support for these binary operators. Given our current structure, this is a simple addition of a default case for our existing binary operator node:

```

let codegen_expr = function
...
| Ast.Binary (op, lhs, rhs) ->
    let lhs_val = codegen_expr lhs in
    let rhs_val = codegen_expr rhs in
    begin
        match op with
        | '+' -> build_add lhs_val rhs_val "addtmp" builder
        | '-' -> build_sub lhs_val rhs_val "subtmp" builder
        | '*' -> build_mul lhs_val rhs_val "multmp" builder
        | '<' ->
            (* Convert bool 0/1 to double 0.0 or 1.0 *)
            let i = build_fcmp Fcmp.Ult lhs_val rhs_val "cmptmp" builder in
            build_uitofp i double_type "booltmp" builder
        | _ ->
            (* If it wasn't a builtin binary operator, it must be a user defined
             * one. Emit a call to it. *)
            let callee = "binary" ^ (String.make 1 op) in
            let callee =
                match lookup_function callee the_module with
                | Some callee -> callee
                | None -> raise (Error "binary operator not found!")
            in
            build_call callee [|lhs_val; rhs_val|] "binop" builder
    end
end

```

As you can see above, the new code is actually really simple. It just does a lookup for the appropriate operator in the symbol table and generates a function call to it. Since user-defined operators are just built as normal functions (because the "prototype" boils down to a function with the right name) everything falls into place.

The final piece of code we are missing, is a bit of top level magic:

```
let codegen_func the_fpm = function
| Ast.Function (proto, body) ->
  Hashtbl.clear named_values;
  let the_function = codegen_proto proto in

  (* If this is an operator, install it. *)
  begin match proto with
  | Ast.BinOpPrototype (name, args, prec) ->
    let op = name.[String.length name - 1] in
    Hashtbl.add Parser.binop_precedence op prec;
  | _ -> ()
  end;

  (* Create a new basic block to start insertion into. *)
  let bb = append_block context "entry" the_function in
  position_at_end bb builder;
  ...
```

Basically, before codegening a function, if it is a user-defined operator, we register it in the precedence table. This allows the binary operator parsing logic we already have in place to handle it. Since we are working on a fully-general operator precedence parser, this is all we need to do to "extend the grammar".

Now we have useful user-defined binary operators. This builds a lot on the previous framework we built for other operators. Adding unary operators is a bit more challenging, because we don't have any framework for it yet - lets see what it takes.

User-defined Unary Operators

Since we don't currently support unary operators in the Kaleidoscope language, we'll need to add everything to support them. Above, we added simple support for the 'unary' keyword to the lexer. In addition to that, we need an AST node:

```
type expr =
...
(* variant for a unary operator. *)
| Unary of char * expr
...
```

This AST node is very simple and obvious by now. It directly mirrors the binary operator AST node, except that it only has one child. With this, we need to add the parsing logic. Parsing a unary operator is pretty simple: we'll add a new function to do it:

```
(* unary
* ::= primary
* ::= '!' unary *)
and parse_unary = parser
(* If this is a unary operator, read it. *)
| [< 'Token.Kwd op when op != '(' && op != ')'; operand=parse_expr >] ->
  Ast.Unary (op, operand)

(* If the current token is not an operator, it must be a primary expr. *)
| [< stream >] -> parse_primary stream
```

The grammar we add is pretty straightforward here. If we see a unary operator when parsing a primary operator, we eat the operator as a prefix and parse the remaining piece as another unary operator. This allows us to handle multiple

unary operators (e.g. "!!x"). Note that unary operators can't have ambiguous parses like binary operators can, so there is no need for precedence information.

The problem with this function, is that we need to call `ParseUnary` from somewhere. To do this, we change previous callers of `ParsePrimary` to call `parse_unary` instead:

```
(* binoprhs
 * ::= ('+' primary)* *)
and parse_bin_rhs expr_prec lhs stream =
    ...
    (* Parse the unary expression after the binary operator. *)
    let rhs = parse_unary stream in
    ...

...

(* expression
 * ::= primary binoprhs *)
and parse_expr = parser
| [< lhs=parse_unary; stream >] -> parse_bin_rhs 0 lhs stream
```

With these two simple changes, we are now able to parse unary operators and build the AST for them. Next up, we need to add parser support for prototypes, to parse the unary operator prototype. We extend the binary operator code above with:

```
(* prototype
 * ::= id '(' id* ')'
 * ::= binary LETTER number? (id, id)
 * ::= unary LETTER number? (id) *)
let parse_prototype =
  let rec parse_args accumulator = parser
    | [< 'Token.Ident' id; e=parse_args (id::accumulator) >] -> e
    | [< >] -> accumulator
  in
  let parse_operator = parser
    | [< 'Token.Unary' >] -> "unary", 1
    | [< 'Token.Binary' >] -> "binary", 2
  in
  let parse_binary_precedence = parser
    | [< 'Token.Number' n >] -> int_of_float n
    | [< >] -> 30
  in
  parser
  | [< 'Token.Ident' id;
    'Token.Kwd' '(' ?? "expected '(' in prototype";
    args=parse_args [];
    'Token.Kwd' ')' ?? "expected ')' in prototype" >] ->
    (* success. *)
    Ast.Prototype (id, Array.of_list (List.rev args))
  | [< (prefix, kind)=parse_operator;
    'Token.Kwd' op ?? "expected an operator";
    (* Read the precedence if present. *)
    binary_precedence=parse_binary_precedence;
    'Token.Kwd' '(' ?? "expected '(' in prototype";
    args=parse_args [];
    'Token.Kwd' ')' ?? "expected ')' in prototype" >] ->
    let name = prefix ^ (String.make 1 op) in
    let args = Array.of_list (List.rev args) in
```

(continues on next page)

(continued from previous page)

```

(* Verify right number of arguments for operator. *)
if Array.length args != kind
then raise (Stream.Error "invalid number of operands for operator")
else
  if kind == 1 then
    Ast.Prototype (name, args)
  else
    Ast.BinOpPrototype (name, args, binary_precedence)
| [< >] ->
  raise (Stream.Error "expected function name in prototype")

```

As with binary operators, we name unary operators with a name that includes the operator character. This assists us at code generation time. Speaking of, the final piece we need to add is codegen support for unary operators. It looks like this:

```

let rec codegen_expr = function
...
| Ast.Unary (op, operand) ->
  let operand = codegen_expr operand in
  let callee = "unary" ^ (String.make 1 op) in
  let callee =
    match lookup_function callee the_module with
    | Some callee -> callee
    | None -> raise (Error "unknown unary operator")
  in
  build_call callee [|operand|] "unop" builder

```

This code is similar to, but simpler than, the code for binary operators. It is simpler primarily because it doesn't need to handle any predefined operators.

Kicking the Tires

It is somewhat hard to believe, but with a few simple extensions we've covered in the last chapters, we have grown a real-ish language. With this, we can do a lot of interesting things, including I/O, math, and a bunch of other things. For example, we can now add a nice sequencing operator (printf is defined to print out the specified value and a newline):

```

ready> extern printf(x);
Read extern: declare double @printf(double)
ready> def binary : 1 (x y) 0; # Low-precedence operator that ignores operands.
..
ready> printf(123) : printf(456) : printf(789);
123.000000
456.000000
789.000000
Evaluated to 0.000000

```

We can also define a bunch of other "primitive" operations, such as:

```

# Logical unary not.
def unary!(v)
  if v then
    0
  else
    1;

```

(continues on next page)

(continued from previous page)

```

# Unary negate.
def unary-(v)
  0-v;

# Define > with the same precedence as <.
def binary> 10 (LHS RHS)
  RHS < LHS;

# Binary logical or, which does not short circuit.
def binary| 5 (LHS RHS)
  if LHS then
    1
  else if RHS then
    1
  else
    0;

# Binary logical and, which does not short circuit.
def binary& 6 (LHS RHS)
  if !LHS then
    0
  else
    !!RHS;

# Define = with slightly lower precedence than relationals.
def binary = 9 (LHS RHS)
  !(LHS < RHS | LHS > RHS);

```

Given the previous if/then/else support, we can also define interesting functions for I/O. For example, the following prints out a character whose "density" reflects the value passed in: the lower the value, the denser the character:

```

ready>

extern putchar(char)
def printdensity(d)
  if d > 8 then
    putchar(32) # ' '
  else if d > 4 then
    putchar(46) # '.'
  else if d > 2 then
    putchar(43) # '+'
  else
    putchar(42); # '*'
...
ready> printdensity(1): printdensity(2): printdensity(3) :
      printdensity(4): printdensity(5): printdensity(9): putchar(10);
*+*+.
Evaluated to 0.000000

```

Based on these simple primitive operations, we can start to define more interesting things. For example, here's a little function that solves for the number of iterations it takes a function in the complex plane to converge:

```

# determine whether the specific location diverges.
# Solve for  $z = z^2 + c$  in the complex plane.
def mandelconverger(real imag iters creal cimag)

```

(continues on next page)

(continued from previous page)

```

if iters > 255 | (real*real + imag*imag > 4) then
    iters
else
    mandelconverger(real*real - imag*imag + creal,
                    2*real*imag + cimag,
                    iters+1, creal, cimag);

# return the number of iterations required for the iteration to escape
def mandelconverge(real imag)
    mandelconverger(real, imag, 0, real, imag);

```

This " $z = z^2 + c$ " function is a beautiful little creature that is the basis for computation of the [Mandelbrot Set](#). Our `mandelconverge` function returns the number of iterations that it takes for a complex orbit to escape, saturating to 255. This is not a very useful function by itself, but if you plot its value over a two-dimensional plane, you can see the Mandelbrot set. Given that we are limited to using `putchart` here, our amazing graphical output is limited, but we can whip together something using the density plotter above:

```
# compute and plot the mandelbrot set with the specified 2 dimensional range
# info.
def mandelhelp(xmin xmax xstep  ymin ymax ystep)
    for y = ymin, y < ymax, ystep in (
        (for x = xmin, x < xmax, xstep in
            printdensity(mandelconverge(x,y)))
        : putchar(10)
    )

# mandel - This is a convenient helper function for plotting the mandelbrot set
# from the specified position with the specified Magnification.
def mandel(realstart imagstart realmag imagmag)
    mandelhelp(realstart, realstart+realmag*78, realmag,
                imagstart, imagstart+imagmag*40, imagmag);
```

Given this, we can try plotting out the mandelbrot set! Lets try it out:

[illegible]

(continues on next page)

[illegible]

(continued from previous page)

[illegible]

At this point, you may be starting to realize that Kaleidoscope is a real and powerful language. It may not be self-similar :), but it can be used to plot things that are!

With this, we conclude the "adding user-defined operators" chapter of the tutorial. We have successfully augmented our language, adding the ability to extend the language in the library, and we have shown how this can be used to

build a simple but interesting end-user application in Kaleidoscope. At this point, Kaleidoscope can build a variety of applications that are functional and can call functions with side-effects, but it can't actually define and mutate a variable itself.

Strikingly, variable mutation is an important feature of some languages, and it is not at all obvious how to [add support for mutable variables](#) without having to add an "SSA construction" phase to your front-end. In the next chapter, we will describe how you can add variable mutation without building SSA in your front-end.

Full Code Listing

Here is the complete code listing for our running example, enhanced with the if/then/else and for expressions.. To build this example, use:

```
# Compile
ocamlbuild toy.byte
# Run
./toy.byte
```

Here is the code:

Chapter 7 Introduction

Welcome to Chapter 7 of the "Implementing a language with LLVM" tutorial. In chapters 1 through 6, we've built a very respectable, albeit simple, [functional programming language](#). In our journey, we learned some parsing techniques, how to build and represent an AST, how to build LLVM IR, and how to optimize the resultant code as well as JIT compile it.

While Kaleidoscope is interesting as a functional language, the fact that it is functional makes it "too easy" to generate LLVM IR for it. In particular, a functional language makes it very easy to build LLVM IR directly in [SSA form](#). Since LLVM requires that the input code be in SSA form, this is a very nice property and it is often unclear to newcomers how to generate code for an imperative language with mutable variables.

The short (and happy) summary of this chapter is that there is no need for your front-end to build SSA form: LLVM provides highly tuned and well tested support for this, though the way it works is a bit unexpected for some.

Why is this a hard problem?

To understand why mutable variables cause complexities in SSA construction, consider this extremely simple C example:

```
int G, H;
int test(_Bool Condition) {
    int X;
    if (Condition)
        X = G;
    else
        X = H;
    return X;
}
```

In this case, we have the variable "X", whose value depends on the path executed in the program. Because there are two different possible values for X before the return instruction, a PHI node is inserted to merge the two values. The LLVM IR that we want for this example looks like this:

```

@G = weak global i32 0    ; type of @G is i32*
@H = weak global i32 0    ; type of @H is i32*

define i32 @test(i1 %Condition) {
entry:
  br i1 %Condition, label %cond_true, label %cond_false

cond_true:
  %X.0 = load i32* @G
  br label %cond_next

cond_false:
  %X.1 = load i32* @H
  br label %cond_next

cond_next:
  %X.2 = phi i32 [ %X.1, %cond_false ], [ %X.0, %cond_true ]
  ret i32 %X.2
}

```

In this example, the loads from the G and H global variables are explicit in the LLVM IR, and they live in the then/else branches of the if statement (cond_true/cond_false). In order to merge the incoming values, the X.2 phi node in the cond_next block selects the right value to use based on where control flow is coming from: if control flow comes from the cond_false block, X.2 gets the value of X.1. Alternatively, if control flow comes from cond_true, it gets the value of X.0. The intent of this chapter is not to explain the details of SSA form. For more information, see one of the many [online references](#).

The question for this article is "who places the phi nodes when lowering assignments to mutable variables?". The issue here is that LLVM *requires* that its IR be in SSA form: there is no "non-ssa" mode for it. However, SSA construction requires non-trivial algorithms and data structures, so it is inconvenient and wasteful for every front-end to have to reproduce this logic.

Memory in LLVM

The 'trick' here is that while LLVM does require all register values to be in SSA form, it does not require (or permit) memory objects to be in SSA form. In the example above, note that the loads from G and H are direct accesses to G and H: they are not renamed or versioned. This differs from some other compiler systems, which do try to version memory objects. In LLVM, instead of encoding dataflow analysis of memory into the LLVM IR, it is handled with [Analysis Passes](#) which are computed on demand.

With this in mind, the high-level idea is that we want to make a stack variable (which lives in memory, because it is on the stack) for each mutable object in a function. To take advantage of this trick, we need to talk about how LLVM represents stack variables.

In LLVM, all memory accesses are explicit with load/store instructions, and it is carefully designed not to have (or need) an "address-of" operator. Notice how the type of the @G/@H global variables is actually "i32*" even though the variable is defined as "i32". What this means is that @G defines *space* for an i32 in the global data area, but its *name* actually refers to the address for that space. Stack variables work the same way, except that instead of being declared with global variable definitions, they are declared with the [LLVM alloca instruction](#):

```

define i32 @example() {
entry:
  %X = alloca i32                ; type of %X is i32*.
  ...
  %tmp = load i32* %X            ; load the stack value %X from the stack.
}

```

(continues on next page)

(continued from previous page)

```

    %tmp2 = add i32 %tmp, 1    ; increment it
    store i32 %tmp2, i32* %X  ; store it back
    ...

```

This code shows an example of how you can declare and manipulate a stack variable in the LLVM IR. Stack memory allocated with the `alloca` instruction is fully general: you can pass the address of the stack slot to functions, you can store it in other variables, etc. In our example above, we could rewrite the example to use the `alloca` technique to avoid using a PHI node:

```

@G = weak global i32 0    ; type of @G is i32*
@H = weak global i32 0    ; type of @H is i32*

define i32 @test(i1 %Condition) {
entry:
    %X = alloca i32        ; type of %X is i32*.
    br i1 %Condition, label %cond_true, label %cond_false

cond_true:
    %X.0 = load i32* @G
    store i32 %X.0, i32* %X    ; Update X
    br label %cond_next

cond_false:
    %X.1 = load i32* @H
    store i32 %X.1, i32* %X    ; Update X
    br label %cond_next

cond_next:
    %X.2 = load i32* %X        ; Read X
    ret i32 %X.2
}

```

With this, we have discovered a way to handle arbitrary mutable variables without the need to create Phi nodes at all:

1. Each mutable variable becomes a stack allocation.
2. Each read of the variable becomes a load from the stack.
3. Each update of the variable becomes a store to the stack.
4. Taking the address of a variable just uses the stack address directly.

While this solution has solved our immediate problem, it introduced another one: we have now apparently introduced a lot of stack traffic for very simple and common operations, a major performance problem. Fortunately for us, the LLVM optimizer has a highly-tuned optimization pass named "mem2reg" that handles this case, promoting allocas like this into SSA registers, inserting Phi nodes as appropriate. If you run this example through the pass, for example, you'll get:

```

$ llvm-as < example.ll | opt -mem2reg | llvm-dis
@G = weak global i32 0
@H = weak global i32 0

define i32 @test(i1 %Condition) {
entry:
    br i1 %Condition, label %cond_true, label %cond_false

cond_true:
    %X.0 = load i32* @G

```

(continues on next page)

(continued from previous page)

```

    br label %cond_next

cond_false:
    %X.1 = load i32* @H
    br label %cond_next

cond_next:
    %X.01 = phi i32 [ %X.1, %cond_false ], [ %X.0, %cond_true ]
    ret i32 %X.01
}

```

The mem2reg pass implements the standard "iterated dominance frontier" algorithm for constructing SSA form and has a number of optimizations that speed up (very common) degenerate cases. The mem2reg optimization pass is the answer to dealing with mutable variables, and we highly recommend that you depend on it. Note that mem2reg only works on variables in certain circumstances:

1. mem2reg is alloca-driven: it looks for allocas and if it can handle them, it promotes them. It does not apply to global variables or heap allocations.
2. mem2reg only looks for alloca instructions in the entry block of the function. Being in the entry block guarantees that the alloca is only executed once, which makes analysis simpler.
3. mem2reg only promotes allocas whose uses are direct loads and stores. If the address of the stack object is passed to a function, or if any funny pointer arithmetic is involved, the alloca will not be promoted.
4. mem2reg only works on allocas of [first class](#) values (such as pointers, scalars and vectors), and only if the array size of the allocation is 1 (or missing in the .ll file). mem2reg is not capable of promoting structs or arrays to registers. Note that the "sroa" pass is more powerful and can promote structs, "unions", and arrays in many cases.

All of these properties are easy to satisfy for most imperative languages, and we'll illustrate it below with Kaleidoscope. The final question you may be asking is: should I bother with this nonsense for my front-end? Wouldn't it be better if I just did SSA construction directly, avoiding use of the mem2reg optimization pass? In short, we strongly recommend that you use this technique for building SSA form, unless there is an extremely good reason not to. Using this technique is:

- Proven and well tested: clang uses this technique for local mutable variables. As such, the most common clients of LLVM are using this to handle a bulk of their variables. You can be sure that bugs are found fast and fixed early.
- Extremely Fast: mem2reg has a number of special cases that make it fast in common cases as well as fully general. For example, it has fast-paths for variables that are only used in a single block, variables that only have one assignment point, good heuristics to avoid insertion of unneeded phi nodes, etc.
- Needed for debug info generation: [Debug information in LLVM](#) relies on having the address of the variable exposed so that debug info can be attached to it. This technique dovetails very naturally with this style of debug info.

If nothing else, this makes it much easier to get your front-end up and running, and is very simple to implement. Lets extend Kaleidoscope with mutable variables now!

Mutable Variables in Kaleidoscope

Now that we know the sort of problem we want to tackle, let's see what this looks like in the context of our little Kaleidoscope language. We're going to add two features:

1. The ability to mutate variables with the '=' operator.
2. The ability to define new variables.

While the first item is really what this is about, we only have variables for incoming arguments as well as for induction variables, and redefining those only goes so far :). Also, the ability to define new variables is a useful thing regardless of whether you will be mutating them. Here's a motivating example that shows how we could use these:

```
# Define ':' for sequencing: as a low-precedence operator that ignores operands
# and just returns the RHS.
def binary : 1 (x y) y;

# Recursive fib, we could do this before.
def fib(x)
  if (x < 3) then
    1
  else
    fib(x-1)+fib(x-2);

# Iterative fib.
def fibi(x)
  var a = 1, b = 1, c in
  (for i = 3, i < x in
    c = a + b :
    a = b :
    b = c) :
  b;

# Call it.
fibi(10);
```

In order to mutate variables, we have to change our existing variables to use the "alloca trick". Once we have that, we'll add our new operator, then extend Kaleidoscope to support new variable definitions.

Adjusting Existing Variables for Mutation

The symbol table in Kaleidoscope is managed at code generation time by the 'named_values' map. This map currently keeps track of the LLVM "Value*" that holds the double value for the named variable. In order to support mutation, we need to change this slightly, so that it named_values holds the *memory location* of the variable in question. Note that this change is a refactoring: it changes the structure of the code, but does not (by itself) change the behavior of the compiler. All of these changes are isolated in the Kaleidoscope code generator.

At this point in Kaleidoscope's development, it only supports variables for two things: incoming arguments to functions and the induction variable of 'for' loops. For consistency, we'll allow mutation of these variables in addition to other user-defined variables. This means that these will both need memory locations.

To start our transformation of Kaleidoscope, we'll change the named_values map so that it maps to AllocaInst* instead of Value*. Once we do this, the C++ compiler will tell us what parts of the code we need to update:

Note: the ocaml bindings currently model both Value*'s and AllocInst*'s as Llvm.llvalue's, but this may change in the future to be more type safe.

```
let named_values: (string, llvalue) Hashtbl.t = Hashtbl.create 10
```

Also, since we will need to create these allocas, we'll use a helper function that ensures that the allocas are created in the entry block of the function:

```
(* Create an alloca instruction in the entry block of the function. This
 * is used for mutable variables etc. *)
let create_entry_block_alloca the_function var_name =
  let builder = builder_at (instr_begin (entry_block the_function)) in
  build_alloca double_type var_name builder
```

This funny looking code creates an `Llvm.llbuilder` object that is pointing at the first instruction of the entry block. It then creates an alloca with the expected name and returns it. Because all values in Kaleidoscope are doubles, there is no need to pass in a type to use.

With this in place, the first functionality change we want to make is to variable references. In our new scheme, variables live on the stack, so code generating a reference to them actually needs to produce a load from the stack slot:

```
let rec codegen_expr = function
...
| Ast.Variable name ->
  let v = try Hashtbl.find named_values name with
  | Not_found -> raise (Error "unknown variable name")
  in
  (* Load the value. *)
  build_load v name builder
```

As you can see, this is pretty straightforward. Now we need to update the things that define the variables to set up the alloca. We'll start with `codegen_expr Ast.For` ... (see the [full code listing](#) for the unabridged code):

```
| Ast.For (var_name, start, end_, step, body) ->
  let the_function = block_parent (insertion_block builder) in

  (* Create an alloca for the variable in the entry block. *)
  let alloca = create_entry_block_alloca the_function var_name in

  (* Emit the start code first, without 'variable' in scope. *)
  let start_val = codegen_expr start in

  (* Store the value into the alloca. *)
  ignore(build_store start_val alloca builder);

  ...

  (* Within the loop, the variable is defined equal to the PHI node. If it
   * shadows an existing variable, we have to restore it, so save it
   * now. *)
  let old_val =
    try Some (Hashtbl.find named_values var_name) with Not_found -> None
  in
  Hashtbl.add named_values var_name alloca;

  ...

  (* Compute the end condition. *)
  let end_cond = codegen_expr end_ in
```

(continues on next page)

(continued from previous page)

```

(* Reload, increment, and restore the alloca. This handles the case where
 * the body of the loop mutates the variable. *)
let cur_var = build_load alloca var_name builder in
let next_var = build_add cur_var step_val "nextvar" builder in
ignore(build_store next_var alloca builder);
...

```

This code is virtually identical to the code before we allowed mutable variables. The big difference is that we no longer have to construct a PHI node, and we use load/store to access the variable as needed.

To support mutable argument variables, we need to also make allocas for them. The code for this is also pretty simple:

```

(* Create an alloca for each argument and register the argument in the symbol
 * table so that references to it will succeed. *)
let create_argument_allocas the_function proto =
  let args = match proto with
  | Ast.Prototype (_, args) | Ast.BinOpPrototype (_, args, _) -> args
  in
  Array.iteri (fun i ai ->
    let var_name = args.(i) in
    (* Create an alloca for this variable. *)
    let alloca = create_entry_block_alloca the_function var_name in

    (* Store the initial value into the alloca. *)
    ignore(build_store ai alloca builder);

    (* Add arguments to variable symbol table. *)
    Hashtbl.add named_values var_name alloca;
  ) (params the_function)

```

For each argument, we make an alloca, store the input value to the function into the alloca, and register the alloca as the memory location for the argument. This method gets invoked by `Codegen.codegen_func` right after it sets up the entry block for the function.

The final missing piece is adding the `mem2reg` pass, which allows us to get good codegen once again:

```

let main () =
  ...
  let the_fpm = PassManager.create_function Codegen.the_module in

  (* Set up the optimizer pipeline. Start with registering info about how the
   * target lays out data structures. *)
  DataLayout.add (ExecutionEngine.target_data the_execution_engine) the_fpm;

  (* Promote allocas to registers. *)
  add_memory_to_register_promotion the_fpm;

  (* Do simple "peephole" optimizations and bit-twiddling optzn. *)
  add_instruction_combining the_fpm;

  (* reassociate expressions. *)
  add_reassociation the_fpm;

```

It is interesting to see what the code looks like before and after the `mem2reg` optimization runs. For example, this is the before/after code for our recursive fib function. Before the optimization:

```
define double @fib(double %x) {
entry:
    %x1 = alloca double
    store double %x, double* %x1
    %x2 = load double* %x1
    %cmptmp = fcmp ult double %x2, 3.000000e+00
    %booltmp = uitofp i1 %cmptmp to double
    %ifcond = fcmp one double %booltmp, 0.000000e+00
    br i1 %ifcond, label %then, label %else

then:    ; preds = %entry
    br label %ifcont

else:    ; preds = %entry
    %x3 = load double* %x1
    %subtmp = fsub double %x3, 1.000000e+00
    %calltmp = call double @fib(double %subtmp)
    %x4 = load double* %x1
    %subtmp5 = fsub double %x4, 2.000000e+00
    %calltmp6 = call double @fib(double %subtmp5)
    %addtmp = fadd double %calltmp, %calltmp6
    br label %ifcont

ifcont:    ; preds = %else, %then
    %iftmp = phi double [ 1.000000e+00, %then ], [ %addtmp, %else ]
    ret double %iftmp
}
```

Here there is only one variable (x, the input argument) but you can still see the extremely simple-minded code generation strategy we are using. In the entry block, an alloca is created, and the initial input value is stored into it. Each reference to the variable does a reload from the stack. Also, note that we didn't modify the if/then/else expression, so it still inserts a PHI node. While we could make an alloca for it, it is actually easier to create a PHI node for it, so we still just make the PHI.

Here is the code after the mem2reg pass runs:

```
define double @fib(double %x) {
entry:
    %cmptmp = fcmp ult double %x, 3.000000e+00
    %booltmp = uitofp i1 %cmptmp to double
    %ifcond = fcmp one double %booltmp, 0.000000e+00
    br i1 %ifcond, label %then, label %else

then:
    br label %ifcont

else:
    %subtmp = fsub double %x, 1.000000e+00
    %calltmp = call double @fib(double %subtmp)
    %subtmp5 = fsub double %x, 2.000000e+00
    %calltmp6 = call double @fib(double %subtmp5)
    %addtmp = fadd double %calltmp, %calltmp6
    br label %ifcont

ifcont:    ; preds = %else, %then
    %iftmp = phi double [ 1.000000e+00, %then ], [ %addtmp, %else ]
    ret double %iftmp
}
```

This is a trivial case for `mem2reg`, since there are no redefinitions of the variable. The point of showing this is to calm your tension about inserting such blatant inefficiencies :).

After the rest of the optimizers run, we get:

```
define double @fib(double %x) {
entry:
    %cmptmp = fcmp ult double %x, 3.000000e+00
    %booltmp = uitofp i1 %cmptmp to double
    %ifcond = fcmp ueq double %booltmp, 0.000000e+00
    br i1 %ifcond, label %else, label %ifcont

else:
    %subtmp = fsub double %x, 1.000000e+00
    %calltmp = call double @fib(double %subtmp)
    %subtmp5 = fsub double %x, 2.000000e+00
    %calltmp6 = call double @fib(double %subtmp5)
    %addtmp = fadd double %calltmp, %calltmp6
    ret double %addtmp

ifcont:
    ret double 1.000000e+00
}
```

Here we see that the `simplifycfg` pass decided to clone the return instruction into the end of the 'else' block. This allowed it to eliminate some branches and the PHI node.

Now that all symbol table references are updated to use stack variables, we'll add the assignment operator.

New Assignment Operator

With our current framework, adding a new assignment operator is really simple. We will parse it just like any other binary operator, but handle it internally (instead of allowing the user to define it). The first step is to set a precedence:

```
let main () =
  (* Install standard binary operators.
   * 1 is the lowest precedence. *)
  Hashtbl.add Parser.binop_precedence '=' 2;
  Hashtbl.add Parser.binop_precedence '<' 10;
  Hashtbl.add Parser.binop_precedence '+' 20;
  Hashtbl.add Parser.binop_precedence '-' 20;
  ...
```

Now that the parser knows the precedence of the binary operator, it takes care of all the parsing and AST generation. We just need to implement codegen for the assignment operator. This looks like:

```
let rec codegen_expr = function
  begin match op with
  | '=' ->
      (* Special case '=' because we don't want to emit the LHS as an
       * expression. *)
      let name =
        match lhs with
        | Ast.Variable name -> name
        | _ -> raise (Error "destination of '=' must be a variable")
      in
```

Unlike the rest of the binary operators, our assignment operator doesn't follow the "emit LHS, emit RHS, do computation" model. As such, it is handled as a special case before the other binary operators are handled. The other strange thing is that it requires the LHS to be a variable. It is invalid to have "(x+1) = expr" - only things like "x = expr" are allowed.

```
(* Codegen the rhs. *)
let val_ = codegen_expr rhs in

(* Lookup the name. *)
let variable = try Hashtbl.find named_values name with
| Not_found -> raise (Error "unknown variable name")
in
ignore(build_store val_ variable builder);
val_
| _ ->
...

```

Once we have the variable, codegen'ing the assignment is straightforward: we emit the RHS of the assignment, create a store, and return the computed value. Returning a value allows for chained assignments like "X = (Y = Z)".

Now that we have an assignment operator, we can mutate loop variables and arguments. For example, we can now run code like this:

```
# Function to print a double.
extern printf(x);

# Define ':' for sequencing: as a low-precedence operator that ignores operands
# and just returns the RHS.
def binary : 1 (x y) y;

def test (x)
  printf(x) :
  x = 4 :
  printf(x);

test(123);

```

When run, this example prints "123" and then "4", showing that we did actually mutate the value! Okay, we have now officially implemented our goal: getting this to work requires SSA construction in the general case. However, to be really useful, we want the ability to define our own local variables, let's add this next!

User-defined Local Variables

Adding var/in is just like any other other extensions we made to Kaleidoscope: we extend the lexer, the parser, the AST and the code generator. The first step for adding our new 'var/in' construct is to extend the lexer. As before, this is pretty trivial, the code looks like this:

```
type token =
...
(* var definition *)
| Var
...

and lex_ident buffer = parser
...

```

(continues on next page)

(continued from previous page)

```

| "in" -> [< 'Token.In; stream >]
| "binary" -> [< 'Token.Binary; stream >]
| "unary" -> [< 'Token.Unary; stream >]
| "var" -> [< 'Token.Var; stream >]
...

```

The next step is to define the AST node that we will construct. For var/in, it looks like this:

```

type expr =
...
(* variant for var/in. *)
| Var of (string * expr option) array * expr
...

```

var/in allows a list of names to be defined all at once, and each name can optionally have an initializer value. As such, we capture this information in the VarNames vector. Also, var/in has a body, this body is allowed to access the variables defined by the var/in.

With this in place, we can define the parser pieces. The first thing we do is add it as a primary expression:

```

(* primary
 * ::= identifier
 * ::= numberexpr
 * ::= parenexpr
 * ::= ifexpr
 * ::= forexpr
 * ::= varexpr *)
let rec parse_primary = parser
...
(* varexpr
 * ::= 'var' identifier ('=' expression?
 *      (' identifier ('=' expression)? * 'in' expression *)
| [< 'Token.Var;
   (* At least one variable name is required. *)
   'Token.Ident id ?? "expected identifier after var";
   init=parse_var_init;
   var_names=parse_var_names [(id, init)];
   (* At this point, we have to have 'in'. *)
   'Token.In ?? "expected 'in' keyword after 'var'";
   body=parse_expr >] ->
   Ast.Var (Array.of_list (List.rev var_names), body)
...

and parse_var_init = parser
(* read in the optional initializer. *)
| [< 'Token.Kwd '='; e=parse_expr >] -> Some e
| [< >] -> None

and parse_var_names accumulator = parser
| [< 'Token.Kwd ',';
   'Token.Ident id ?? "expected identifier list after var";
   init=parse_var_init;
   e=parse_var_names ((id, init) :: accumulator) >] -> e
| [< >] -> accumulator

```

Now that we can parse and represent the code, we need to support emission of LLVM IR for it. This code starts out

with:

```
let rec codegen_expr = function
...
| Ast.Var (var_names, body)
    let old_bindings = ref [] in

    let the_function = block_parent (insertion_block builder) in

    (* Register all variables and emit their initializer. *)
    Array.iter (fun (var_name, init) ->
```

Basically it loops over all the variables, installing them one at a time. For each variable we put into the symbol table, we remember the previous value that we replace in OldBindings.

```
(* Emit the initializer before adding the variable to scope, this
 * prevents the initializer from referencing the variable itself, and
 * permits stuff like this:
 *   var a = 1 in
 *   var a = a in ...   # refers to outer 'a'. *)
let init_val =
  match init with
  | Some init -> codegen_expr init
  (* If not specified, use 0.0. *)
  | None -> const_float double_type 0.0
in

let alloca = create_entry_block_alloca the_function var_name in
ignore(build_store init_val alloca builder);

(* Remember the old variable binding so that we can restore the binding
 * when we unrecurse. *)

begin
  try
    let old_value = Hashtbl.find named_values var_name in
    old_bindings := (var_name, old_value) :: !old_bindings;
    with Not_found > ()
  end;

  (* Remember this binding. *)
  Hashtbl.add named_values var_name alloca;
) var_names;
```

There are more comments here than code. The basic idea is that we emit the initializer, create the alloca, then update the symbol table to point to it. Once all the variables are installed in the symbol table, we evaluate the body of the var/in expression:

```
(* Codegen the body, now that all vars are in scope. *)
let body_val = codegen_expr body in
```

Finally, before returning, we restore the previous variable bindings:

```
(* Pop all our variables from scope. *)
List.iter (fun (var_name, old_value) ->
  Hashtbl.add named_values var_name old_value
) !old_bindings;
```

(continues on next page)

(continued from previous page)

```
(* Return the body computation. *)
body_val
```

The end result of all of this is that we get properly scoped variable definitions, and we even (trivially) allow mutation of them :).

With this, we completed what we set out to do. Our nice iterative fib example from the intro compiles and runs just fine. The mem2reg pass optimizes all of our stack variables into SSA registers, inserting PHI nodes where needed, and our front-end remains simple: no "iterated dominance frontier" computation anywhere in sight.

Full Code Listing

Here is the complete code listing for our running example, enhanced with mutable variables and var/in support. To build this example, use:

```
# Compile
ocamlbuild toy.byte
# Run
./toy.byte
```

Here is the code:

Tutorial Conclusion

Welcome to the final chapter of the "[Implementing a language with LLVM](#)" tutorial. In the course of this tutorial, we have grown our little Kaleidoscope language from being a useless toy, to being a semi-interesting (but probably still useless) toy. :)

It is interesting to see how far we've come, and how little code it has taken. We built the entire lexer, parser, AST, code generator, and an interactive run-loop (with a JIT!) by-hand in under 700 lines of (non-comment/non-blank) code.

Our little language supports a couple of interesting features: it supports user defined binary and unary operators, it uses JIT compilation for immediate evaluation, and it supports a few control flow constructs with SSA construction.

Part of the idea of this tutorial was to show you how easy and fun it can be to define, build, and play with languages. Building a compiler need not be a scary or mystical process! Now that you've seen some of the basics, I strongly encourage you to take the code and hack on it. For example, try adding:

- **global variables** - While global variables have questional value in modern software engineering, they are often useful when putting together quick little hacks like the Kaleidoscope compiler itself. Fortunately, our current setup makes it very easy to add global variables: just have value lookup check to see if an unresolved variable is in the global variable symbol table before rejecting it. To create a new global variable, make an instance of the `LLVMGlobalVariable` class.
- **typed variables** - Kaleidoscope currently only supports variables of type double. This gives the language a very nice elegance, because only supporting one type means that you never have to specify types. Different languages have different ways of handling this. The easiest way is to require the user to specify types for every variable definition, and record the type of the variable in the symbol table along with its `Value*`.
- **arrays, structs, vectors, etc** - Once you add types, you can start extending the type system in all sorts of interesting ways. Simple arrays are very easy and are quite useful for many different applications. Adding them is mostly an exercise in learning how the LLVM `getelementptr` instruction works: it is so nifty/unconventional, it has its own FAQ! If you add support for recursive types (e.g. linked lists), make sure to read the [section in the LLVM Programmer's Manual](#) that describes how to construct them.
- **standard runtime** - Our current language allows the user to access arbitrary external functions, and we use it for things like "printf" and "putchar". As you extend the language to add higher-level constructs, often these constructs make the most sense if they are lowered to calls into a language-supplied runtime. For example, if you add hash tables to the language, it would probably make sense to add the routines to a runtime, instead of inlining them all the way.

- **memory management** - Currently we can only access the stack in Kaleidoscope. It would also be useful to be able to allocate heap memory, either with calls to the standard libc malloc/free interface or with a garbage collector. If you would like to use garbage collection, note that LLVM fully supports [Accurate Garbage Collection](#) including algorithms that move objects and need to scan/update the stack.
- **debugger support** - LLVM supports generation of [DWARF Debug info](#) which is understood by common debuggers like GDB. Adding support for debug info is fairly straightforward. The best way to understand it is to compile some C/C++ code with "`clang -g -O0`" and taking a look at what it produces.
- **exception handling support** - LLVM supports generation of [zero cost exceptions](#) which interoperate with code compiled in other languages. You could also generate code by implicitly making every function return an error value and checking it. You could also make explicit use of `setjmp/longjmp`. There are many different ways to go here.
- **object orientation, generics, database access, complex numbers, geometric programming, ...** - Really, there is no end of crazy features that you can add to the language.
- **unusual domains** - We've been talking about applying LLVM to a domain that many people are interested in: building a compiler for a specific language. However, there are many other domains that can use compiler technology that are not typically considered. For example, LLVM has been used to implement OpenGL graphics acceleration, translate C++ code to ActionScript, and many other cute and clever things. Maybe you will be the first to JIT compile a regular expression interpreter into native code with LLVM?

Have fun - try doing something crazy and unusual. Building a language like everyone else always has, is much less fun than trying something a little crazy or off the wall and seeing how it turns out. If you get stuck or want to talk about it, feel free to email the [llvm-dev mailing list](#): it has lots of people who are interested in languages and are often willing to help out.

Before we end this tutorial, I want to talk about some "tips and tricks" for generating LLVM IR. These are some of the more subtle things that may not be obvious, but are very useful if you want to take advantage of LLVM's capabilities.

Properties of the LLVM IR

We have a couple common questions about code in the LLVM IR form - lets just get these out of the way right now, shall we?

Target Independence

Kaleidoscope is an example of a "portable language": any program written in Kaleidoscope will work the same way on any target that it runs on. Many other languages have this property, e.g. lisp, java, haskell, javascript, python, etc (note that while these languages are portable, not all their libraries are).

One nice aspect of LLVM is that it is often capable of preserving target independence in the IR: you can take the LLVM IR for a Kaleidoscope-compiled program and run it on any target that LLVM supports, even emitting C code and compiling that on targets that LLVM doesn't support natively. You can trivially tell that the Kaleidoscope compiler generates target-independent code because it never queries for any target-specific information when generating code.

The fact that LLVM provides a compact, target-independent, representation for code gets a lot of people excited. Unfortunately, these people are usually thinking about C or a language from the C family when they are asking questions about language portability. I say "unfortunately", because there is really no way to make (fully general) C code portable, other than shipping the source code around (and of course, C source code is not actually portable in general either - ever port a really old application from 32- to 64-bits?).

The problem with C (again, in its full generality) is that it is heavily laden with target specific assumptions. As one simple example, the preprocessor often destructively removes target-independence from the code when it processes the input text:

```
#ifdef __i386__
    int X = 1;
#else
    int X = 42;
#endif
```

While it is possible to engineer more and more complex solutions to problems like this, it cannot be solved in full generality in a way that is better than shipping the actual source code.

That said, there are interesting subsets of C that can be made portable. If you are willing to fix primitive types to a fixed size (say `int` = 32-bits, and `long` = 64-bits), don't care about ABI compatibility with existing binaries, and are willing to give up some other minor features, you can have portable code. This can make sense for specialized domains such as an in-kernel language.

Safety Guarantees

Many of the languages above are also "safe" languages: it is impossible for a program written in Java to corrupt its address space and crash the process (assuming the JVM has no bugs). Safety is an interesting property that requires a combination of language design, runtime support, and often operating system support.

It is certainly possible to implement a safe language in LLVM, but LLVM IR does not itself guarantee safety. The LLVM IR allows unsafe pointer casts, use after free bugs, buffer over-runs, and a variety of other problems. Safety needs to be implemented as a layer on top of LLVM and, conveniently, several groups have investigated this. Ask on the [llvm-dev mailing list](#) if you are interested in more details.

Language-Specific Optimizations

One thing about LLVM that turns off many people is that it does not solve all the world's problems in one system (sorry 'world hunger', someone else will have to solve you some other day). One specific complaint is that people perceive LLVM as being incapable of performing high-level language-specific optimization: LLVM "loses too much information".

Unfortunately, this is really not the place to give you a full and unified version of "Chris Lattner's theory of compiler design". Instead, I'll make a few observations:

First, you're right that LLVM does lose information. For example, as of this writing, there is no way to distinguish in the LLVM IR whether an SSA-value came from a C "int" or a C "long" on an ILP32 machine (other than debug info). Both get compiled down to an 'i32' value and the information about what it came from is lost. The more general issue here, is that the LLVM type system uses "structural equivalence" instead of "name equivalence". Another place this surprises people is if you have two types in a high-level language that have the same structure (e.g. two different structs that have a single int field): these types will compile down into a single LLVM type and it will be impossible to tell what it came from.

Second, while LLVM does lose information, LLVM is not a fixed target: we continue to enhance and improve it in many different ways. In addition to adding new features (LLVM did not always support exceptions or debug info), we also extend the IR to capture important information for optimization (e.g. whether an argument is sign or zero extended, information about pointers aliasing, etc). Many of the enhancements are user-driven: people want LLVM to include some specific feature, so they go ahead and extend it.

Third, it is *possible and easy* to add language-specific optimizations, and you have a number of choices in how to do it. As one trivial example, it is easy to add language-specific optimization passes that "know" things about code compiled for a language. In the case of the C family, there is an optimization pass that "knows" about the standard C library functions. If you call "exit(0)" in main(), it knows that it is safe to optimize that into "return 0;" because C specifies what the 'exit' function does.

In addition to simple library knowledge, it is possible to embed a variety of other language-specific information into the LLVM IR. If you have a specific need and run into a wall, please bring the topic up on the `llvm-dev` list. At the very worst, you can always treat LLVM as if it were a "dumb code generator" and implement the high-level optimizations you desire in your front-end, on the language-specific AST.

Tips and Tricks

There is a variety of useful tips and tricks that you come to know after working on/with LLVM that aren't obvious at first glance. Instead of letting everyone rediscover them, this section talks about some of these issues.

Implementing portable `offsetof/sizeof`

One interesting thing that comes up, if you are trying to keep the code generated by your compiler "target independent", is that you often need to know the size of some LLVM type or the offset of some field in an `llvm` structure. For example, you might need to pass the size of a type into a function that allocates memory.

Unfortunately, this can vary widely across targets: for example the width of a pointer is trivially target-specific. However, there is a [clever way to use the `getelementptr` instruction](#) that allows you to compute this in a portable way.

Garbage Collected Stack Frames

Some languages want to explicitly manage their stack frames, often so that they are garbage collected or to allow easy implementation of closures. There are often better ways to implement these features than explicit stack frames, but [LLVM does support them](#), if you want. It requires your front-end to convert the code into [Continuation Passing Style](#) and the use of tail calls (which LLVM also supports).

2.20.3 Building a JIT in LLVM

Building a JIT: Starting out with KaleidoscopeJIT

- *Chapter 1 Introduction*
- *JIT API Basics*
- *KaleidoscopeJIT*
- *Full Code Listing*

Chapter 1 Introduction

Warning: This tutorial is currently being updated to account for ORC API changes. Only Chapters 1 and 2 are up-to-date.

Example code from Chapters 3 to 5 will compile and run, but has not been updated

Welcome to Chapter 1 of the "Building an ORC-based JIT in LLVM" tutorial. This tutorial runs through the implementation of a JIT compiler using LLVM's On-Request-Compilation (ORC) APIs. It begins with a simplified version of the `KaleidoscopeJIT` class used in the [Implementing a language with LLVM](#) tutorials and then introduces new features like concurrent compilation, optimization, lazy compilation and remote execution.

The goal of this tutorial is to introduce you to LLVM's ORC JIT APIs, show how these APIs interact with other parts of LLVM, and to teach you how to recombine them to build a custom JIT that is suited to your use-case.

The structure of the tutorial is:

- **Chapter #1:** Investigate the simple `KaleidoscopeJIT` class. This will introduce some of the basic concepts of the ORC JIT APIs, including the idea of an ORC *Layer*.
- **Chapter #2:** Extend the basic `KaleidoscopeJIT` by adding a new layer that will optimize IR and generated code.
- **Chapter #3:** Further extend the JIT by adding a `Compile-On-Demand` layer to lazily compile IR.
- **Chapter #4:** Improve the laziness of our JIT by replacing the `Compile-On-Demand` layer with a custom layer that uses the ORC `Compile Callbacks` API directly to defer IR-generation until functions are called.
- **Chapter #5:** Add process isolation by JITing code into a remote process with reduced privileges using the JIT Remote APIs.

To provide input for our JIT we will use a lightly modified version of the `Kaleidoscope REPL` from [Chapter 7](#) of the "Implementing a language in LLVM tutorial".

Finally, a word on API generations: ORC is the 3rd generation of LLVM JIT API. It was preceded by MCJIT, and before that by the (now deleted) legacy JIT. These tutorials don't assume any experience with these earlier APIs, but readers acquainted with them will see many familiar elements. Where appropriate we will make this connection with the earlier APIs explicit to help people who are transitioning from them to ORC.

JIT API Basics

The purpose of a JIT compiler is to compile code "on-the-fly" as it is needed, rather than compiling whole programs to disk ahead of time as a traditional compiler does. To support that aim our initial, bare-bones JIT API will have just two functions:

1. `Error addModule(std::unique_ptr<Module> M)`: Make the given IR module available for execution.
2. `Expected<JITEvaluatedSymbol> lookup()`: Search for pointers to symbols (functions or variables) that have been added to the JIT.

A basic use-case for this API, executing the 'main' function from a module, will look like:

```
JIT J;
J.addModule(buildModule());
auto *Main = (int (*)(int, char*))J.lookup("main").getAddress();
int Result = Main();
```

The APIs that we build in these tutorials will all be variations on this simple theme. Behind this API we will refine the implementation of the JIT to add support for concurrent compilation, optimization and lazy compilation. Eventually we will extend the API itself to allow higher-level program representations (e.g. ASTs) to be added to the JIT.

KaleidoscopeJIT

In the previous section we described our API, now we examine a simple implementation of it: The KaleidoscopeJIT class¹ that was used in the [Implementing a language with LLVM](#) tutorials. We will use the REPL code from [Chapter 7](#) of that tutorial to supply the input for our JIT: Each time the user enters an expression the REPL will add a new IR module containing the code for that expression to the JIT. If the expression is a top-level expression like '1+1' or 'sin(x)', the REPL will also use the lookup method of our JIT class find and execute the code for the expression. In later chapters of this tutorial we will modify the REPL to enable new interactions with our JIT class, but for now we will take this setup for granted and focus our attention on the implementation of our JIT itself.

Our KaleidoscopeJIT class is defined in the KaleidoscopeJIT.h header. After the usual include guards and #includes², we get to the definition of our class:

```
#ifndef LLVM_EXECUTIONENGINE_ORC_KALEIDOSCOPEJIT_H
#define LLVM_EXECUTIONENGINE_ORC_KALEIDOSCOPEJIT_H

#include "llvm/ADT/StringRef.h"
#include "llvm/ExecutionEngine/JITSymbol.h"
#include "llvm/ExecutionEngine/Orc/CompileUtils.h"
#include "llvm/ExecutionEngine/Orc/Core.h"
#include "llvm/ExecutionEngine/Orc/ExecutionUtils.h"
#include "llvm/ExecutionEngine/Orc/IRCompileLayer.h"
#include "llvm/ExecutionEngine/Orc/JITTargetMachineBuilder.h"
#include "llvm/ExecutionEngine/Orc/RTDyldObjectLinkingLayer.h"
#include "llvm/ExecutionEngine/SectionMemoryManager.h"
#include "llvm/IR/DataLayout.h"
#include "llvm/IR/LLVMContext.h"
#include <memory>

namespace llvm {
namespace orc {

class KaleidoscopeJIT {
private:
    ExecutionSession ES;
    RTDyldObjectLinkingLayer ObjectLayer;
    IRCompileLayer CompileLayer;

    DataLayout DL;
    ManglerAndInterner Mangler;
    ThreadSafeContext Ctx;
};
};
};
```

(continues on next page)

¹ Actually we use a cut-down version of KaleidoscopeJIT that makes a simplifying assumption: symbols cannot be re-defined. This will make it impossible to re-define symbols in the REPL, but will make our symbol lookup logic simpler. Re-introducing support for symbol redefinition is left as an exercise for the reader. (The KaleidoscopeJIT.h used in the original tutorials will be a helpful reference).

²

File	Reason for inclusion
JITSymbol.h	Defines the lookup result type JITEvaluatedSymbol

(continued from previous page)

```

public:
    KaleidoscopeJIT(JITTargetMachineBuilder JTMB, DataLayout DL)
        : ObjectLayer(ES,
            []() { return llvm::make_unique<SectionMemoryManager>(); }),
        CompileLayer(ES, ObjectLayer, ConcurrentIRCompiler(std::move(JTMB)),
            DL(std::move(DL)), Mangler(ES, this->DL),
            Ctx(llvm::make_unique<LLVMContext>()) {
        ES.getMainJITDylib().setGenerator(
            cantFail(DynamicLibrarySearchGenerator::GetForCurrentProcess(DL)));
    }

```

Our class begins with six member variables: An `ExecutionSession` member, `ES`, which provides context for our running JIT'd code (including the string pool, global mutex, and error reporting facilities); An `RTDyldObjectLinkingLayer`, `ObjectLayer`, that can be used to add object files to our JIT (though we will not use it directly); An `IRCompileLayer`, `CompileLayer`, that can be used to add LLVM Modules to our JIT (and which builds on the `ObjectLayer`); A `DataLayout` and `MangleAndInterner`, `DL` and `Mangler`, that will be used for symbol mangling (more on that later); and finally an `LLVMContext` that clients will use when building IR files for the JIT.

Next up we have our class constructor, which takes a `JITTargetMachineBuilder` that will be used by our `IRCompiler`, and a `DataLayout` that we will use to initialize our `DL` member. The constructor begins by initializing our `ObjectLayer`. The `ObjectLayer` requires a reference to the `ExecutionSession`, and a function object that will build a JIT memory manager for each module that is added (a JIT memory manager manages memory allocations, memory permissions, and registration of exception handlers for JIT'd code). For this we use a lambda that returns a `SectionMemoryManager`, an off-the-shelf utility that provides all the basic memory management functionality required for this chapter. Next we initialize our `CompileLayer`. The `CompileLayer` needs three things: (1) A reference to the `ExecutionSession`, (2) A reference to our object layer, and (3) a compiler instance to use to perform the actual compilation from IR to object files. We use the off-the-shelf `ConcurrentIRCompiler` utility as our compiler, which we construct using this constructor's `JITTargetMachineBuilder` argument. The `ConcurrentIRCompiler` utility will use the `JITTargetMachineBuilder` to build `llvm TargetMachines` (which are not thread safe) as needed for compiles. After this, we initialize our supporting members: `DL`, `Mangler` and `Ctx` with the input `DataLayout`, the `ExecutionSession` and `DL` member, and a new default constructed `LLVMContext` respectively. Now that our members have been initialized, so the one thing that remains to do is to tweak the configuration of the `JITDylib` that we will store our code in. We want to modify this dylib to contain not only the symbols that we add to it, but also the symbols from our REPL process as well. We do this by attaching a `DynamicLibrarySearchGenerator` instance using the `DynamicLibrarySearchGenerator::GetForCurrentProcess` method.

```

static Expected<std::unique_ptr<KaleidoscopeJIT>> Create() {
    auto JTMB = JITTargetMachineBuilder::detectHost();

    if (!JTMB)
        return JTMB.takeError();

    auto DL = JTMB->getDefaultDataLayoutForTarget();
    if (!DL)
        return DL.takeError();

    return llvm::make_unique<KaleidoscopeJIT>(std::move(*JTMB), std::move(*DL));
}

const DataLayout &getDataLayout() const { return DL; }

LLVMContext &getContext() { return *Ctx.getContext(); }

```

Next we have a named constructor, `Create`, which will build a `KaleidoscopeJIT` instance that is configured to generate code for our host process. It does this by first generating a `JITTargetMachineBuilder` instance using that class's

detectHost method and then using that instance to generate a datalayout for the target process. Each of these operations can fail, so each returns its result wrapped in an Expected value³ that we must check for error before continuing. If both operations succeed we can unwrap their results (using the dereference operator) and pass them into KaleidoscopeJIT's constructor on the last line of the function.

Following the named constructor we have the getDataLayout() and getContext() methods. These are used to make data structures created and managed by the JIT (especially the LLVMContext) available to the REPL code that will build our IR modules.

```
void addModule(std::unique_ptr<Module> M) {
    cantFail(CompileLayer.add(ES.getMainJITDylib(),
                             ThreadSafeModule(std::move(M), Ctx)));
}

Expected<JITEvaluatedSymbol> lookup(StringRef Name) {
    return ES.lookup({&ES.getMainJITDylib()}, Mangle(Name.str()));
}
```

Now we come to the first of our JIT API methods: addModule. This method is responsible for adding IR to the JIT and making it available for execution. In this initial implementation of our JIT we will make our modules "available for execution" by adding them to the CompileLayer, which will in turn store the Module in the main JITDylib. This process will create new symbol table entries in the JITDylib for each definition in the module, and will defer compilation of the module until any of its definitions is looked up. Note that this is not lazy compilation: just referencing a definition, even if it is never used, will be enough to trigger compilation. In later chapters we will teach our JIT to defer compilation of functions until they're actually called. To add our Module we must first wrap it in a ThreadSafeModule instance, which manages the lifetime of the Module's LLVMContext (our Ctx member) in a thread-friendly way. In our example, all modules will share the Ctx member, which will exist for the duration of the JIT. Once we switch to concurrent compilation in later chapters we will use a new context per module.

Our last method is lookup, which allows us to look up addresses for function and variable definitions added to the JIT based on their symbol names. As noted above, lookup will implicitly trigger compilation for any symbol that has not already been compiled. Our lookup method calls through to *ExecutionSession::lookup*, passing in a list of dylibs to search (in our case just the main dylib), and the symbol name to search for, with a twist: We have to *mangle* the name of the symbol we're searching for first. The ORC JIT components use mangled symbols internally the same way a static compiler and linker would, rather than using plain IR symbol names. This allows JIT'd code to interoperate easily with precompiled code in the application or shared libraries. The kind of mangling will depend on the DataLayout, which in turn depends on the target platform. To allow us to remain portable and search based on the un-mangled name, we just re-produce this mangling ourselves using our Mangle member function object.

This brings us to the end of Chapter 1 of Building a JIT. You now have a basic but fully functioning JIT stack that you can use to take LLVM IR and make it executable within the context of your JIT process. In the next chapter we'll look at how to extend this JIT to produce better quality code, and in the process take a deeper look at the ORC layer concept.

Next: Extending the KaleidoscopeJIT

³ See the ErrorHandling section in the LLVM Programmer's Manual (<http://llvm.org/docs/ProgrammersManual.html#error-handling>)

Full Code Listing

Here is the complete code listing for our running example. To build this example, use:

```
# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orcjit_
↪native` -O3 -o toy
# Run
./toy
```

Here is the code:

```

Building a JIT: Adding Optimizations -- An introduction to ORC Layers

- *Chapter 2 Introduction*
- *Optimizing Modules using the IRTransformLayer*
- *Full Code Listing*

This tutorial is under active development. It is incomplete and details may change frequently. Nonetheless we invite you to try it out as it stands, and we welcome any feedback.

Chapter 2 Introduction

Warning: This tutorial is currently being updated to account for ORC API changes. Only Chapters 1 and 2 are up-to-date.

Example code from Chapters 3 to 5 will compile and run, but has not been updated

Welcome to Chapter 2 of the "Building an ORC-based JIT in LLVM" tutorial. In [Chapter 1](#) of this series we examined a basic JIT class, KaleidoscopeJIT, that could take LLVM IR modules as input and produce executable code in memory. KaleidoscopeJIT was able to do this with relatively little code by composing two off-the-shelf *ORC layers*: IRCompileLayer and ObjectLinkingLayer, to do much of the heavy lifting.

In this layer we'll learn more about the ORC layer concept by using a new layer, IRTransformLayer, to add IR optimization support to KaleidoscopeJIT.

Optimizing Modules using the IRTransformLayer

In [Chapter 4](#) of the "Implementing a language with LLVM" tutorial series the `llvm::FunctionPassManager` is introduced as a means for optimizing LLVM IR. Interested readers may read that chapter for details, but in short: to optimize a Module we create an `llvm::FunctionPassManager` instance, configure it with a set of optimizations, then run the PassManager on a Module to mutate it into a (hopefully) more optimized but semantically equivalent form. In the original tutorial series the FunctionPassManager was created outside the KaleidoscopeJIT and modules were optimized before being added to it. In this Chapter we will make optimization a phase of our JIT instead. For now this will provide us a motivation to learn more about ORC layers, but in the long term making optimization part of our JIT will yield an important benefit: When we begin lazily compiling code (i.e. deferring compilation of each function until the first time it's run) having optimization managed by our JIT will allow us to optimize lazily too, rather than having to do all our optimization up-front.

To add optimization support to our JIT we will take the KaleidoscopeJIT from Chapter 1 and compose an ORC *IRTransformLayer* on top. We will look at how the IRTransformLayer works in more detail below, but the interface is simple: the constructor for this layer takes a reference to the execution session and the layer below (as all layers do) plus an *IR optimization function* that it will apply to each Module that is added via `addModule`:

```
class KaleidoscopeJIT {
private:
    ExecutionSession ES;
    RTDyldObjectLinkingLayer ObjectLayer;
    IRCompileLayer CompileLayer;
    IRTransformLayer TransformLayer;

    DataLayout DL;
    ManglerAndInterner Mangler;
    ThreadSafeContext Ctx;

public:
    KaleidoscopeJIT(JITTargetMachineBuilder JTMB, DataLayout DL)
        : ObjectLayer(ES,
            []() { return llvm::make_unique<SectionMemoryManager>(); }),
          CompileLayer(ES, ObjectLayer, ConcurrentIRCompiler(std::move(JTMB))),
          TransformLayer(ES, CompileLayer, optimizeModule),
          DL(std::move(DL)), Mangler(ES, this->DL),
          Ctx(llvm::make_unique<LLVMContext>()) {
        ES.getMainJITDylib().setGenerator(
            cantFail(DynamicLibrarySearchGenerator::GetForCurrentProcess(DL)));
    }
}
```

Our extended KaleidoscopeJIT class starts out the same as it did in Chapter 1, but after the CompileLayer we introduce a new member, TransformLayer, which sits on top of our CompileLayer. We initialize our OptimizeLayer with a reference to the ExecutionSession and output layer (standard practice for layers), along with a *transform function*. For our transform function we supply our classes optimizeModule static method.

```
// ...
return cantFail(OptimizeLayer.addModule(std::move(M),
                                         std::move(Resolver)));
// ...
```

Next we need to update our addModule method to replace the call to CompileLayer::add with a call to OptimizeLayer::add instead.

```
static Expected<ThreadSafeModule>
optimizeModule(ThreadSafeModule M, const MaterializationResponsibility &R) {
    // Create a function pass manager.
    auto FPM = llvm::make_unique<legacy::FunctionPassManager>(M.get());

    // Add some optimizations.
    FPM->add(createInstructionCombiningPass());
    FPM->add(createReassociatePass());
    FPM->add(createGVNPass());
    FPM->add(createCFGSimplificationPass());
    FPM->doInitialization();

    // Run the optimizations over all functions in the module being added to
    // the JIT.
    for (auto &F : *M)
        FPM->run(F);

    return M;
}
```

At the bottom of our JIT we add a private method to do the actual optimization: *optimizeModule*. This function takes the module to be transformed as input (as a ThreadSafeModule) along with a reference to a new class: MaterializationResponsibility. The MaterializationResponsibility argument can be used to query JIT state for the module being transformed, such as the set of definitions in the module that JIT'd code is actively trying to call/access. For now we will ignore this argument and use a standard optimization pipeline. To do this we set up a FunctionPassManager, add some passes to it, run it over every function in the module, and then return the mutated module. The specific optimizations are the same ones used in [Chapter 4](#) of the "Implementing a language with LLVM" tutorial series. Readers may visit that chapter for a more in-depth discussion of these, and of IR optimization in general.

And that's it in terms of changes to KaleidoscopeJIT: When a module is added via addModule the OptimizeLayer will call our optimizeModule function before passing the transformed module on to the CompileLayer below. Of course, we could have called optimizeModule directly in our addModule function and not gone to the bother of using the IRTransformLayer, but doing so gives us another opportunity to see how layers compose. It also provides a neat entry point to the *layer* concept itself, because IRTransformLayer is one of the simplest layers that can be implemented.

```
// From IRTransformLayer.h:
class IRTransformLayer : public IRLayer {
public:
    using TransformFunction = std::function<Expected<ThreadSafeModule>(
        ThreadSafeModule, const MaterializationResponsibility &R)>;

    IRTransformLayer(ExecutionSession &ES, IRLayer &BaseLayer,
                    TransformFunction Transform = identityTransform);
```

(continues on next page)

(continued from previous page)

```

void setTransform(TransformFunction Transform) {
    this->Transform = std::move(Transform);
}

static ThreadSafeModule
identityTransform(ThreadSafeModule TSM,
                  const MaterializationResponsibility &R) {
    return TSM;
}

void emit(MaterializationResponsibility R, ThreadSafeModule TSM) override;

private:
    IRLayer &BaseLayer;
    TransformFunction Transform;
};

// From IRTransformLayer.cpp:

IRTransformLayer::IRTransformLayer(ExecutionSession &ES,
                                   IRLayer &BaseLayer,
                                   TransformFunction Transform)
    : IRLayer(ES), BaseLayer(BaseLayer), Transform(std::move(Transform)) {}

void IRTransformLayer::emit(MaterializationResponsibility R,
                            ThreadSafeModule TSM) {
    assert(TSM.getModule() && "Module must not be null");

    if (auto TransformedTSM = Transform(std::move(TSM), R))
        BaseLayer.emit(std::move(R), std::move(*TransformedTSM));
    else {
        R.failMaterialization();
        getExecutionSession().reportError(TransformedTSM.takeError());
    }
}

```

This is the whole definition of `IRTransformLayer`, from `llvm/include/llvm/ExecutionEngine/Orc/IRTransformLayer.h` and `llvm/lib/ExecutionEngine/Orc/IRTransformLayer.cpp`. This class is concerned with two very simple jobs: (1) Running every IR Module that is emitted via this layer through the transform function object, and (2) implementing the ORC `IRLayer` interface (which itself conforms to the general ORC Layer concept, more on that below). Most of the class is straightforward: a typedef for the transform function, a constructor to initialize the members, a setter for the transform function value, and a default no-op transform. The most important method is `emit` as this is half of our `IRLayer` interface. The `emit` method applies our transform to each module that it is called on and, if the transform succeeds, passes the transformed module to the base layer. If the transform fails, our `emit` function calls `MaterializationResponsibility::failMaterialization` (this JIT clients who may be waiting on other threads know that the code they were waiting for has failed to compile) and logs the error with the execution session before bailing out.

The other half of the `IRLayer` interface we inherit unmodified from the `IRLayer` class:

```

Error IRLayer::add(JITDylib &JD, ThreadSafeModule TSM, VModuleKey K) {
    return JD.define(llvm::make_unique<BasicIRLayerMaterializationUnit>(
        *this, std::move(K), std::move(TSM)));
}

```

This code, from `llvm/lib/ExecutionEngine/Orc/Layer.cpp`, adds a `ThreadSafeMod-`

ule to a given JITDylib by wrapping it up in a MaterializationUnit (in this case a BasicIRLayerMaterializationUnit). Most layers that derived from IRLayer can rely on this default implementation of the add method.

These two operations, add and emit, together constitute the layer concept: A layer is a way to wrap a portion of a compiler pipeline (in this case the "opt" phase of an LLVM compiler) whose API is opaque to ORC in an interface that allows ORC to invoke it when needed. The add method takes an module in some input program representation (in this case an LLVM IR module) and stores it in the target JITDylib, arranging for it to be passed back to the Layer's emit method when any symbol defined by that module is requested. Layers can compose neatly by calling the 'emit' method of a base layer to complete their work. For example, in this tutorial our IRTransformLayer calls through to our IRCompileLayer to compile the transformed IR, and our IRCompileLayer in turn calls our ObjectLayer to link the object file produced by our compiler.

So far we have learned how to optimize and compile our LLVM IR, but we have not focused on when compilation happens. Our current REPL is eager: Each function definition is optimized and compiled as soon as it is referenced by any other code, regardless of whether it is ever called at runtime. In the next chapter we will introduce fully lazy compilation, in which functions are not compiled until they are first called at run-time. At this point the trade-offs get much more interesting: the lazier we are, the quicker we can start executing the first function, but the more often we will have to pause to compile newly encountered functions. If we only code-gen lazily, but optimize eagerly, we will have a longer startup time (as everything is optimized) but relatively short pauses as each function just passes through code-gen. If we both optimize and code-gen lazily we can start executing the first function more quickly, but we will have longer pauses as each function has to be both optimized and code-gen'd when it is first executed. Things become even more interesting if we consider interprocedural optimizations like inlining, which must be performed eagerly. These are complex trade-offs, and there is no one-size-fits all solution to them, but by providing composable layers we leave the decisions to the person implementing the JIT, and make it easy for them to experiment with different configurations.

Next: Adding Per-function Lazy Compilation

Full Code Listing

Here is the complete code listing for our running example with an IRTransformLayer added to enable optimization. To build this example, use:

```
# Compile

Building a JIT: Per-function Lazy Compilation

- [Chapter 3 Introduction](#)
- [Lazy Compilation](#)
- [Full Code Listing](#)

This tutorial is under active development. It is incomplete and details may change frequently. Nonetheless we invite you to try it out as it stands, and we welcome any feedback.

Chapter 3 Introduction

Warning: This text is currently out of date due to ORC API updates.

The example code has been updated and can be used. The text will be updated once the API churn dies down.

Welcome to Chapter 3 of the "Building an ORC-based JIT in LLVM" tutorial. This chapter discusses lazy JITing and shows you how to enable it by adding an ORC CompileOnDemand layer the JIT from [Chapter 2](#).

Lazy Compilation

When we add a module to the KaleidoscopeJIT class from Chapter 2 it is immediately optimized, compiled and linked for us by the IRTransformLayer, IRCompileLayer and RTDyldObjectLinkingLayer respectively. This scheme, where all the work to make a Module executable is done up front, is simple to understand and its performance characteristics are easy to reason about. However, it will lead to very high startup times if the amount of code to be compiled is large, and may also do a lot of unnecessary compilation if only a few compiled functions are ever called at runtime. A truly "just-in-time" compiler should allow us to defer the compilation of any given function until the moment that function is first called, improving launch times and eliminating redundant work. In fact, the ORC APIs provide us with a layer to lazily compile LLVM IR: *CompileOnDemandLayer*.

The CompileOnDemandLayer class conforms to the layer interface described in Chapter 2, but its addModule method behaves quite differently from the layers we have seen so far: rather than doing any work up front, it just scans the Modules being added and arranges for each function in them to be compiled the first time it is called. To do this, the CompileOnDemandLayer creates two small utilities for each function that it scans: a *stub* and a *compile callback*. The stub is a pair of a function pointer (which will be pointed at the function's implementation once the function has been compiled) and an indirect jump through the pointer. By fixing the address of the indirect jump for the lifetime of the program we can give the function a permanent "effective address", one that can be safely used for indirection and function pointer comparison even if the function's implementation is never compiled, or if it is compiled more than once (due to, for example, recompiling the function at a higher optimization level) and changes address. The second utility, the compile callback, represents a re-entry point from the program into the compiler that will trigger compilation and then execution of a function. By initializing the function's stub to point at the function's compile callback, we enable lazy compilation: The first attempted call to the function will follow the function pointer and trigger the compile callback instead. The compile callback will compile the function, update the function pointer for the stub, then execute the function. On all subsequent calls to the function, the function pointer will point at the already-compiled function, so there is no further overhead from the compiler. We will look at this process in more detail in the next chapter of this tutorial, but for now we'll trust the CompileOnDemandLayer to set all the stubs and callbacks up for us. All we need to do is to add the CompileOnDemandLayer to the top of our stack and we'll get the benefits of lazy compilation. We just need a few changes to the source:

```
...
#include "llvm/ExecutionEngine/SectionMemoryManager.h"
#include "llvm/ExecutionEngine/Orc/CompileOnDemandLayer.h"
#include "llvm/ExecutionEngine/Orc/CompileUtils.h"
...

...
class KaleidoscopeJIT {
private:
    std::unique_ptr<TargetMachine> TM;
    const DataLayout DL;
    RTDyldObjectLinkingLayer ObjectLayer;
    IRCompileLayer<decltype(ObjectLayer), SimpleCompiler> CompileLayer;

    using OptimizeFunction =
        std::function<std::shared_ptr<Module>(std::shared_ptr<Module>)>;
```

(continues on next page)

(continued from previous page)

```

IRTransformLayer<decltype(CompileLayer), OptimizeFunction> OptimizeLayer;

std::unique_ptr<JITCompileCallbackManager> CompileCallbackManager;
CompileOnDemandLayer<decltype(OptimizeLayer)> CODLayer;

public:
    using ModuleHandle = decltype(CODLayer)::ModuleHandleT;

```

First we need to include the `CompileOnDemandLayer.h` header, then add two new members: a `std::unique_ptr<JITCompileCallbackManager>` and a `CompileOnDemandLayer`, to our class. The `CompileCallbackManager` member is used by the `CompileOnDemandLayer` to create the compile callback needed for each function.

```

KaleidoscopeJIT()
: TM(EngineBuilder().selectTarget()), DL(TM->createDataLayout()),
  ObjectLayer([]() { return std::make_shared<SectionMemoryManager>(); }),
  CompileLayer(ObjectLayer, SimpleCompiler(*TM)),
  OptimizeLayer(CompileLayer,
    [this](std::shared_ptr<Module> M) {
        return optimizeModule(std::move(M));
    }),
  CompileCallbackManager(
    orc::createLocalCompileCallbackManager(TM->getTargetTriple(), 0)),
  CODLayer(OptimizeLayer,
    [this](Function &F) { return std::set<Function*>({&F}); },
    *CompileCallbackManager,
    orc::createLocalIndirectStubsManagerBuilder(
      TM->getTargetTriple())) {
    llvm::sys::DynamicLibrary::LoadLibraryPermanently(nullptr);
}

```

Next we have to update our constructor to initialize the new members. To create an appropriate compile callback manager we use the `createLocalCompileCallbackManager` function, which takes a `TargetMachine` and a `JITTargetAddress` to call if it receives a request to compile an unknown function. In our simple JIT this situation is unlikely to come up, so we'll cheat and just pass '0' here. In a production quality JIT you could give the address of a function that throws an exception in order to unwind the JIT'd code's stack.

Now we can construct our `CompileOnDemandLayer`. Following the pattern from previous layers we start by passing a reference to the next layer down in our stack -- the `OptimizeLayer`. Next we need to supply a 'partitioning function': when a not-yet-compiled function is called, the `CompileOnDemandLayer` will call this function to ask us what we would like to compile. At a minimum we need to compile the function being called (given by the argument to the partitioning function), but we could also request that the `CompileOnDemandLayer` compile other functions that are unconditionally called (or highly likely to be called) from the function being called. For `KaleidoscopeJIT` we'll keep it simple and just request compilation of the function that was called. Next we pass a reference to our `CompileCallbackManager`. Finally, we need to supply an "indirect stubs manager builder": a utility function that constructs `IndirectStubManagers`, which are in turn used to build the stubs for the functions in each module. The `CompileOnDemandLayer` will call the indirect stub manager builder once for each call to `addModule`, and use the resulting indirect stubs manager to create stubs for all functions in all modules in the set. If/when the module set is removed from the JIT the indirect stubs manager will be deleted, freeing any memory allocated to the stubs. We supply this function by using the `createLocalIndirectStubsManagerBuilder` utility.

```

// ...
    if (auto Sym = CODLayer.findSymbol(Name, false))
// ...
return cantFail(CODLayer.addModule(std::move(Ms),

```

(continues on next page)

(continued from previous page)

```

std::move(Resolver));
// ...
// ...
return CODLayer.findSymbol(MangledNameStream.str(), true);
// ...
// ...
CODLayer.removeModule(H);
// ...

```

Finally, we need to replace the references to `OptimizeLayer` in our `addModule`, `findSymbol`, and `removeModule` methods. With that, we're up and running.

To be done:

**** Chapter conclusion.****

Full Code Listing

Here is the complete code listing for our running example with a `CompileOnDemand` layer added to enable lazy function-at-a-time compilation. To build this example, use:

```

# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orcjit_
↪native` -O3 -o toy
# Run
./toy

```

Here is the code:

```

Building a JIT: Extreme Laziness - Using Compile Callbacks to JIT from ASTs

- *Chapter 4 Introduction*
- *Full Code Listing*

This tutorial is under active development. It is incomplete and details may change frequently. Nonetheless we invite you to try it out as it stands, and we welcome any feedback.

Chapter 4 Introduction

Welcome to Chapter 4 of the "Building an ORC-based JIT in LLVM" tutorial. This chapter introduces the Compile Callbacks and Indirect Stubs APIs and shows how they can be used to replace the CompileOnDemand layer from [Chapter 3](#) with a custom lazy-JITing scheme that JITs directly from Kaleidoscope ASTs.

To be done:

- (1) **Describe the drawbacks of JITing from IR (have to compile to IR first, which reduces the benefits of laziness).**
- (2) **Describe CompileCallbackManagers and IndirectStubManagers in detail.**
- (3) **Run through the implementation of addFunctionAST.**

Full Code Listing

Here is the complete code listing for our running example that JITs lazily from Kaleidoscope ASTs. To build this example, use:

```

# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orcjit_
↪native` -O3 -o toy
# Run
./toy

```

Here is the code:

Next: Remote-JITing -- Process-isolation and laziness-at-a-distance

Building a JIT: Remote-JITing -- Process Isolation and Laziness at a Distance

- *Chapter 5 Introduction*
- *Full Code Listing*

This tutorial is under active development. It is incomplete and details may change frequently. Nonetheless we invite you to try it out as it stands, and we welcome any feedback.

Chapter 5 Introduction

Welcome to Chapter 5 of the "Building an ORC-based JIT in LLVM" tutorial. This chapter introduces the ORC RemoteJIT Client/Server APIs and shows how to use them to build a JIT stack that will execute its code via a communications channel with a different process. This can be a separate process on the same machine, a process on a different machine, or even a process on a different platform/architecture. The code builds on top of the lazy-AST-compiling JIT stack from [Chapter 4](#).

To be done -- this is going to be a long one:

- (1) Introduce channels, RPC, RemoteJIT Client and Server APIs
- (2) Describe the client code in greater detail. Discuss modifications of the KaleidoscopeJIT class, and the REPL itself.
- (3) Describe the server code.
- (4) Describe how to run the demo.

Full Code Listing

Here is the complete code listing for our running example that JITs lazily from Kaleidoscope ASTS. To build this example, use:

```

# Compile
clang++ -g toy.cpp `llvm-config --cxxflags --ldflags --system-libs --libs core orcjit_
↪native` -O3 -o toy
clang++ -g Server/server.cpp `llvm-config --cxxflags --ldflags --system-libs --libs_
↪core orcjit native` -O3 -o toy-server
# Run
./toy-server &
./toy

```

Here is the code for the modified KaleidoscopeJIT:

```

//===- KaleidoscopeJIT.h - A simple JIT for Kaleidoscope -----*- C++ -*-===//

- *Additional Information*

2.21.1 Introduction

This document contains the release notes for the LLVM Compiler Infrastructure, release 9.0.0. Here we describe the status of LLVM, including major improvements from the previous release, improvements in various subprojects of LLVM, and some of the current users of the code. All LLVM releases may be downloaded from the [LLVM releases web site](#).

For more information about LLVM, including information about the latest release, please check out the [main LLVM web site](#). If you have questions or comments, the [LLVM Developer's Mailing List](#) is a good place to send them.

2.21.2 Known Issues

These are issues that couldn't be fixed before the release. See the bug reports for the latest status.

- [PR40547](#) Clang gets miscompiled by GCC 9.

2.21.3 Non-comprehensive list of changes in this release

- Two new extension points, namely `EP_FullLinkTimeOptimizationEarly` and `EP_FullLinkTimeOptimizationLast` are available for plugins to specialize the legacy pass manager full LTO pipeline.
- `llvm-objcopy/llvm-strip` got support for COFF object files/executables, supporting the most common copying/stripping options.
- The CMake parameter `CLANG_ANALYZER_ENABLE_Z3_SOLVER` has been replaced by `LLVM_ENABLE_Z3_SOLVER`.
- The RISCv target is no longer "experimental" (see *Changes to the RISCv Target* below for more details).
- The ORCv1 JIT API has been deprecated. Please see [Transitioning from ORCv1 to ORCv2](#).
- Support for target-independent hardware loops in IR has been added, with PowerPC and Arm implementations.

Noteworthy optimizations

- LLVM will now remove stores to constant memory (since this is a contradiction) under the assumption the code in question must be dead. This has proven to be problematic for some C/C++ code bases which expect to be able to cast away 'const'. This is (and has always been) undefined behavior, but up until now had not been actively utilized for optimization purposes in this exact way. For more information, please see: [bug 42763](#) and [post commit discussion](#).
- The optimizer will now convert calls to `memcmp` into a calls to `bcmp` in some circumstances. Users who are building freestanding code (not depending on the platform's libc) without specifying `-ffreestanding` may need to either pass `-fno-builtin-bcmp`, or provide a `bcmp` function.
- LLVM will now pattern match wide scalar values stored by a succession of narrow stores. For example, Clang will compile the following function that writes a 32-bit value in big-endian order in a portable manner:

```
void write32be(unsigned char *dst, uint32_t x) {
    dst[0] = x >> 24;
    dst[1] = x >> 16;
    dst[2] = x >> 8;
    dst[3] = x >> 0;
}
```

into the x86_64 code below:

```
write32be:
    bswap    esi
    mov     dword ptr [rdi], esi
    ret
```

(The corresponding read patterns have been matched since LLVM 5.)

- LLVM will now omit range checks for jump tables when lowering switches with unreachable default destination. For example, the switch dispatch in the C++ code below

```
int g(int);
enum e { A, B, C, D, E };
int f(e x, int y, int z) {
    switch(x) {
        case A: return g(y);
        case B: return g(z);
        case C: return g(y+z);
        case D: return g(x-z);
        case E: return g(x+z);
    }
}
```

will result in the following x86_64 machine code when compiled with Clang. This is because falling off the end of a non-void function is undefined behaviour in C++, and the end of the function therefore being treated as unreachable:

```
_Z1flei:
    mov     eax, edi
    jmp     qword ptr [8*rax + .LJTI0_0]
```

- LLVM can now sink similar instructions to a common successor block also when the instructions have no uses, such as calls to void functions. This allows code such as

```
void g(int);
enum e { A, B, C, D };
void f(e x, int y, int z) {
    switch(x) {
        case A: g(6); break;
        case B: g(3); break;
        case C: g(9); break;
        case D: g(2); break;
    }
}
```

to be optimized to a single call to `g`, with the argument loaded from a lookup table.

Changes to the LLVM IR

- Added `immarg` parameter attribute. This indicates an intrinsic parameter is required to be a simple constant. This annotation must be accurate to avoid possible miscompiles.
- The 2-field form of global variables `@llvm.global_ctors` and `@llvm.global_dtors` has been deleted. The third field of their element type is now mandatory. Specify *i8* null* to migrate from the obsolete 2-field form.
- The `byval` attribute can now take a type parameter: `byval(<ty>)`. If present it must be identical to the argument's pointee type. In the next release we intend to make this parameter mandatory in preparation for opaque pointer types.
- `atomicrmw xchg` now allows floating point types
- `atomicrmw` now supports `fadd` and `fsub`

Changes to building LLVM

- Building LLVM with Visual Studio now requires version 2017 or later.

Changes to the AArch64 Backend

- Assembly-level support was added for: Scalable Vector Extension 2 (SVE2) and Memory Tagging Extensions (MTE).

Changes to the ARM Backend

- Assembly-level support was added for the Armv8.1-M architecture, including the M-Profile Vector Extension (MVE).
- A pipeline model was added for Cortex-M4. This pipeline model is also used to tune for cores where this gives a benefit too: Cortex-M3, SC300, Cortex-M33 and Cortex-M35P.
- Code generation support for M-profile low-overhead loops.

Changes to the MIPS Target

- Support for `.cplocal` assembler directive.
- Support for `sge`, `sgeu`, `sgt`, `sgtu` pseudo instructions.
- Support for `o` inline asm constraint.
- Improved support of GlobalISel instruction selection framework. This feature is still in experimental state for MIPS targets though.
- Various code-gen improvements, related to improved and fixed instruction selection and encoding and floating-point registers allocation.
- Complete P5600 scheduling model.

Changes to the PowerPC Target

- Improved handling of TOC pointer spills for indirect calls
- Improve precision of square root reciprocal estimate
- Enabled MachinePipeliner support for P9 with `-ppc-enable-pipeliner`.
- MMX/SSE/SSE2 intrinsics headers have been ported to PowerPC using AltiVec.
- Machine verification failures cleaned, `EXPENSIVE_CHECKS` will run `MachineVerification` by default now.
- PowerPC scheduling enhancements, with customized PPC specific scheduler strategy.
- Inner most loop now always align to 32 bytes.
- Enhancements of hardware loops interaction with LSR.
- New builtins added, eg: `__builtin_setrnd`.
- Various codegen improvements for both scalar and vector code
- Various new exploitations and bug fixes, e.g: exploited P9 `maddld`.

Changes to the SystemZ Target

- Support for the arch13 architecture has been added. When using the `-march=arch13` option, the compiler will generate code making use of new instructions introduced with the vector enhancement facility 2 and the miscellaneous instruction extension facility 2. The `-mtune=arch13` option enables arch13 specific instruction scheduling and tuning without making use of new instructions.
- Builtins for the new vector instructions have been added and can be enabled using the `-mzvector` option. Support for these builtins is indicated by the compiler predefining the `__VEC__` macro to the value 10303.
- The compiler now supports and automatically generates alignment hints on vector load and store instructions.
- Various code-gen improvements, in particular related to improved instruction selection and register allocation.

Changes to the X86 Target

- Fixed a bug in generating DWARF unwind information for 32 bit MinGW

Changes to the AMDGPU Target

- Function call support is now enabled by default
- Improved support for 96-bit loads and stores
- DPP combiner pass is now enabled by default
- Support for gfx10

Changes to the RISC-V Target

The RISC-V target is no longer "experimental"! It's now built by default, rather than needing to be enabled with `LLVM_EXPERIMENTAL_TARGETS_TO_BUILD`.

The backend has full codegen support for the RV32I and RV64I base RISC-V instruction set variants, with the MAFDC standard extensions. We support the hard and soft-float ABIs for these targets. Testing has been performed with both Linux and bare-metal targets, including the compilation of a large corpus of Linux applications (through buildroot).

2.21.4 Changes to LLDB

- Backtraces are now color highlighting in the terminal.
- DWARF4 (`debug_types`) and DWARF5 (`debug_info`) type units are now supported.
- This release will be the last where `lldb-mi` is shipped as part of LLDB. The tool will still be available in a [downstream repository on GitHub](#).

2.21.5 External Open Source Projects Using LLVM 9

Mull - Mutation Testing tool for C and C++

[Mull](#) is an LLVM-based tool for mutation testing with a strong focus on C and C++ languages.

Portable Computing Language (pocl)

In addition to producing an easily portable open source OpenCL implementation, another major goal of [pocl](#) is improving performance portability of OpenCL programs with compiler optimizations, reducing the need for target-dependent manual optimizations. An important part of [pocl](#) is a set of LLVM passes used to statically parallelize multiple work-items with the kernel compiler, even in the presence of work-group barriers. This enables static parallelization of the fine-grained static concurrency in the work groups in multiple ways.

TTA-based Co-design Environment (TCE)

TCE is an open source toolset for designing customized processors based on the Transport Triggered Architecture (TTA). The toolset provides a complete co-design flow from C/C++ programs down to synthesizable VHDL/Verilog and parallel program binaries. Processor customization points include register files, function units, supported operations, and the interconnection network.

TCE uses Clang and LLVM for C/C++/OpenCL C language support, target independent optimizations and also for parts of code generation. It generates new LLVM-based code generators "on the fly" for the designed TTA processors and loads them in to the compiler backend as runtime libraries to avoid per-target recompilation of larger parts of the compiler chain.

Zig Programming Language

Zig is a system programming language intended to be an alternative to C. It provides high level features such as generics, compile time function execution, and partial evaluation, while exposing low level LLVM IR features such as aliases and intrinsics. Zig uses Clang to provide automatic import of .h symbols, including inline functions and simple macros. Zig uses LLD combined with lazily building compiler-rt to provide out-of-the-box cross-compiling for all supported targets.

LDC - the LLVM-based D compiler

D is a language with C-like syntax and static typing. It pragmatically combines efficiency, control, and modeling power, with safety and programmer productivity. D supports powerful concepts like Compile-Time Function Execution (CTFE) and Template Meta-Programming, provides an innovative approach to concurrency and offers many classical paradigms.

LDC uses the frontend from the reference compiler combined with LLVM as backend to produce efficient native code. LDC targets x86/x86_64 systems like Linux, OS X, FreeBSD and Windows and also Linux on ARM and PowerPC (32/64 bit). Ports to other architectures are underway.

2.21.6 Additional Information

A wide variety of additional information is available on the [LLVM web page](#), in particular in the [documentation](#) section. The web page also contains versions of the API documentation which is up-to-date with the Subversion version of the source code. You can access versions of these documents specific to this release by going into the `llvm/docs/` directory in the LLVM tree.

If you have any questions or comments about LLVM, please feel free to contact us via the [mailing lists](#).

2.22 LLVM's Analysis and Transform Passes

- *Introduction*
- *Analysis Passes*

2.22.1 Introduction

This document serves as a high level summary of the optimization features that LLVM provides. Optimizations are implemented as Passes that traverse some portion of a program to either collect information or transform the program. The table below divides the passes that LLVM provides into three categories. Analysis passes compute information that other passes can use or for debugging or program visualization purposes. Transform passes can use (or invalidate) the analysis passes. Transform passes all mutate the program in some way. Utility passes provides some utility but don't otherwise fit categorization. For example passes to extract functions to bitcode or write a module to bitcode are neither analysis nor transform passes. The table of contents above provides a quick summary of each pass and links to the more complete pass description later in the document.

2.22.2 Analysis Passes

This section describes the LLVM Analysis Passes.

`-aa-eval1`: Exhaustive Alias Analysis Precision Evaluator

This is a simple N^2 alias analysis accuracy evaluator. Basically, for each function in the program, it simply queries to see how the alias analysis implementation answers alias queries between each pair of pointers in the function.

This is inspired and adapted from code by: Naveen Neelakantam, Francesco Spadini, and Wojciech Stryjewski.

`-basicaa`: Basic Alias Analysis (stateless AA impl)

A basic alias analysis pass that implements identities (two different globals cannot alias, etc), but does no stateful analysis.

`-basiccg`: Basic CallGraph Construction

Yet to be written.

`-count-aa`: Count Alias Analysis Query Responses

A pass which can be used to count how many alias queries are being made and how the alias analysis implementation being used responds.

-da: Dependence Analysis

Dependence analysis framework, which is used to detect dependences in memory accesses.

-debug-aa: AA use debugger

This simple pass checks alias analysis users to ensure that if they create a new value, they do not query AA without informing it of the value. It acts as a shim over any other AA pass you want.

Yes keeping track of every value in the program is expensive, but this is a debugging pass.

-domfrontier: Dominance Frontier Construction

This pass is a simple dominator construction algorithm for finding forward dominator frontiers.

-domtree: Dominator Tree Construction

This pass is a simple dominator construction algorithm for finding forward dominators.

-dot-callgraph: Print Call Graph to "dot" file

This pass, only available in `opt`, prints the call graph into a `.dot` graph. This graph can then be processed with the `"dot"` tool to convert it to postscript or some other suitable format.

-dot-cfg: Print CFG of function to "dot" file

This pass, only available in `opt`, prints the control flow graph into a `.dot` graph. This graph can then be processed with the `dot` tool to convert it to postscript or some other suitable format.

-dot-cfg-only: Print CFG of function to "dot" file (with no function bodies)

This pass, only available in `opt`, prints the control flow graph into a `.dot` graph, omitting the function bodies. This graph can then be processed with the `dot` tool to convert it to postscript or some other suitable format.

-dot-dom: Print dominance tree of function to "dot" file

This pass, only available in `opt`, prints the dominator tree into a `.dot` graph. This graph can then be processed with the `dot` tool to convert it to postscript or some other suitable format.

-dot-dom-only: Print dominance tree of function to "dot" file (with no function bodies)

This pass, only available in `opt`, prints the dominator tree into a `.dot` graph, omitting the function bodies. This graph can then be processed with the `dot` tool to convert it to postscript or some other suitable format.

-dot-postdom: Print postdominance tree of function to ".dot" file

This pass, only available in `opt`, prints the post dominator tree into a `.dot` graph. This graph can then be processed with the `dot` tool to convert it to postscript or some other suitable format.

-dot-postdom-only: Print postdominance tree of function to ".dot" file (with no function bodies)

This pass, only available in `opt`, prints the post dominator tree into a `.dot` graph, omitting the function bodies. This graph can then be processed with the `dot` tool to convert it to postscript or some other suitable format.

-globalsmodref-aa: Simple mod/ref analysis for globals

This simple pass provides alias and mod/ref information for global values that do not have their address taken, and keeps track of whether functions read or write memory (are "pure"). For this simple (but very common) case, we can provide pretty accurate and useful information.

-instcount: Counts the various types of Instructions

This pass collects the count of all instructions and reports them.

-intervals: Interval Partition Construction

This analysis calculates and represents the interval partition of a function, or a preexisting interval partition.

In this way, the interval partition may be used to reduce a flow graph down to its degenerate single node interval partition (unless it is irreducible).

-iv-users: Induction Variable Users

Bookkeeping for "interesting" users of expressions computed from induction variables.

-lazy-value-info: Lazy Value Information Analysis

Interface for lazy computation of value constraint information.

-libcall-aa: LibCall Alias Analysis

LibCall Alias Analysis.

-lint: Statically lint-checks LLVM IR

This pass statically checks for common and easily-identified constructs which produce undefined or likely unintended behavior in LLVM IR.

It is not a guarantee of correctness, in two ways. First, it isn't comprehensive. There are checks which could be done statically which are not yet implemented. Some of these are indicated by TODO comments, but those aren't comprehensive either. Second, many conditions cannot be checked statically. This pass does no dynamic instrumentation, so it can't check for all possible problems.

Another limitation is that it assumes all code will be executed. A store through a null pointer in a basic block which is never reached is harmless, but this pass will warn about it anyway.

Optimization passes may make conditions that this pass checks for more or less obvious. If an optimization pass appears to be introducing a warning, it may be that the optimization pass is merely exposing an existing condition in the code.

This code may be run before *instcombine*. In many cases, instcombine checks for the same kinds of things and turns instructions with undefined behavior into unreachable (or equivalent). Because of this, this pass makes some effort to look through bitcasts and so on.

-loops: Natural Loop Information

This analysis is used to identify natural loops and determine the loop depth of various nodes of the CFG. Note that the loops identified may actually be several natural loops that share the same header node... not just a single natural loop.

-memdep: Memory Dependence Analysis

An analysis that determines, for a given memory operation, what preceding memory operations it depends on. It builds on alias analysis information, and tries to provide a lazy, caching interface to a common kind of alias information query.

-module-debuginfo: Decodes module-level debug info

This pass decodes the debug info metadata in a module and prints in a (sufficiently-prepared-) human-readable form. For example, run this pass from `opt` along with the `-analyze` option, and it'll print to standard output.

-postdomfrontier: Post-Dominance Frontier Construction

This pass is a simple post-dominator construction algorithm for finding post-dominator frontiers.

-postdomtree: Post-Dominator Tree Construction

This pass is a simple post-dominator construction algorithm for finding post-dominators.

-print-alias-sets: Alias Set Printer

Yet to be written.

-print-callgraph: Print a call graph

This pass, only available in `opt`, prints the call graph to standard error in a human-readable form.

-print-callgraph-sccs: Print SCCs of the Call Graph

This pass, only available in `opt`, prints the SCCs of the call graph to standard error in a human-readable form.

-print-cfg-sccs: Print SCCs of each function CFG

This pass, only available in `opt`, prints the SCCs of each function CFG to standard error in a human-readable form.

-print-dom-info: Dominator Info Printer

Dominator Info Printer.

-print-externalfnconstants: Print external fn callsites passed constants

This pass, only available in `opt`, prints out call sites to external functions that are called with constant arguments. This can be useful when looking for standard library functions we should constant fold or handle in alias analyses.

-print-function: Print function to stderr

The `PrintFunctionPass` class is designed to be pipelined with other `FunctionPasses`, and prints out the functions of the module as they are processed.

-print-module: Print module to stderr

This pass simply prints out the entire module when it is executed.

-print-used-types: Find Used Types

This pass is used to seek out all of the types in use by the program. Note that this analysis explicitly does not include types only used by the symbol table.

-regions: Detect single entry single exit regions

The `RegionInfo` pass detects single entry single exit regions in a function, where a region is defined as any subgraph that is connected to the remaining graph at only two spots. Furthermore, an hierarchical region tree is built.

-scalar-evolution: Scalar Evolution Analysis

The `ScalarEvolution` analysis can be used to analyze and categorize scalar expressions in loops. It specializes in recognizing general induction variables, representing them with the abstract and opaque `SCEV` class. Given this analysis, trip counts of loops and other important properties can be obtained.

This analysis is primarily useful for induction variable substitution and strength reduction.

-scev-aa: ScalarEvolution-based Alias Analysis

Simple alias analysis implemented in terms of `ScalarEvolution` queries.

This differs from traditional loop dependence analysis in that it tests for dependencies within a single iteration of a loop, rather than dependencies between different iterations.

`ScalarEvolution` has a more complete understanding of pointer arithmetic than `BasicAliasAnalysis`' collection of ad-hoc analyses.

-stack-safety: Stack Safety Analysis

The `StackSafety` analysis can be used to determine if stack allocated variables can be considered safe from memory access bugs.

This analysis' primary purpose is to be used by sanitizers to avoid unnecessary instrumentation of safe variables.

-targetdata: Target Data Layout

Provides other passes access to information on how the size and alignment required by the target ABI for various data types.

2.22.3 Transform Passes

This section describes the LLVM Transform Passes.

-adce: Aggressive Dead Code Elimination

ADCE aggressively tries to eliminate code. This pass is similar to *DCE* but it assumes that values are dead until proven otherwise. This is similar to *SCCP*, except applied to the liveness of values.

-always-inline: Inliner for `always_inline` functions

A custom inliner that handles only functions that are marked as "always inline".

-argpromotion: Promote 'by reference' arguments to scalars

This pass promotes "by reference" arguments to be "by value" arguments. In practice, this means looking for internal functions that have pointer arguments. If it can prove, through the use of alias analysis, that an argument is *only* loaded, then it can pass the value into the function instead of the address of the value. This can cause recursive simplification of code and lead to the elimination of allocas (especially in C++ template code like the STL).

This pass also handles aggregate arguments that are passed into a function, scalarizing them if the elements of the aggregate are only loaded. Note that it refuses to scalarize aggregates which would require passing in more than three operands to the function, because passing thousands of operands for a large array or structure is unprofitable!

Note that this transformation could also be done for arguments that are only stored to (returning the value instead), but does not currently. This case would be best handled when and if LLVM starts supporting multiple return values from functions.

-bb-vectorize: Basic-Block Vectorization

This pass combines instructions inside basic blocks to form vector instructions. It iterates over each basic block, attempting to pair compatible instructions, repeating this process until no additional pairs are selected for vectorization. When the outputs of some pair of compatible instructions are used as inputs by some other pair of compatible instructions, those pairs are part of a potential vectorization chain. Instruction pairs are only fused into vector instructions when they are part of a chain longer than some threshold length. Moreover, the pass attempts to find the best possible chain for each pair of compatible instructions. These heuristics are intended to prevent vectorization in cases where it would not yield a performance increase of the resulting code.

-block-placement: Profile Guided Basic Block Placement

This pass is a very simple profile guided basic block placement algorithm. The idea is to put frequently executed blocks together at the start of the function and hopefully increase the number of fall-through conditional branches. If there is no profile information for a particular function, this pass basically orders blocks in depth-first order.

-break-crit-edges: Break critical edges in CFG

Break all of the critical edges in the CFG by inserting a dummy basic block. It may be "required" by passes that cannot deal with critical edges. This transformation obviously invalidates the CFG, but can update forward dominator (set, immediate dominators, tree, and frontier) information.

-codegenprepare: Optimize for code generation

This pass munges the code in the input function to better prepare it for SelectionDAG-based code generation. This works around limitations in its basic-block-at-a-time approach. It should eventually be removed.

-constmerge: Merge Duplicate Global Constants

Merges duplicate global constants together into a single constant that is shared. This is useful because some passes (i.e., TraceValues) insert a lot of string constants into the program, regardless of whether or not an existing string is available.

-constprop: Simple constant propagation

This pass implements constant propagation and merging. It looks for instructions involving only constant operands and replaces them with a constant value instead of an instruction. For example:

```
add i32 1, 2
```

becomes

```
i32 3
```

NOTE: this pass has a habit of making definitions be dead. It is a good idea to run a *Dead Instruction Elimination* pass sometime after running this pass.

-dce: Dead Code Elimination

Dead code elimination is similar to *dead instruction elimination*, but it rechecks instructions that were used by removed instructions to see if they are newly dead.

-deadargelim: Dead Argument Elimination

This pass deletes dead arguments from internal functions. Dead argument elimination removes arguments which are directly dead, as well as arguments only passed into function calls as dead arguments of other functions. This pass also deletes dead arguments in a similar way.

This pass is often useful as a cleanup pass to run after aggressive interprocedural passes, which add possibly-dead arguments.

-deadtypeelim: Dead Type Elimination

This pass is used to cleanup the output of GCC. It eliminate names for types that are unused in the entire translation unit, using the *find used types* pass.

-die: Dead Instruction Elimination

Dead instruction elimination performs a single pass over the function, removing instructions that are obviously dead.

-dse: Dead Store Elimination

A trivial dead store elimination that only considers basic-block local redundant stores.

-functionattrs: Deduce function attributes

A simple interprocedural pass which walks the call-graph, looking for functions which do not access or only read non-local memory, and marking them *readnone/readonly*. In addition, it marks function arguments (of pointer type) "nocapture" if a call to the function does not create any copies of the pointer value that outlive the call. This more or less means that the pointer is only dereferenced, and not returned from the function or stored in a global. This pass is implemented as a bottom-up traversal of the call-graph.

-globaldce: Dead Global Elimination

This transform is designed to eliminate unreachable internal globals from the program. It uses an aggressive algorithm, searching out globals that are known to be alive. After it finds all of the globals which are needed, it deletes whatever is left over. This allows it to delete recursive chunks of the program which are unreachable.

-globalopt: Global Variable Optimizer

This pass transforms simple global variables that never have their address taken. If obviously true, it marks read/write globals as constant, deletes variables only stored to, etc.

-gvn: Global Value Numbering

This pass performs global value numbering to eliminate fully and partially redundant instructions. It also performs redundant load elimination.

-indvars: Canonicalize Induction Variables

This transformation analyzes and transforms the induction variables (and computations derived from them) into simpler forms suitable for subsequent analysis and transformation.

This transformation makes the following changes to each loop with an identifiable induction variable:

- All loops are transformed to have a *single* canonical induction variable which starts at zero and steps by one.
- The canonical induction variable is guaranteed to be the first PHI node in the loop header block.
- Any pointer arithmetic recurrences are raised to use array subscripts.

If the trip count of a loop is computable, this pass also makes the following changes:

- The exit condition for the loop is canonicalized to compare the induction value against the exit value. This turns loops like:

```
for (i = 7; i*i < 1000; ++i)
    into
```

```
for (i = 0; i != 25; ++i)
```

- Any use outside of the loop of an expression derived from the indvar is changed to compute the derived value outside of the loop, eliminating the dependence on the exit value of the induction variable. If the only purpose of the loop is to compute the exit value of some derived expression, this transformation will make the loop dead.

This transformation should be followed by strength reduction after all of the desired loop transformations have been performed. Additionally, on targets where it is profitable, the loop could be transformed to count down to zero (the "do loop" optimization).

-inline: Function Integration/Inlining

Bottom-up inlining of functions into callees.

-instcombine: Combine redundant instructions

Combine instructions to form fewer, simple instructions. This pass does not modify the CFG. This pass is where algebraic simplification happens.

This pass combines things like:

```
%Y = add i32 %X, 1
%Z = add i32 %Y, 1
```

into:

```
%Z = add i32 %X, 2
```

This is a simple worklist driven algorithm.

This pass guarantees that the following canonicalizations are performed on the program:

1. If a binary operator has a constant operand, it is moved to the right-hand side.
2. Bitwise operators with constant operands are always grouped so that shifts are performed first, then `ors`, then `ands`, then `xors`.
3. Compare instructions are converted from `<`, `>`, `,` or `to =` or if possible.
4. All `cmp` instructions on boolean values are replaced with logical operations.
5. `add X, X` is represented as `mul X, 2 shl X, 1`
6. Multiplies with a constant power-of-two argument are transformed into shifts.
7. ... etc.

This pass can also simplify calls to specific well-known function calls (e.g. runtime library functions). For example, a call `exit(3)` that occurs within the `main()` function can be transformed into simply `return 3`. Whether or not library calls are simplified is controlled by the `-functionattrs` pass and LLVM's knowledge of library calls on different targets.

-aggressive-instcombine: Combine expression patterns

Combine expression patterns to form expressions with fewer, simple instructions. This pass does not modify the CFG.

For example, this pass reduce width of expressions post-dominated by `TruncInst` into smaller width when applicable.

It differs from `instcombine` pass in that it contains pattern optimization that requires higher complexity than the $O(1)$, thus, it should run fewer times than `instcombine` pass.

-internalize: Internalize Global Symbols

This pass loops over all of the functions in the input module, looking for a main function. If a main function is found, all other functions and all global variables with initializers are marked as internal.

-ipconstprop: Interprocedural constant propagation

This pass implements an *extremely* simple interprocedural constant propagation pass. It could certainly be improved in many different ways, like using a worklist. This pass makes arguments dead, but does not remove them. The existing dead argument elimination pass should be run after this to clean up the mess.

-ipsccp: Interprocedural Sparse Conditional Constant Propagation

An interprocedural variant of *Sparse Conditional Constant Propagation*.

-jump-threading: Jump Threading

Jump threading tries to find distinct threads of control flow running through a basic block. This pass looks at blocks that have multiple predecessors and multiple successors. If one or more of the predecessors of the block can be proven to always cause a jump to one of the successors, we forward the edge from the predecessor to the successor by duplicating the contents of this block.

An example of when this can occur is code like this:

```
if () { ...
    X = 4;
}
if (X < 3) {
```

In this case, the unconditional branch at the end of the first if can be revectorized to the false side of the second if.

-lcssa: Loop-Closed SSA Form Pass

This pass transforms loops by placing phi nodes at the end of the loops for all values that are live across the loop boundary. For example, it turns the left into the right code:

<pre>for (...) if (c) X1 = ... else X2 = ... X3 = phi(X1, X2) ... = X3 + 4</pre>	<pre>for (...) if (c) X1 = ... else X2 = ... X3 = phi(X1, X2) X4 = phi(X3) ... = X4 + 4</pre>
--	---

This is still valid LLVM; the extra phi nodes are purely redundant, and will be trivially eliminated by `InstCombine`. The major benefit of this transformation is that it makes many other loop optimizations, such as `LoopUnswitching`, simpler.

-licm: Loop Invariant Code Motion

This pass performs loop invariant code motion, attempting to remove as much code from the body of a loop as possible. It does this by either hoisting code into the preheader block, or by sinking code to the exit blocks if it is safe. This pass also promotes must-aliased memory locations in the loop to live in registers, thus hoisting and sinking "invariant" loads and stores.

This pass uses alias analysis for two purposes:

1. Moving loop invariant loads and calls out of loops. If we can determine that a load or call inside of a loop never aliases anything stored to, we can hoist it or sink it like any other instruction.
2. Scalar Promotion of Memory. If there is a store instruction inside of the loop, we try to move the store to happen AFTER the loop instead of inside of the loop. This can only happen if a few conditions are true:
 1. The pointer stored through is loop invariant.
 2. There are no stores or loads in the loop which *may* alias the pointer. There are no calls in the loop which mod/ref the pointer.

If these conditions are true, we can promote the loads and stores in the loop of the pointer to use a temporary alloca'd variable. We then use the *mem2reg* functionality to construct the appropriate SSA form for the variable.

-loop-deletion: Delete dead loops

This file implements the Dead Loop Deletion Pass. This pass is responsible for eliminating loops with non-infinite computable trip counts that have no side effects or volatile instructions, and do not contribute to the computation of the function's return value.

-loop-extract: Extract loops into new functions

A pass wrapper around the `ExtractLoop()` scalar transformation to extract each top-level loop into its own new function. If the loop is the *only* loop in a given function, it is not touched. This is a pass most useful for debugging via `bugpoint`.

-loop-extract-single: Extract at most one loop into a new function

Similar to *Extract loops into new functions*, this pass extracts one natural loop from the program into a function if it can. This is used by `bugpoint`.

-loop-reduce: Loop Strength Reduction

This pass performs a strength reduction on array references inside loops that have as one or more of their components the loop induction variable. This is accomplished by creating a new value to hold the initial value of the array access for the first iteration, and then creating a new GEP instruction in the loop to increment the value by the appropriate amount.

-loop-rotate: Rotate Loops

A simple loop rotation transformation.

-loop-simplify: Canonicalize natural loops

This pass performs several transformations to transform natural loops into a simpler form, which makes subsequent analyses and transformations simpler and more effective.

Loop pre-header insertion guarantees that there is a single, non-critical entry edge from outside of the loop to the loop header. This simplifies a number of analyses and transformations, such as *LICM*.

Loop exit-block insertion guarantees that all exit blocks from the loop (blocks which are outside of the loop that have predecessors inside of the loop) only have predecessors from inside of the loop (and are thus dominated by the loop header). This simplifies transformations such as store-sinking that are built into *LICM*.

This pass also guarantees that loops will have exactly one backedge.

Note that the *simplifycfg* pass will clean up blocks which are split out but end up being unnecessary, so usage of this pass should not pessimize generated code.

This pass obviously modifies the CFG, but updates loop information and dominator information.

-loop-unroll: Unroll loops

This pass implements a simple loop unroller. It works best when loops have been canonicalized by the *indvars* pass, allowing it to determine the trip counts of loops easily.

-loop-unroll-and-jam: Unroll and Jam loops

This pass implements a simple unroll and jam classical loop optimisation pass. It transforms loop from:

<pre>for i.. i+= 1 for j.. code(i, j)</pre>	<pre>for i.. i+= 4 for j.. code(i, j) code(i+1, j) code(i+2, j) code(i+3, j) remainder loop</pre>
---	---

Which can be seen as unrolling the outer loop and "jamming" (fusing) the inner loops into one. When variables or loads can be shared in the new inner loop, this can lead to significant performance improvements. It uses *Dependence Analysis* for proving the transformations are safe.

-loop-unswitch: Unswitch loops

This pass transforms loops that contain branches on loop-invariant conditions to have multiple loops. For example, it turns the left into the right code:

<pre>for (...) A if (lic) B C</pre>	<pre>if (lic) for (...) A; B; C else for (...) A; C</pre>
---	---

This can increase the size of the code exponentially (doubling it every time a loop is unswitched) so we only unswitch if the resultant code will be smaller than a threshold.

This pass expects *LICM* to be run before it to hoist invariant conditions out of the loop, to make the unswitching opportunity obvious.

-loweratomic: Lower atomic intrinsics to non-atomic form

This pass lowers atomic intrinsics to non-atomic form for use in a known non-preemptible environment.

The pass does not verify that the environment is non-preemptible (in general this would require knowledge of the entire call graph of the program including any libraries which may not be available in bitcode form); it simply lowers every atomic intrinsic.

-lowerinvoke: Lower invokes to calls, for unwindless code generators

This transformation is designed for use by code generators which do not yet support stack unwinding. This pass converts *invoke* instructions to *call* instructions, so that any exception-handling *landingpad* blocks become dead code (which can be removed by running the *-simplifycfg* pass afterwards).

-lowerswitch: Lower SwitchInsts to branches

Rewrites switch instructions with a sequence of branches, which allows targets to get away with not implementing the switch instruction until it is convenient.

-mem2reg: Promote Memory to Register

This file promotes memory references to be register references. It promotes *alloca* instructions which only have loads and stores as uses. An *alloca* is transformed by using dominator frontiers to place phi nodes, then traversing the function in depth-first order to rewrite loads and stores as appropriate. This is just the standard SSA construction algorithm to construct "pruned" SSA form.

-memcpyopt: MemCpy Optimization

This pass performs various transformations related to eliminating *memcpy* calls, or transforming sets of stores into *memset*s.

-mergefunc: Merge Functions

This pass looks for equivalent functions that are mergable and folds them.

Total-ordering is introduced among the functions set: we define comparison that answers for every two functions which of them is greater. It allows to arrange functions into the binary tree.

For every new function we check for equivalent in tree.

If equivalent exists we fold such functions. If both functions are overridable, we move the functionality into a new internal function and leave two overridable thanks to it.

If there is no equivalent, then we add this function to tree.

Lookup routine has $O(\log(n))$ complexity, while whole merging process has complexity of $O(n*\log(n))$.

Read [this](#) article for more details.

-mergereturn: Unify function exit nodes

Ensure that functions have at most one `ret` instruction in them. Additionally, it keeps track of which node is the new exit node of the CFG.

-partial-inliner: Partial Inliner

This pass performs partial inlining, typically by inlining an `if` statement that surrounds the body of the function.

-prune-eh: Remove unused exception handling info

This file implements a simple interprocedural pass which walks the call-graph, turning `invoke` instructions into `call` instructions if and only if the callee cannot throw an exception. It implements this as a bottom-up traversal of the call-graph.

-reassociate: Reassociate expressions

This pass reassociates commutative expressions in an order that is designed to promote better constant propagation, GCSE, *LICM*, PRE, etc.

For example: $4 + (x + 5) \rightarrow x + (4 + 5)$

In the implementation of this algorithm, constants are assigned rank = 0, function arguments are rank = 1, and other values are assigned ranks corresponding to the reverse post order traversal of current function (starting at 2), which effectively gives values in deep loops higher rank than values not in loops.

-reg2mem: Demote all values to stack slots

This file demotes all registers to memory references. It is intended to be the inverse of *mem2reg*. By converting to `load` instructions, the only values live across basic blocks are `alloca` instructions and `load` instructions before `phi` nodes. It is intended that this should make CFG hacking much easier. To make later hacking easier, the entry block is split into two, such that all introduced `alloca` instructions (and nothing else) are in the entry block.

-sroa: Scalar Replacement of Aggregates

The well-known scalar replacement of aggregates transformation. This transform breaks up `alloca` instructions of aggregate type (structure or array) into individual `alloca` instructions for each member if possible. Then, if possible, it transforms the individual `alloca` instructions into nice clean scalar SSA form.

-sccp: Sparse Conditional Constant Propagation

Sparse conditional constant propagation and merging, which can be summarized as:

- Assumes values are constant unless proven otherwise
- Assumes BasicBlocks are dead unless proven otherwise
- Proves values to be constant, and replaces them with constants
- Proves conditional branches to be unconditional

Note that this pass has a habit of making definitions be dead. It is a good idea to run a *DCE* pass sometime after running this pass.

-simplifycfg: Simplify the CFG

Performs dead code elimination and basic block merging. Specifically:

- Removes basic blocks with no predecessors.
- Merges a basic block into its predecessor if there is only one and the predecessor only has one successor.
- Eliminates PHI nodes for basic blocks with a single predecessor.
- Eliminates a basic block that only contains an unconditional branch.

-sink: Code sinking

This pass moves instructions into successor blocks, when possible, so that they aren't executed on paths where their results aren't needed.

-strip: Strip all symbols from a module

Performs code stripping. This transformation can delete:

- names for virtual registers
- symbols for internal globals and functions
- debug information

Note that this transformation makes code much less readable, so it should only be used in situations where the strip utility would be used, such as reducing code size or making it harder to reverse engineer code.

-strip-dead-debug-info: Strip debug info for unused symbols

performs code stripping. this transformation can delete:

- names for virtual registers
- symbols for internal globals and functions
- debug information

note that this transformation makes code much less readable, so it should only be used in situations where the strip utility would be used, such as reducing code size or making it harder to reverse engineer code.

-strip-dead-prototypes: Strip Unused Function Prototypes

This pass loops over all of the functions in the input module, looking for dead declarations and removes them. Dead declarations are declarations of functions for which no implementation is available (i.e., declarations for unused library functions).

-strip-debug-declare: Strip all `llvm.dbg.declare` intrinsics

This pass implements code stripping. Specifically, it can delete:

1. names for virtual registers
2. symbols for internal globals and functions
3. debug information

Note that this transformation makes code much less readable, so it should only be used in situations where the 'strip' utility would be used, such as reducing code size or making it harder to reverse engineer code.

-strip-nondebug: Strip all symbols, except `dbg` symbols, from a module

This pass implements code stripping. Specifically, it can delete:

1. names for virtual registers
2. symbols for internal globals and functions
3. debug information

Note that this transformation makes code much less readable, so it should only be used in situations where the 'strip' utility would be used, such as reducing code size or making it harder to reverse engineer code.

-tailcallelim: Tail Call Elimination

This file transforms calls of the current function (self recursion) followed by a return instruction with a branch to the entry of the function, creating a loop. This pass also implements the following extensions to the basic algorithm:

1. Trivial instructions between the call and return do not prevent the transformation from taking place, though currently the analysis cannot support moving any really useful instructions (only dead ones).
2. This pass transforms functions that are prevented from being tail recursive by an associative expression to use an accumulator variable, thus compiling the typical naive factorial or fib implementation into efficient code.
3. TRE is performed if the function returns void, if the return returns the result returned by the call, or if the function returns a run-time constant on all exits from the function. It is possible, though unlikely, that the return returns something else (like constant 0), and can still be TRE'd. It can be TRE'd if *all other* return instructions in the function return the exact same value.
4. If it can prove that callees do not access their caller stack frame, they are marked as eligible for tail call elimination (by the code generator).

2.22.4 Utility Passes

This section describes the LLVM Utility Passes.

-deadarghaX0r: Dead Argument Hacking (BUGPOINT USE ONLY; DO NOT USE)

Same as dead argument elimination, but deletes arguments to functions which are external. This is only for use by *bugpoint*.

-extract-blocks: Extract Basic Blocks From Module (for bugpoint use)

This pass is used by bugpoint to extract all blocks from the module into their own functions.

-instnamer: Assign names to anonymous instructions

This is a little utility pass that gives instructions names, this is mostly useful when diffing the effect of an optimization because deleting an unnamed instruction can change all other instruction numbering, making the diff very noisy.

-verify: Module Verifier

Verifies an LLVM IR code. This is useful to run after an optimization which is undergoing testing. Note that llvm-as verifies its input before emitting bitcode, and also that malformed bitcode is likely to make LLVM crash. All language front-ends are therefore encouraged to verify their output before performing optimizing transformations.

1. Both of a binary operator's parameters are of the same type.
2. Verify that the indices of mem access instructions match other operands.
3. Verify that arithmetic and other things are only performed on first-class types. Verify that shifts and logicals only happen on integrals f.e.
4. All of the constants in a switch statement are of the correct type.
5. The code is in valid SSA form.
6. It is illegal to put a label into any other type (like a structure) or to return one.
7. Only phi nodes can be self referential: `%x = add i32 %x, %x` is invalid.
8. PHI nodes must have an entry for each predecessor, with no extras.
9. PHI nodes must be the first thing in a basic block, all grouped together.
10. PHI nodes must have at least one entry.
11. All basic blocks should only end with terminator insts, not contain them.
12. The entry node to a function must not have predecessors.
13. All Instructions must be embedded into a basic block.
14. Functions cannot take a void-typed parameter.
15. Verify that a function's argument list agrees with its declared type.
16. It is illegal to specify a name for a void value.
17. It is illegal to have an internal global value with no initializer.
18. It is illegal to have a `ret` instruction that returns a value that does not agree with the function return value type.
19. Function call argument types match the function prototype.
20. All other things that are tested by asserts spread about the code.

Note that this does not provide full security verification (like Java), but instead just tries to ensure that code is well-formed.

-view-cfg: View CFG of function

Displays the control flow graph using the GraphViz tool.

-view-cfg-only: View CFG of function (with no function bodies)

Displays the control flow graph using the GraphViz tool, but omitting function bodies.

-view-dom: View dominance tree of function

Displays the dominator tree using the GraphViz tool.

-view-dom-only: View dominance tree of function (with no function bodies)

Displays the dominator tree using the GraphViz tool, but omitting function bodies.

-view-postdom: View postdominance tree of function

Displays the post dominator tree using the GraphViz tool.

-view-postdom-only: View postdominance tree of function (with no function bodies)

Displays the post dominator tree using the GraphViz tool, but omitting function bodies.

-transform-warning: Report missed forced transformations

Emits warnings about not yet applied forced transformations (e.g. from `#pragma omp simd`).

2.23.1 Introduction to YAML

YAML is a human readable data serialization language. The full YAML language spec can be read at yaml.org. The simplest form of yaml is just "scalars", "mappings", and "sequences". A scalar is any number or string. The pound/hash symbol (#) begins a comment line. A mapping is a set of key-value pairs where the key ends with a colon. For example:

```
# a mapping
name:      Tom
hat-size:  7
```

A sequence is a list of items where each item starts with a leading dash ('-'). For example:

```
# a sequence
- x86
- x86_64
- PowerPC
```

You can combine mappings and sequences by indenting. For example a sequence of mappings in which one of the mapping values is itself a sequence:

```
# a sequence of mappings with one key's value being a sequence
- name:      Tom
  cpus:
    - x86
```

(continues on next page)

(continued from previous page)

```

    - x86_64
- name:      Bob
  cpus:
    - x86
- name:      Dan
  cpus:
    - PowerPC
    - x86

```

Sometime sequences are known to be short and the one entry per line is too verbose, so YAML offers an alternate syntax for sequences called a "Flow Sequence" in which you put comma separated sequence elements into square brackets. The above example could then be simplified to :

```

# a sequence of mappings with one key's value being a flow sequence
- name:      Tom
  cpus:      [ x86, x86_64 ]
- name:      Bob
  cpus:      [ x86 ]
- name:      Dan
  cpus:      [ PowerPC, x86 ]

```

2.23.2 Introduction to YAML I/O

The use of indenting makes the YAML easy for a human to read and understand, but having a program read and write YAML involves a lot of tedious details. The YAML I/O library structures and simplifies reading and writing YAML documents.

YAML I/O assumes you have some "native" data structures which you want to be able to dump as YAML and recreate from YAML. The first step is to try writing example YAML for your data structures. You may find after looking at possible YAML representations that a direct mapping of your data structures to YAML is not very readable. Often the fields are not in the order that a human would find readable. Or the same information is replicated in multiple locations, making it hard for a human to write such YAML correctly.

In relational database theory there is a design step called normalization in which you reorganize fields and tables. The same considerations need to go into the design of your YAML encoding. But, you may not want to change your existing native data structures. Therefore, when writing out YAML there may be a normalization step, and when reading YAML there would be a corresponding denormalization step.

YAML I/O uses a non-invasive, traits based design. YAML I/O defines some abstract base templates. You specialize those templates on your data types. For instance, if you have an enumerated type FooBar you could specialize ScalarEnumerationTraits on that type and define the enumeration() method:

```

using llvm::yaml::ScalarEnumerationTraits;
using llvm::yaml::IO;

template <>
struct ScalarEnumerationTraits<FooBar> {
    static void enumeration(IO &io, FooBar &value) {
        ...
    }
};

```

As with all YAML I/O template specializations, the ScalarEnumerationTraits is used for both reading and writing YAML. That is, the mapping between in-memory enum values and the YAML string representation is only in one place. This assures that the code for writing and parsing of YAML stays in sync.

To specify a YAML mappings, you define a specialization on `llvm::yaml::MappingTraits`. If your native data structure happens to be a struct that is already normalized, then the specialization is simple. For example:

```
using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

template <>
struct MappingTraits<Person> {
    static void mapping(IO &io, Person &info) {
        io.mapRequired("name",      info.name);
        io.mapOptional("hat-size",   info.hatSize);
    }
};
```

A YAML sequence is automatically inferred if you data type has `begin()/end()` iterators and a `push_back()` method. Therefore any of the STL containers (such as `std::vector<>`) will automatically translate to YAML sequences.

Once you have defined specializations for your data types, you can programmatically use YAML I/O to write a YAML document:

```
using llvm::yaml::Output;

Person tom;
tom.name = "Tom";
tom.hatSize = 8;
Person dan;
dan.name = "Dan";
dan.hatSize = 7;
std::vector<Person> persons;
persons.push_back(tom);
persons.push_back(dan);

Output yout(llvm::outs());
yout << persons;
```

This would write the following:

```
- name:      Tom
  hat-size:  8
- name:      Dan
  hat-size:  7
```

And you can also read such YAML documents with the following code:

```
using llvm::yaml::Input;

typedef std::vector<Person> PersonList;
std::vector<PersonList> docs;

Input yin(document.getBuffer());
yin >> docs;

if ( yin.error() )
    return;

// Process read document
for ( PersonList &pl : docs ) {
    for ( Person &person : pl ) {
```

(continues on next page)

(continued from previous page)

```

    cout << "name=" << person.name;
  }
}

```

One other feature of YAML is the ability to define multiple documents in a single file. That is why reading YAML produces a vector of your document type.

2.23.3 Error Handling

When parsing a YAML document, if the input does not match your schema (as expressed in your XxxTraits<> specializations). YAML I/O will print out an error message and your Input object's error() method will return true. For instance the following document:

```

- name: Tom
  shoe-size: 12
- name: Dan
  hat-size: 7

```

Has a key (shoe-size) that is not defined in the schema. YAML I/O will automatically generate this error:

```

YAML:2:2: error: unknown key 'shoe-size'
  shoe-size:      12
  ^~~~~~

```

Similar errors are produced for other input not conforming to the schema.

2.23.4 Scalars

YAML scalars are just strings (i.e. not a sequence or mapping). The YAML I/O library provides support for translating between YAML scalars and specific C++ types.

Built-in types

The following types have built-in support in YAML I/O:

- bool
- float
- double
- StringRef
- std::string
- int64_t
- int32_t
- int16_t
- int8_t
- uint64_t
- uint32_t

- `uint16_t`
- `uint8_t`

That is, you can use those types in fields of `MappingTraits` or as element type in sequence. When reading, YAML I/O will validate that the string found is convertible to that type and error out if not.

Unique types

Given that YAML I/O is trait based, the selection of how to convert your data to YAML is based on the type of your data. But in C++ type matching, typedefs do not generate unique type names. That means if you have two typedefs of unsigned int, to YAML I/O both types look exactly like unsigned int. To facilitate make unique type names, YAML I/O provides a macro which is used like a typedef on built-in types, but expands to create a class with conversion operators to and from the base type. For example:

```
LLVM_YAML_STRONG_TYPEDEF(uint32_t, MyFooFlags)
LLVM_YAML_STRONG_TYPEDEF(uint32_t, MyBarFlags)
```

This generates two classes `MyFooFlags` and `MyBarFlags` which you can use in your native data structures instead of `uint32_t`. They are implicitly converted to and from `uint32_t`. The point of creating these unique types is that you can now specify traits on them to get different YAML conversions.

Hex types

An example use of a unique type is that YAML I/O provides fixed sized unsigned integers that are written with YAML I/O as hexadecimal instead of the decimal format used by the built-in integer types:

- `Hex64`
- `Hex32`
- `Hex16`
- `Hex8`

You can use `llvm::yaml::Hex32` instead of `uint32_t` and the only different will be that when YAML I/O writes out that type it will be formatted in hexadecimal.

ScalarEnumerationTraits

YAML I/O supports translating between in-memory enumerations and a set of string values in YAML documents. This is done by specializing `ScalarEnumerationTraits` on your enumeration type and define a `enumeration()` method. For instance, suppose you had an enumeration of CPUs and a struct with it as a field:

```
enum CPUs {
    cpu_x86_64 = 5,
    cpu_x86    = 7,
    cpu_PowerPC = 8
};

struct Info {
    CPUs    cpu;
    uint32_t flags;
};
```

To support reading and writing of this enumeration, you can define a `ScalarEnumerationTraits` specialization on `CPUs`, which can then be used as a field type:

```

using llvm::yaml::ScalarEnumerationTraits;
using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

template <>
struct ScalarEnumerationTraits<CPUs> {
    static void enumeration(IO &io, CPUs &value) {
        io.enumCase(value, "x86_64", cpu_x86_64);
        io.enumCase(value, "x86", cpu_x86);
        io.enumCase(value, "PowerPC", cpu_PowerPC);
    }
};

template <>
struct MappingTraits<Info> {
    static void mapping(IO &io, Info &info) {
        io.mapRequired("cpu", info.cpu);
        io.mapOptional("flags", info.flags, 0);
    }
};

```

When reading YAML, if the string found does not match any of the strings specified by `enumCase()` methods, an error is automatically generated. When writing YAML, if the value being written does not match any of the values specified by the `enumCase()` methods, a runtime assertion is triggered.

BitValue

Another common data structure in C++ is a field where each bit has a unique meaning. This is often used in a "flags" field. YAML I/O has support for converting such fields to a flow sequence. For instance suppose you had the following bit flags defined:

```

enum {
    flagsPointy = 1
    flagsHollow = 2
    flagsFlat   = 4
    flagsRound  = 8
};

LLVM_YAML_STRONG_TYPEDEF(uint32_t, MyFlags)

```

To support reading and writing of `MyFlags`, you specialize `ScalarBitSetTraits<>` on `MyFlags` and provide the bit values and their names.

```

using llvm::yaml::ScalarBitSetTraits;
using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

template <>
struct ScalarBitSetTraits<MyFlags> {
    static void bitset(IO &io, MyFlags &value) {
        io.bitSetCase(value, "hollow", flagHollow);
        io.bitSetCase(value, "flat",   flagFlat);
        io.bitSetCase(value, "round",  flagRound);
        io.bitSetCase(value, "pointy", flagPointy);
    }
};

```

(continues on next page)

(continued from previous page)

```

struct Info {
   StringRef    name;
    MyFlags     flags;
};

template <>
struct MappingTraits<Info> {
    static void mapping(IO &io, Info& info) {
        io.mapRequired("name",  info.name);
        io.mapRequired("flags", info.flags);
    }
};

```

With the above, YAML I/O (when writing) will test mask each value in the bitset trait against the flags field, and each that matches will cause the corresponding string to be added to the flow sequence. The opposite is done when reading and any unknown string values will result in a error. With the above schema, a same valid YAML document is:

```

name:      Tom
flags:    [ pointy, flat ]

```

Sometimes a "flags" field might contains an enumeration part defined by a bit-mask.

```

enum {
    flagsFeatureA = 1,
    flagsFeatureB = 2,
    flagsFeatureC = 4,

    flagsCPUMask = 24,

    flagsCPU1 = 8,
    flagsCPU2 = 16
};

```

To support reading and writing such fields, you need to use the `maskedBitSet()` method and provide the bit values, their names and the enumeration mask.

```

template <>
struct ScalarBitSetTraits<MyFlags> {
    static void bitset(IO &io, MyFlags &value) {
        io.bitSetCase(value, "featureA",  flagsFeatureA);
        io.bitSetCase(value, "featureB",  flagsFeatureB);
        io.bitSetCase(value, "featureC",  flagsFeatureC);
        io.maskedBitSetCase(value, "CPU1",  flagsCPU1, flagsCPUMask);
        io.maskedBitSetCase(value, "CPU2",  flagsCPU2, flagsCPUMask);
    }
};

```

YAML I/O (when writing) will apply the enumeration mask to the flags field, and compare the result and values from the bitset. As in case of a regular bitset, each that matches will cause the corresponding string to be added to the flow sequence.

Custom Scalar

Sometimes for readability a scalar needs to be formatted in a custom way. For instance your internal data structure may use an integer for time (seconds since some epoch), but in YAML it would be much nicer to express that integer in some time format (e.g. 4-May-2012 10:30pm). YAML I/O has a way to support custom formatting and parsing of scalar types by specializing `ScalarTraits<>` on your data type. When writing, YAML I/O will provide the native type and your specialization must create a temporary `llvm::StringRef`. When reading, YAML I/O will provide an `llvm::StringRef` of scalar and your specialization must convert that to your native data type. An outline of a custom scalar type looks like:

```
using llvm::yaml::ScalarTraits;
using llvm::yaml::IO;

template <>
struct ScalarTraits<MyCustomType> {
    static void output(const MyCustomType &value, void*,
                      llvm::raw_ostream &out) {
        out << value; // do custom formatting here
    }
    static StringRef input(StringRef scalar, void*, MyCustomType &value) {
        // do custom parsing here. Return the empty string on success,
        // or an error message on failure.
        return StringRef();
    }
    // Determine if this scalar needs quotes.
    static QuotingType mustQuote(StringRef) { return QuotingType::Single; }
};
```

Block Scalars

YAML block scalars are string literals that are represented in YAML using the literal block notation, just like the example shown below:

```
text: |
  First line
  Second line
```

The YAML I/O library provides support for translating between YAML block scalars and specific C++ types by allowing you to specialize `BlockScalarTraits<>` on your data type. The library doesn't provide any built-in support for block scalar I/O for types like `std::string` and `llvm::StringRef` as they are already supported by YAML I/O and use the ordinary scalar notation by default.

`BlockScalarTraits` specializations are very similar to the `ScalarTraits` specialization - YAML I/O will provide the native type and your specialization must create a temporary `llvm::StringRef` when writing, and it will also provide an `llvm::StringRef` that has the value of that block scalar and your specialization must convert that to your native data type when reading. An example of a custom type with an appropriate specialization of `BlockScalarTraits` is shown below:

```
using llvm::yaml::BlockScalarTraits;
using llvm::yaml::IO;

struct MyStringType {
    std::string Str;
};
```

(continues on next page)

(continued from previous page)

```

template <>
struct BlockScalarTraits<MyStringType> {
    static void output(const MyStringType &Value, void *Ctxt,
                      llvm::raw_ostream &OS) {
        OS << Value.Str;
    }

    staticStringRef input(StringRef Scalar, void *Ctxt,
                        MyStringType &Value) {
        Value.Str = Scalar.str();
        return StringRef();
    }
};

```

2.23.5 Mappings

To be translated to or from a YAML mapping for your type `T` you must specialize `llvm::yaml::MappingTraits` on `T` and implement the "void mapping(IO &io, T&)" method. If your native data structures use pointers to a class everywhere, you can specialize on the class pointer. Examples:

```

using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

// Example of struct Foo which is used by value
template <>
struct MappingTraits<Foo> {
    static void mapping(IO &io, Foo &foo) {
        io.mapOptional("size", foo.size);
        ...
    }
};

// Example of struct Bar which is natively always a pointer
template <>
struct MappingTraits<Bar*> {
    static void mapping(IO &io, Bar *&bar) {
        io.mapOptional("size", bar->size);
        ...
    }
};

```

No Normalization

The `mapping()` method is responsible, if needed, for normalizing and denormalizing. In a simple case where the native data structure requires no normalization, the mapping method just uses `mapOptional()` or `mapRequired()` to bind the struct's fields to YAML key names. For example:

```

using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

template <>
struct MappingTraits<Person> {
    static void mapping(IO &io, Person &info) {

```

(continues on next page)

(continued from previous page)

```

    io.mapRequired("name",      info.name);
    io.mapOptional("hat-size",  info.hatSize);
}
};

```

Normalization

When [de]normalization is required, the mapping() method needs a way to access normalized values as fields. To help with this, there is a template MappingNormalization<> which you can then use to automatically do the normalization and denormalization. The template is used to create a local variable in your mapping() method which contains the normalized keys.

Suppose you have native data type Polar which specifies a position in polar coordinates (distance, angle):

```

struct Polar {
    float distance;
    float angle;
};

```

but you've decided the normalized YAML for should be in x,y coordinates. That is, you want the yaml to look like:

```

x:  10.3
y: -4.7

```

You can support this by defining a MappingTraits that normalizes the polar coordinates to x,y coordinates when writing YAML and denormalizes x,y coordinates into polar when reading YAML.

```

using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

template <>
struct MappingTraits<Polar> {

    class NormalizedPolar {
    public:
        NormalizedPolar(IO &io)
            : x(0.0), y(0.0) {}
        NormalizedPolar(IO &, Polar &polar)
            : x(polar.distance * cos(polar.angle)),
              y(polar.distance * sin(polar.angle)) {}
        Polar denormalize(IO &) {
            return Polar(sqrt(x*x+y*y), atan(x,y));
        }

        float x;
        float y;
    };

    static void mapping(IO &io, Polar &polar) {
        MappingNormalization<NormalizedPolar, Polar> keys(io, polar);

        io.mapRequired("x",      keys->x);
        io.mapRequired("y",      keys->y);
    }
};

```

(continues on next page)

(continued from previous page)

```

    }
};

```

When writing YAML, the local variable "keys" will be a stack allocated instance of `NormalizedPolar`, constructed from the supplied polar object which initializes its `x` and `y` fields. The `mapRequired()` methods then write out the `x` and `y` values as key/value pairs.

When reading YAML, the local variable "keys" will be a stack allocated instance of `NormalizedPolar`, constructed by the empty constructor. The `mapRequired` methods will find the matching key in the YAML document and fill in the `x` and `y` fields of the `NormalizedPolar` object keys. At the end of the `mapping()` method when the local `keys` variable goes out of scope, the `denormalize()` method will automatically be called to convert the read values back to polar coordinates, and then assigned back to the second parameter to `mapping()`.

In some cases, the normalized class may be a subclass of the native type and could be returned by the `denormalize()` method, except that the temporary normalized instance is stack allocated. In these cases, the utility template `MappingNormalizationHeap<>` can be used instead. It just like `MappingNormalization<>` except that it heap allocates the normalized object when reading YAML. It never destroys the normalized object. The `denormalize()` method can then return "this".

Default values

Within a `mapping()` method, calls to `io.mapRequired()` mean that that key is required to exist when parsing YAML documents, otherwise YAML I/O will issue an error.

On the other hand, keys registered with `io.mapOptional()` are allowed to not exist in the YAML document being read. So what value is put in the field for those optional keys? There are two steps to how those optional fields are filled in. First, the second parameter to the `mapping()` method is a reference to a native class. That native class must have a default constructor. Whatever value the default constructor initially sets for an optional field will be that field's value. Second, the `mapOptional()` method has an optional third parameter. If provided it is the value that `mapOptional()` should set that field to if the YAML document does not have that key.

There is one important difference between those two ways (default constructor and third parameter to `mapOptional()`). When YAML I/O generates a YAML document, if the `mapOptional()` third parameter is used, if the actual value being written is the same as (using `==`) the default value, then that key/value is not written.

Order of Keys

When writing out a YAML document, the keys are written in the order that the calls to `mapRequired()/mapOptional()` are made in the `mapping()` method. This gives you a chance to write the fields in an order that a human reader of the YAML document would find natural. This may be different than the order of the fields in the native class.

When reading in a YAML document, the keys in the document can be in any order, but they are processed in the order that the calls to `mapRequired()/mapOptional()` are made in the `mapping()` method. That enables some interesting functionality. For instance, if the first field bound is the `cpu` and the second field bound is `flags`, and the `flags` are `cpu` specific, you can programmatically switch how the `flags` are converted to and from YAML based on the `cpu`. This works for both reading and writing. For example:

```

using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

struct Info {
    CPUs      cpu;
    uint32_t   flags;
};

```

(continues on next page)

(continued from previous page)

```

template <>
struct MappingTraits<Info> {
    static void mapping(IO &io, Info &info) {
        io.mapRequired("cpu",      info.cpu);
        // flags must come after cpu for this to work when reading yaml
        if ( info.cpu == cpu_x86_64 )
            io.mapRequired("flags",  *(My86_64Flags*)&info.flags);
        else
            io.mapRequired("flags",  *(My86Flags*)&info.flags);
    }
};

```

Tags

The YAML syntax supports tags as a way to specify the type of a node before it is parsed. This allows dynamic types of nodes. But the YAML I/O model uses static typing, so there are limits to how you can use tags with the YAML I/O model. Recently, we added support to YAML I/O for checking/setting the optional tag on a map. Using this functionality it is even possible to support different mappings, as long as they are convertible.

To check a tag, inside your mapping() method you can use io.mapTag() to specify what the tag should be. This will also add that tag when writing yaml.

Validation

Sometimes in a yaml map, each key/value pair is valid, but the combination is not. This is similar to something having no syntax errors, but still having semantic errors. To support semantic level checking, YAML I/O allows an optional validate() method in a MappingTraits template specialization.

When parsing yaml, the validate() method is called *after* all key/values in the map have been processed. Any error message returned by the validate() method during input will be printed just like a syntax error would be printed. When writing yaml, the validate() method is called *before* the yaml key/values are written. Any error during output will trigger an assert() because it is a programming error to have invalid struct values.

```

using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

struct Stuff {
    ...
};

template <>
struct MappingTraits<Stuff> {
    static void mapping(IO &io, Stuff &stuff) {
        ...
    }
    staticStringRef validate(IO &io, Stuff &stuff) {
        // Look at all fields in 'stuff' and if there
        // are any bad values return a string describing
        // the error. Otherwise return an empty string.
        return StringRef();
    }
};

```

Flow Mapping

A YAML "flow mapping" is a mapping that uses the inline notation (e.g { x: 1, y: 0 }) when written to YAML. To specify that a type should be written in YAML using flow mapping, your MappingTraits specialization should add "static const bool flow = true;". For instance:

```
using llvm::yaml::MappingTraits;
using llvm::yaml::IO;

struct Stuff {
    ...
};

template <>
struct MappingTraits<Stuff> {
    static void mapping(IO &io, Stuff &stuff) {
        ...
    }

    static const bool flow = true;
}
```

Flow mappings are subject to line wrapping according to the Output object configuration.

2.23.6 Sequence

To be translated to or from a YAML sequence for your type T you must specialize llvm::yaml::SequenceTraits on T and implement two methods: size_t size(IO &io, T&) and T::value_type& element(IO &io, T&, size_t indx). For example:

```
template <>
struct SequenceTraits<MySeq> {
    static size_t size(IO &io, MySeq &list) { ... }
    static MySeqEl &element(IO &io, MySeq &list, size_t index) { ... }
};
```

The size() method returns how many elements are currently in your sequence. The element() method returns a reference to the i'th element in the sequence. When parsing YAML, the element() method may be called with an index one bigger than the current size. Your element() method should allocate space for one more element (using default constructor if element is a C++ object) and returns a reference to that new allocated space.

Flow Sequence

A YAML "flow sequence" is a sequence that when written to YAML it uses the inline notation (e.g [foo, bar]). To specify that a sequence type should be written in YAML as a flow sequence, your SequenceTraits specialization should add "static const bool flow = true;". For instance:

```
template <>
struct SequenceTraits<MyList> {
    static size_t size(IO &io, MyList &list) { ... }
    static MyListEl &element(IO &io, MyList &list, size_t index) { ... }

    // The existence of this member causes YAML I/O to use a flow sequence
    static const bool flow = true;
};
```

With the above, if you used `MyList` as the data type in your native data structures, then when converted to YAML, a flow sequence of integers will be used (e.g. `[10, -3, 4]`).

Flow sequences are subject to line wrapping according to the Output object configuration.

Utility Macros

Since a common source of sequences is `std::vector<>`, YAML I/O provides macros: `LLVM_YAML_IS_SEQUENCE_VECTOR()` and `LLVM_YAML_IS_FLOW_SEQUENCE_VECTOR()` which can be used to easily specify `SequenceTraits<>` on a `std::vector` type. YAML I/O does not partial specialize `SequenceTraits` on `std::vector<>` because that would force all vectors to be sequences. An example use of the macros:

```
std::vector<MyType1>;
std::vector<MyType2>;
LLVM_YAML_IS_SEQUENCE_VECTOR(MyType1)
LLVM_YAML_IS_FLOW_SEQUENCE_VECTOR(MyType2)
```

2.23.7 Document List

YAML allows you to define multiple "documents" in a single YAML file. Each new document starts with a left aligned `"---`" token. The end of all documents is denoted with a left aligned `"..."` token. Many users of YAML will never have need for multiple documents. The top level node in their YAML schema will be a mapping or sequence. For those cases, the following is not needed. But for cases where you do want multiple documents, you can specify a trait for your document list type. The trait has the same methods as `SequenceTraits` but is named `DocumentListTraits`. For example:

```
template <>
struct DocumentListTraits<MyDocList> {
    static size_t size(IO &io, MyDocList &list) { ... }
    static MyDocType element(IO &io, MyDocList &list, size_t index) { ... }
};
```

2.23.8 User Context Data

When an `llvm::yaml::Input` or `llvm::yaml::Output` object is created their constructors take an optional "context" parameter. This is a pointer to whatever state information you might need.

For instance, in a previous example we showed how the conversion type for a flags field could be determined at runtime based on the value of another field in the mapping. But what if an inner mapping needs to know some field value of an outer mapping? That is where the "context" parameter comes in. You can set values in the context in the outer map's `mapping()` method and retrieve those values in the inner map's `mapping()` method.

The context value is just a `void*`. All your traits which use the context and operate on your native data types, need to agree what the context value actually is. It could be a pointer to an object or struct which your various traits use to shared context sensitive information.

2.23.9 Output

The `llvm::yaml::Output` class is used to generate a YAML document from your in-memory data structures, using traits defined on your data types. To instantiate an `Output` object you need an `llvm::raw_ostream`, an optional context pointer and an optional wrapping column:

```
class Output : public IO {
public:
    Output(llvm::raw_ostream &, void *context = NULL, int WrapColumn = 70);
```

Once you have an `Output` object, you can use the C++ stream operator on it to write your native data as YAML. One thing to recall is that a YAML file can contain multiple "documents". If the top level data structure you are streaming as YAML is a mapping, scalar, or sequence, then `Output` assumes you are generating one document and wraps the mapping output with "---" and trailing "...".

The `WrapColumn` parameter will cause the flow mappings and sequences to line-wrap when they go over the supplied column. Pass 0 to completely suppress the wrapping.

```
using llvm::yaml::Output;

void dumpMyMapDoc(const MyMapType &info) {
    Output yout(llvm::outs());
    yout << info;
}
```

The above could produce output like:

```
---
name:      Tom
hat-size:  7
...
```

On the other hand, if the top level data structure you are streaming as YAML has a `DocumentListTraits` specialization, then `Output` walks through each element of your `DocumentList` and generates a "---" before the start of each element and ends with a "...".

```
using llvm::yaml::Output;

void dumpMyMapDoc(const MyDocListType &docList) {
    Output yout(llvm::outs());
    yout << docList;
}
```

The above could produce output like:

```
---
name:      Tom
hat-size:  7
---
name:      Tom
shoe-size: 11
...
```

2.23.10 Input

The `llvm::yaml::Input` class is used to parse YAML document(s) into your native data structures. To instantiate an `Input` object you need a `StringRef` to the entire YAML file, and optionally a context pointer:

```
class Input : public IO {
public:
    Input(StringRef inputContent, void *context=NULL);
```

Once you have an `Input` object, you can use the C++ stream operator to read the document(s). If you expect there might be multiple YAML documents in one file, you'll need to specialize `DocumentListTraits` on a list of your document type and stream in that document list type. Otherwise you can just stream in the document type. Also, you can check if there was any syntax errors in the YAML by calling the `error()` method on the `Input` object. For example:

```
// Reading a single document
using llvm::yaml::Input;

Input yin(mb.getBuffer());

// Parse the YAML file
MyDocType theDoc;
yin >> theDoc;

// Check for error
if ( yin.error() )
    return;
```

```
// Reading multiple documents in one file
using llvm::yaml::Input;

LLVM_YAML_IS_DOCUMENT_LIST_VECTOR(MyDocType)

Input yin(mb.getBuffer());

// Parse the YAML file
std::vector<MyDocType> theDocList;
yin >> theDocList;

// Check for error
if ( yin.error() )
    return;
```

2.24 The Often Misunderstood GEP Instruction

- *Summary*

2.24.1 Introduction

This document seeks to dispel the mystery and confusion surrounding LLVM's `GetElementPtr` (GEP) instruction. Questions about the wily GEP instruction are probably the most frequently occurring questions once a developer gets down to coding with LLVM. Here we lay out the sources of confusion and show that the GEP instruction is really quite simple.

2.24.2 Address Computation

When people are first confronted with the GEP instruction, they tend to relate it to known concepts from other programming paradigms, most notably C array indexing and field selection. GEP closely resembles C array indexing and field selection, however it is a little different and this leads to the following questions.

What is the first index of the GEP instruction?

Quick answer: The index stepping through the second operand.

The confusion with the first index usually arises from thinking about the `GetElementPtr` instruction as if it was a C index operator. They aren't the same. For example, when we write, in "C":

```
AType *Foo;
...
X = &Foo->F;
```

it is natural to think that there is only one index, the selection of the field `F`. However, in this example, `Foo` is a pointer. That pointer must be indexed explicitly in LLVM. C, on the other hand, indices through it transparently. To arrive at the same address location as the C code, you would provide the GEP instruction with two index operands. The first operand indexes through the pointer; the second operand indexes the field `F` of the structure, just as if you wrote:

```
X = &Foo[0].F;
```

Sometimes this question gets rephrased as:

Why is it okay to index through the first pointer, but subsequent pointers won't be dereferenced?

The answer is simply because memory does not have to be accessed to perform the computation. The second operand to the GEP instruction must be a value of a pointer type. The value of the pointer is provided directly to the GEP instruction as an operand without any need for accessing memory. It must, therefore be indexed and requires an index operand. Consider this example:

```
struct munger_struct {
    int f1;
    int f2;
};
void munge(struct munger_struct *P) {
    P[0].f1 = P[1].f1 + P[2].f2;
}
...
struct munger_struct Array[3];
...
munge(Array);
```

In this "C" example, the front end compiler (Clang) will generate three GEP instructions for the three indices through "P" in the assignment statement. The function argument `P` will be the second operand of each of these GEP instructions. The third operand indexes through that pointer. The fourth operand will be the field offset into the `struct munger_struct` type, for either the `f1` or `f2` field. So, in LLVM assembly the `munge` function looks like:

```
define void @munge(%struct.munger_struct* %P) {
entry:
    %tmp = getelementptr %struct.munger_struct, %struct.munger_struct* %P, i32 1, i32 0
    %tmp1 = load i32, i32* %tmp
    %tmp2 = getelementptr %struct.munger_struct, %struct.munger_struct* %P, i32 2, i32 1
    %tmp3 = load i32, i32* %tmp2
    %tmp4 = add i32 %tmp3, %tmp1
    %tmp5 = getelementptr %struct.munger_struct, %struct.munger_struct* %P, i32 0, i32 0
    store i32 %tmp4, i32* %tmp5
    ret void
}
```

In each case the second operand is the pointer through which the GEP instruction starts. The same is true whether the second operand is an argument, allocated memory, or a global variable.

To make this clear, let's consider a more obtuse example:

```
%MyVar = uninitialized global i32
...
%idx1 = getelementptr i32, i32* %MyVar, i64 0
%idx2 = getelementptr i32, i32* %MyVar, i64 1
%idx3 = getelementptr i32, i32* %MyVar, i64 2
```

These GEP instructions are simply making address computations from the base address of `%MyVar`. They compute, as follows (using C syntax):

```
idx1 = (char*) &MyVar + 0
idx2 = (char*) &MyVar + 4
idx3 = (char*) &MyVar + 8
```

Since the type `i32` is known to be four bytes long, the indices 0, 1 and 2 translate into memory offsets of 0, 4, and 8, respectively. No memory is accessed to make these computations because the address of `%MyVar` is passed directly to the GEP instructions.

The obtuse part of this example is in the cases of `%idx2` and `%idx3`. They result in the computation of addresses that point to memory past the end of the `%MyVar` global, which is only one `i32` long, not three `i32`s long. While this is legal in LLVM, it is inadvisable because any load or store with the pointer that results from these GEP instructions would produce undefined results.

Why is the extra 0 index required?

Quick answer: there are no superfluous indices.

This question arises most often when the GEP instruction is applied to a global variable which is always a pointer type. For example, consider this:

```
%MyStruct = uninitialized global { float*, i32 }
...
%idx = getelementptr { float*, i32 }, { float*, i32 }* %MyStruct, i64 0, i32 1
```

The GEP above yields an `i32*` by indexing the `i32` typed field of the structure `%MyStruct`. When people first look at it, they wonder why the `i64 0` index is needed. However, a closer inspection of how globals and GEPs work reveals the need. Becoming aware of the following facts will dispel the confusion:

1. The type of `%MyStruct` is *not* `{ float*, i32 }` but rather `{ float*, i32 }*`. That is, `%MyStruct` is a pointer to a structure containing a pointer to a `float` and an `i32`.
2. Point #1 is evidenced by noticing the type of the second operand of the GEP instruction (`%MyStruct`) which is `{ float*, i32 }*`.
3. The first index, `i64 0` is required to step over the global variable `%MyStruct`. Since the second argument to the GEP instruction must always be a value of pointer type, the first index steps through that pointer. A value of 0 means 0 elements offset from that pointer.
4. The second index, `i32 1` selects the second field of the structure (the `i32`).

What is dereferenced by GEP?

Quick answer: nothing.

The `GetElementPtr` instruction dereferences nothing. That is, it doesn't access memory in any way. That's what the `Load` and `Store` instructions are for. GEP is only involved in the computation of addresses. For example, consider this:

```
%MyVar = uninitialized global { [40 x i32] * }
...
%idx = getelementptr { [40 x i32] * }, { [40 x i32] * } * %MyVar, i64 0, i32 0, i64 0,
↳ i64 17
```

In this example, we have a global variable, `%MyVar` that is a pointer to a structure containing a pointer to an array of 40 ints. The GEP instruction seems to be accessing the 18th integer of the structure's array of ints. However, this is actually an illegal GEP instruction. It won't compile. The reason is that the pointer in the structure *must* be dereferenced in order to index into the array of 40 ints. Since the GEP instruction never accesses memory, it is illegal.

In order to access the 18th integer in the array, you would need to do the following:

```
%idx = getelementptr { [40 x i32] * }, { [40 x i32] * } * %, i64 0, i32 0
%arr = load [40 x i32] *, [40 x i32] ** %idx
%idx = getelementptr [40 x i32], [40 x i32] * %arr, i64 0, i64 17
```

In this case, we have to load the pointer in the structure with a `load` instruction before we can index into the array. If the example was changed to:

```
%MyVar = uninitialized global { [40 x i32] }
...
%idx = getelementptr { [40 x i32] }, { [40 x i32] } *, i64 0, i32 0, i64 17
```

then everything works fine. In this case, the structure does not contain a pointer and the GEP instruction can index through the global variable, into the first field of the structure and access the 18th `i32` in the array there.

Why don't GEP x,0,0,1 and GEP x,1 alias?

Quick Answer: They compute different address locations.

If you look at the first indices in these GEP instructions you find that they are different (0 and 1), therefore the address computation diverges with that index. Consider this example:

```
%MyVar = global { [10 x i32] }
%idx1 = getelementptr { [10 x i32] }, { [10 x i32] } * %MyVar, i64 0, i32 0, i64 1
%idx2 = getelementptr { [10 x i32] }, { [10 x i32] } * %MyVar, i64 1
```

In this example, `idx1` computes the address of the second integer in the array that is in the structure in `%MyVar`, that is `MyVar+4`. The type of `idx1` is `i32*`. However, `idx2` computes the address of *the next* structure after `%MyVar`. The type of `idx2` is `{ [10 x i32] }*` and its value is equivalent to `MyVar + 40` because it indexes past the ten 4-byte integers in `MyVar`. Obviously, in such a situation, the pointers don't alias.

Why do GEP x,1,0,0 and GEP x,1 alias?

Quick Answer: They compute the same address location.

These two GEP instructions will compute the same address because indexing through the 0th element does not change the address. However, it does change the type. Consider this example:

```
%MyVar = global { [10 x i32] }
%idx1 = getelementptr { [10 x i32] }, { [10 x i32] }* %MyVar, i64 1, i32 0, i64 0
%idx2 = getelementptr { [10 x i32] }, { [10 x i32] }* %MyVar, i64 1
```

In this example, the value of %idx1 is %MyVar+40 and its type is i32*. The value of %idx2 is also MyVar+40 but its type is { [10 x i32] }*.

Can GEP index into vector elements?

This hasn't always been forcefully disallowed, though it's not recommended. It leads to awkward special cases in the optimizers, and fundamental inconsistency in the IR. In the future, it will probably be outright disallowed.

What effect do address spaces have on GEPs?

None, except that the address space qualifier on the second operand pointer type always matches the address space qualifier on the result type.

How is GEP different from ptrtoint, arithmetic, and inttoptr?

It's very similar; there are only subtle differences.

With ptrtoint, you have to pick an integer type. One approach is to pick i64; this is safe on everything LLVM supports (LLVM internally assumes pointers are never wider than 64 bits in many places), and the optimizer will actually narrow the i64 arithmetic down to the actual pointer size on targets which don't support 64-bit arithmetic in most cases. However, there are some cases where it doesn't do this. With GEP you can avoid this problem.

Also, GEP carries additional pointer aliasing rules. It's invalid to take a GEP from one object, address into a different separately allocated object, and dereference it. IR producers (front-ends) must follow this rule, and consumers (optimizers, specifically alias analysis) benefit from being able to rely on it. See the [Rules](#) section for more information.

And, GEP is more concise in common cases.

However, for the underlying integer computation implied, there is no difference.

I'm writing a backend for a target which needs custom lowering for GEP. How do I do this?

You don't. The integer computation implied by a GEP is target-independent. Typically what you'll need to do is make your backend pattern-match expressions trees involving ADD, MUL, etc., which are what GEP is lowered into. This has the advantage of letting your code work correctly in more cases.

GEP does use target-dependent parameters for the size and layout of data types, which targets can customize.

If you require support for addressing units which are not 8 bits, you'll need to fix a lot of code in the backend, with GEP lowering being only a small piece of the overall picture.

How does VLA addressing work with GEPs?

GEPs don't natively support VLAs. LLVM's type system is entirely static, and GEP address computations are guided by an LLVM type.

VLA indices can be implemented as linearized indices. For example, an expression like `X[a][b][c]`, must be effectively lowered into a form like `X[a*m+b*n+c]`, so that it appears to the GEP as a single-dimensional array reference.

This means if you want to write an analysis which understands array indices and you want to support VLAs, your code will have to be prepared to reverse-engineer the linearization. One way to solve this problem is to use the `ScalarEvolution` library, which always presents VLA and non-VLA indexing in the same manner.

2.24.3 Rules

What happens if an array index is out of bounds?

There are two senses in which an array index can be out of bounds.

First, there's the array type which comes from the (static) type of the first operand to the GEP. Indices greater than the number of elements in the corresponding static array type are valid. There is no problem with out of bounds indices in this sense. Indexing into an array only depends on the size of the array element, not the number of elements.

A common example of how this is used is arrays where the size is not known. It's common to use array types with zero length to represent these. The fact that the static type says there are zero elements is irrelevant; it's perfectly valid to compute arbitrary element indices, as the computation only depends on the size of the array element, not the number of elements. Note that zero-sized arrays are not a special case here.

This sense is unconnected with `inbounds` keyword. The `inbounds` keyword is designed to describe low-level pointer arithmetic overflow conditions, rather than high-level array indexing rules.

Analysis passes which wish to understand array indexing should not assume that the static array type bounds are respected.

The second sense of being out of bounds is computing an address that's beyond the actual underlying allocated object.

With the `inbounds` keyword, the result value of the GEP is undefined if the address is outside the actual underlying allocated object and not the address one-past-the-end.

Without the `inbounds` keyword, there are no restrictions on computing out-of-bounds addresses. Obviously, performing a load or a store requires an address of allocated and sufficiently aligned memory. But the GEP itself is only concerned with computing addresses.

Can array indices be negative?

Yes. This is basically a special case of array indices being out of bounds.

Can I compare two values computed with GEPs?

Yes. If both addresses are within the same allocated object, or one-past-the-end, you'll get the comparison result you expect. If either is outside of it, integer arithmetic wrapping may occur, so the comparison may not be meaningful.

Can I do GEP with a different pointer type than the type of the underlying object?

Yes. There are no restrictions on bitcasting a pointer value to an arbitrary pointer type. The types in a GEP serve only to define the parameters for the underlying integer computation. They need not correspond with the actual type of the underlying object.

Furthermore, loads and stores don't have to use the same types as the type of the underlying object. Types in this context serve only to specify memory size and alignment. Beyond that there are merely a hint to the optimizer indicating how the value will likely be used.

Can I cast an object's address to integer and add it to null?

You can compute an address that way, but if you use GEP to do the add, you can't use that pointer to actually access the object, unless the object is managed outside of LLVM.

The underlying integer computation is sufficiently defined; null has a defined value --- zero --- and you can add whatever value you want to it.

However, it's invalid to access (load from or store to) an LLVM-aware object with such a pointer. This includes `GlobalVariables`, `Allocas`, and objects pointed to by noalias pointers.

If you really need this functionality, you can do the arithmetic with explicit integer instructions, and use `inttoptr` to convert the result to an address. Most of GEP's special aliasing rules do not apply to pointers computed from `ptrtoint`, arithmetic, and `inttoptr` sequences.

Can I compute the distance between two objects, and add that value to one address to compute the other address?

As with arithmetic on null, you can use GEP to compute an address that way, but you can't use that pointer to actually access the object if you do, unless the object is managed outside of LLVM.

Also as above, `ptrtoint` and `inttoptr` provide an alternative way to do this which do not have this restriction.

Can I do type-based alias analysis on LLVM IR?

You can't do type-based alias analysis using LLVM's built-in type system, because LLVM has no restrictions on mixing types in addressing, loads or stores.

LLVM's type-based alias analysis pass uses metadata to describe a different type system (such as the C type system), and performs type-based aliasing on top of that. Further details are in the [language reference](#).

What happens if a GEP computation overflows?

If the GEP lacks the `inbounds` keyword, the value is the result from evaluating the implied two's complement integer computation. However, since there's no guarantee of where an object will be allocated in the address space, such values have limited meaning.

If the GEP has the `inbounds` keyword, the result value is undefined (a "trap value") if the GEP overflows (i.e. wraps around the end of the address space).

As such, there are some ramifications of this for inbounds GEPs: scales implied by array/vector/pointer indices are always known to be "nsw" since they are signed values that are scaled by the element size. These values are also allowed to be negative (e.g. `gep i32 *%P, i32 -1`) but the pointer itself is logically treated as an unsigned value. This means that GEPs have an asymmetric relation between the pointer base (which is treated as unsigned) and the offset applied to it (which is treated as signed). The result of the additions within the offset calculation cannot have signed overflow, but when applied to the base pointer, there can be signed overflow.

How can I tell if my front-end is following the rules?

There is currently no checker for the `getelementptr` rules. Currently, the only way to do this is to manually check each place in your front-end where `GetElementPtr` operators are created.

It's not possible to write a checker which could find all rule violations statically. It would be possible to write a checker which works by instrumenting the code with dynamic checks though. Alternatively, it would be possible to write a static checker which catches a subset of possible problems. However, no such checker exists today.

2.24.4 Rationale

Why is GEP designed this way?

The design of GEP has the following goals, in rough unofficial order of priority:

- Support C, C-like languages, and languages which can be conceptually lowered into C (this covers a lot).
- Support optimizations such as those that are common in C compilers. In particular, GEP is a cornerstone of LLVM's [pointer aliasing model](#).
- Provide a consistent method for computing addresses so that address computations don't need to be a part of load and store instructions in the IR.
- Support non-C-like languages, to the extent that it doesn't interfere with other goals.
- Minimize target-specific information in the IR.

Why do struct member indices always use `i32`?

The specific type `i32` is probably just a historical artifact, however it's wide enough for all practical purposes, so there's been no need to change it. It doesn't necessarily imply `i32` address arithmetic; it's just an identifier which identifies a field in a struct. Requiring that all struct indices be the same reduces the range of possibilities for cases where two GEPs are effectively the same but have distinct operand types.

What's an uglygep?

Some LLVM optimizers operate on GEPs by internally lowering them into more primitive integer expressions, which allows them to be combined with other integer expressions and/or split into multiple separate integer expressions. If they've made non-trivial changes, translating back into LLVM IR can involve reverse-engineering the structure of the addressing in order to fit it into the static type of the original first operand. It isn't always possible to fully reconstruct this structure; sometimes the underlying addressing doesn't correspond with the static type at all. In such cases the optimizer instead will emit a GEP with the base pointer casted to a simple address-unit pointer, using the name "uglygep". This isn't pretty, but it's just as valid, and it's sufficient to preserve the pointer aliasing guarantees that GEP provides.

2.24.5 Summary

In summary, here's some things to always remember about the `GetElementPtr` instruction:

1. The GEP instruction never accesses memory, it only provides pointer computations.
2. The second operand to the GEP instruction is always a pointer and it must be indexed.
3. There are no superfluous indices for the GEP instruction.
4. Trailing zero indices are superfluous for pointer aliasing, but not for the types of the pointers.
5. Leading zero indices are not superfluous for pointer aliasing nor the types of the pointers.

2.25.1 Abstract

The intended audience of this document is developers of language frontends targeting LLVM IR. This document is home to a collection of tips on how to generate IR that optimizes well.

2.25.2 IR Best Practices

As with any optimizer, LLVM has its strengths and weaknesses. In some cases, surprisingly small changes in the source IR can have a large effect on the generated code.

Beyond the specific items on the list below, it's worth noting that the most mature frontend for LLVM is Clang. As a result, the further your IR gets from what Clang might emit, the less likely it is to be effectively optimized. It can often be useful to write a quick C program with the semantics you're trying to model and see what decisions Clang's IRTGen makes about what IR to emit. Studying Clang's CodeGen directory can also be a good source of ideas. Note that Clang and LLVM are explicitly version locked so you'll need to make sure you're using a Clang built from the same svn revision or release as the LLVM library you're using. As always, it's *strongly* recommended that you track tip of tree development, particularly during bring up of a new project.

The Basics

1. Make sure that your Modules contain both a data layout specification and target triple. Without these pieces, none of the target specific optimization will be enabled. This can have a major effect on the generated code quality.
2. For each function or global emitted, use the most private linkage type possible (private, internal or linkonce_odr preferably). Doing so will make LLVM's inter-procedural optimizations much more effective.
3. Avoid high in-degree basic blocks (e.g. basic blocks with dozens or hundreds of predecessors). Among other issues, the register allocator is known to perform badly when confronted with such structures. The only exception to this guidance is that a unified return block with high in-degree is fine.

Use of allocas

An alloca instruction can be used to represent a function scoped stack slot, but can also represent dynamic frame expansion. When representing function scoped variables or locations, placing alloca instructions at the beginning of the entry block should be preferred. In particular, place them before any call instructions. Call instructions might get inlined and replaced with multiple basic blocks. The end result is that a following alloca instruction would no longer be in the entry basic block afterward.

The SROA (Scalar Replacement Of Aggregates) and Mem2Reg passes only attempt to eliminate alloca instructions that are in the entry basic block. Given SSA is the canonical form expected by much of the optimizer; if allocas can not be eliminated by Mem2Reg or SROA, the optimizer is likely to be less effective than it could be.

Avoid loads and stores of large aggregate type

LLVM currently does not optimize well loads and stores of large *aggregate types* (i.e. structs and arrays). As an alternative, consider loading individual fields from memory.

Aggregates that are smaller than the largest (performant) load or store instruction supported by the targeted hardware are well supported. These can be an effective way to represent collections of small packed fields.

Prefer zext over sext when legal

On some architectures (X86_64 is one), sign extension can involve an extra instruction whereas zero extension can be folded into a load. LLVM will try to replace a sext with a zext when it can be proven safe, but if you have information in your source language about the range of a integer value, it can be profitable to use a zext rather than a sext.

Alternatively, you can *specify the range of the value using metadata* and LLVM can do the sext to zext conversion for you.

Zext GEP indices to machine register width

Internally, LLVM often promotes the width of GEP indices to machine register width. When it does so, it will default to using sign extension (sext) operations for safety. If your source language provides information about the range of the index, you may wish to manually extend indices to machine register width using a zext instruction.

When to specify alignment

LLVM will always generate correct code if you don't specify alignment, but may generate inefficient code. For example, if you are targeting MIPS (or older ARM ISAs) then the hardware does not handle unaligned loads and stores, and so you will enter a trap-and-emulate path if you do a load or store with lower-than-natural alignment. To avoid this, LLVM will emit a slower sequence of loads, shifts and masks (or load-right + load-left on MIPS) for all cases where the load / store does not have a sufficiently high alignment in the IR.

The alignment is used to guarantee the alignment on allocas and globals, though in most cases this is unnecessary (most targets have a sufficiently high default alignment that they'll be fine). It is also used to provide a contract to the back end saying 'either this load/store has this alignment, or it is undefined behavior'. This means that the back end is free to emit instructions that rely on that alignment (and mid-level optimizers are free to perform transforms that require that alignment). For x86, it doesn't make much difference, as almost all instructions are alignment-independent. For MIPS, it can make a big difference.

Note that if your loads and stores are atomic, the backend will be unable to lower an under aligned access into a sequence of natively aligned accesses. As a result, alignment is mandatory for atomic loads and stores.

Other Things to Consider

1. Use ptrtoint/inttoptr sparingly (they interfere with pointer aliasing analysis), prefer GEPs
2. Prefer globals over inttoptr of a constant address - this gives you dereferencability information. In MCJIT, use `getSymbolAddress` to provide actual address.
3. Be wary of ordered and atomic memory operations. They are hard to optimize and may not be well optimized by the current optimizer. Depending on your source language, you may consider using fences instead.
4. If calling a function which is known to throw an exception (unwind), use an invoke with a normal destination which contains an unreachable instruction. This form conveys to the optimizer that the call returns abnormally. For an invoke which neither returns normally or requires unwind code in the current function, you can use a `noreturn` call instruction if desired. This is generally not required because the optimizer will convert an invoke with an unreachable unwind destination to a call instruction.
5. Use profile metadata to indicate statically known cold paths, even if dynamic profiling information is not available. This can make a large difference in code placement and thus the performance of tight loops.
6. When generating code for loops, try to avoid terminating the header block of the loop earlier than necessary. If the terminator of the loop header block is a loop exiting conditional branch, the effectiveness of LICM will be limited for loads not in the header. (This is due to the fact that LLVM may not know such a load is safe to speculatively execute and thus can't lift an otherwise loop invariant load unless it can prove the exiting condition

is not taken.) It can be profitable, in some cases, to emit such instructions into the header even if they are not used along a rarely executed path that exits the loop. This guidance specifically does not apply if the condition which terminates the loop header is itself invariant, or can be easily discharged by inspecting the loop index variables.

7. In hot loops, consider duplicating instructions from small basic blocks which end in highly predictable terminators into their successor blocks. If a hot successor block contains instructions which can be vectorized with the duplicated ones, this can provide a noticeable throughput improvement. Note that this is not always profitable and does involve a potentially large increase in code size.
8. When checking a value against a constant, emit the check using a consistent comparison type. The GVN pass *will* optimize redundant equalities even if the type of comparison is inverted, but GVN only runs late in the pipeline. As a result, you may miss the opportunity to run other important optimizations. Improvements to EarlyCSE to remove this issue are tracked in Bug 23333.
9. Avoid using arithmetic intrinsics unless you are *required* by your source language specification to emit a particular code sequence. The optimizer is quite good at reasoning about general control flow and arithmetic, it is not anywhere near as strong at reasoning about the various intrinsics. If profitable for code generation purposes, the optimizer will likely form the intrinsics itself late in the optimization pipeline. It is *very* rarely profitable to emit these directly in the language frontend. This item explicitly includes the use of the *overflow intrinsics*.
10. Avoid using the *assume intrinsic* until you've established that a) there's no other way to express the given fact and b) that fact is critical for optimization purposes. Assumes are a great prototyping mechanism, but they can have negative effects on both compile time and optimization effectiveness. The former is fixable with enough effort, but the later is fairly fundamental to their designed purpose.

2.25.3 Describing Language Specific Properties

When translating a source language to LLVM, finding ways to express concepts and guarantees available in your source language which are not natively provided by LLVM IR will greatly improve LLVM's ability to optimize your code. As an example, C/C++'s ability to mark every add as "no signed wrap (nsw)" goes a long way to assisting the optimizer in reasoning about loop induction variables and thus generating more optimal code for loops.

The LLVM LangRef includes a number of mechanisms for annotating the IR with additional semantic information. It is *strongly* recommended that you become highly familiar with this document. The list below is intended to highlight a couple of items of particular interest, but is by no means exhaustive.

Restricted Operation Semantics

1. Add nsw/nuw flags as appropriate. Reasoning about overflow is generally hard for an optimizer so providing these facts from the frontend can be very impactful.
2. Use fast-math flags on floating point operations if legal. If you don't need strict IEEE floating point semantics, there are a number of additional optimizations that can be performed. This can be highly impactful for floating point intensive computations.

Describing Aliasing Properties

1. Add `noalias/align/dereferenceable/nonnull` to function arguments and return values as appropriate
2. Use pointer aliasing metadata, especially `tbaa` metadata, to communicate otherwise-non-deducible pointer aliasing facts
3. Use `inbounds` on `geps`. This can help to disambiguate some aliasing queries.

Modeling Memory Effects

1. Mark functions as `readnone/readonly/argmemonly` or `noreturn/nounwind` when known. The optimizer will try to infer these flags, but may not always be able to. Manual annotations are particularly important for external functions that the optimizer can not analyze.
2. Use the `lifetime.start/lifetime.end` and `invariant.start/invariant.end` intrinsics where possible. Common profitable uses are for stack like data structures (thus allowing dead store elimination) and for describing life times of `allocas` (thus allowing smaller stack sizes).
3. Mark invariant locations using `!invariant.load` and `TBAA`'s constant flags

Pass Ordering

One of the most common mistakes made by new language frontend projects is to use the existing `-O2` or `-O3` pass pipelines as is. These pass pipelines make a good starting point for an optimizing compiler for any language, but they have been carefully tuned for C and C++, not your target language. You will almost certainly need to use a custom pass order to achieve optimal performance. A couple specific suggestions:

1. For languages with numerous rarely executed guard conditions (e.g. null checks, type checks, range checks) consider adding an extra execution or two of `LoopUnswitch` and `LICM` to your pass order. The standard pass order, which is tuned for C and C++ applications, may not be sufficient to remove all dischargeable checks from loops.
2. If your language uses range checks, consider using the `IRCE` pass. It is not currently part of the standard pass order.
3. A useful sanity check to run is to run your optimized IR back through the `-O2` pipeline again. If you see noticeable improvement in the resulting IR, you likely need to adjust your pass order.

I Still Can't Find What I'm Looking For

If you didn't find what you were looking for above, consider proposing a piece of metadata which provides the optimization hint you need. Such extensions are relatively common and are generally well received by the community. You will need to ensure that your proposal is sufficiently general so that it benefits others if you wish to contribute it upstream.

You should also consider describing the problem you're facing on [llvm-dev](#) and asking for advice. It's entirely possible someone has encountered your problem before and can give good advice. If there are multiple interested parties, that also increases the chances that a metadata extension would be well received by the community as a whole.

2.25.4 Adding to this document

If you run across a case that you feel deserves to be covered here, please send a patch to [llvm-commits](#) for review.

If you have questions on these items, please direct them to [llvm-dev](#). The more relevant context you are able to give to your question, the more likely it is to be answered.

2.26 MCJIT Design and Implementation

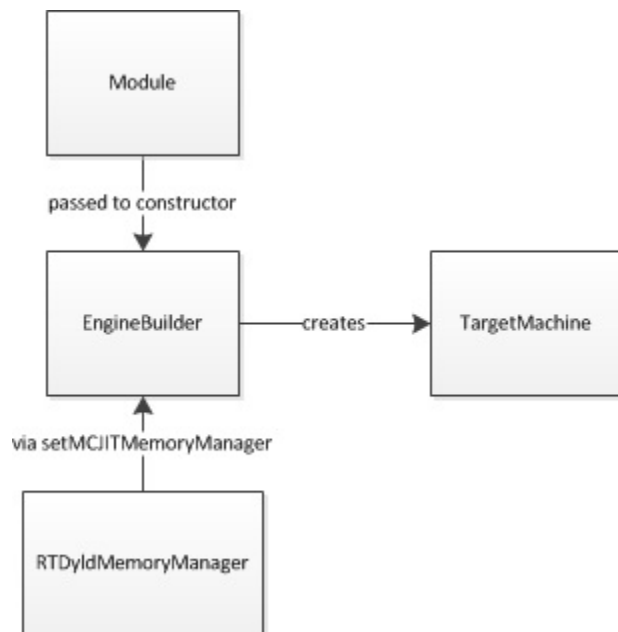

2.26.1 Introduction

This document describes the internal workings of the MCJIT execution engine and the RuntimeDyld component. It is intended as a high level overview of the implementation, showing the flow and interactions of objects throughout the code generation and dynamic loading process.

2.26.2 Engine Creation

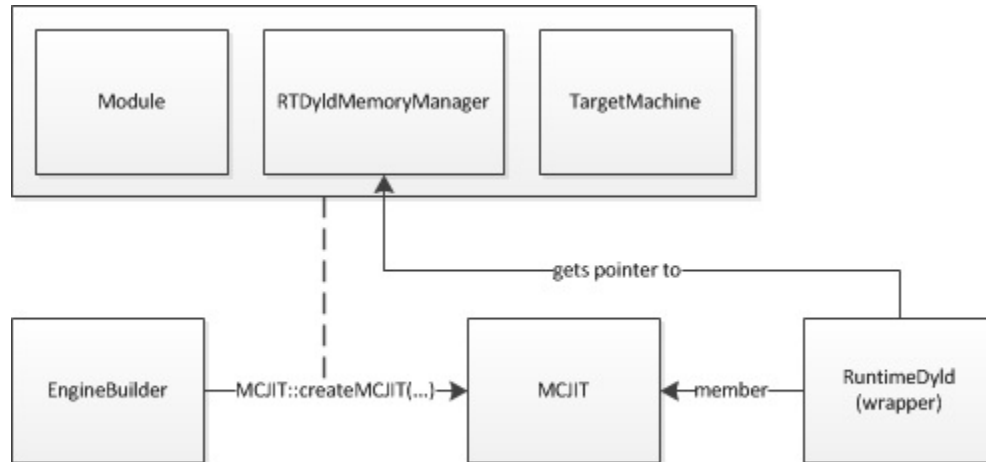

In most cases, an EngineBuilder object is used to create an instance of the MCJIT execution engine. The EngineBuilder takes an `llvm::Module` object as an argument to its constructor. The client may then set various options that we control the later be passed along to the MCJIT engine, including the selection of MCJIT as the engine type to be created. Of particular interest is the `EngineBuilder::setMCJITMemoryManager` function. If the client does not explicitly create a memory manager at this time, a default memory manager (specifically `SectionMemoryManager`) will be created when the MCJIT engine is instantiated.

Once the options have been set, a client calls `EngineBuilder::create` to create an instance of the MCJIT engine. If the client does not use the form of this function that takes a `TargetMachine` as a parameter, a new `TargetMachine` will be created based on the target triple associated with the `Module` that was used to create the `EngineBuilder`.

`EngineBuilder::create` will call the static `MCJIT::createJIT` function, passing in its pointers to the module, memory manager and target machine objects, all of which will subsequently be owned by the MCJIT object.

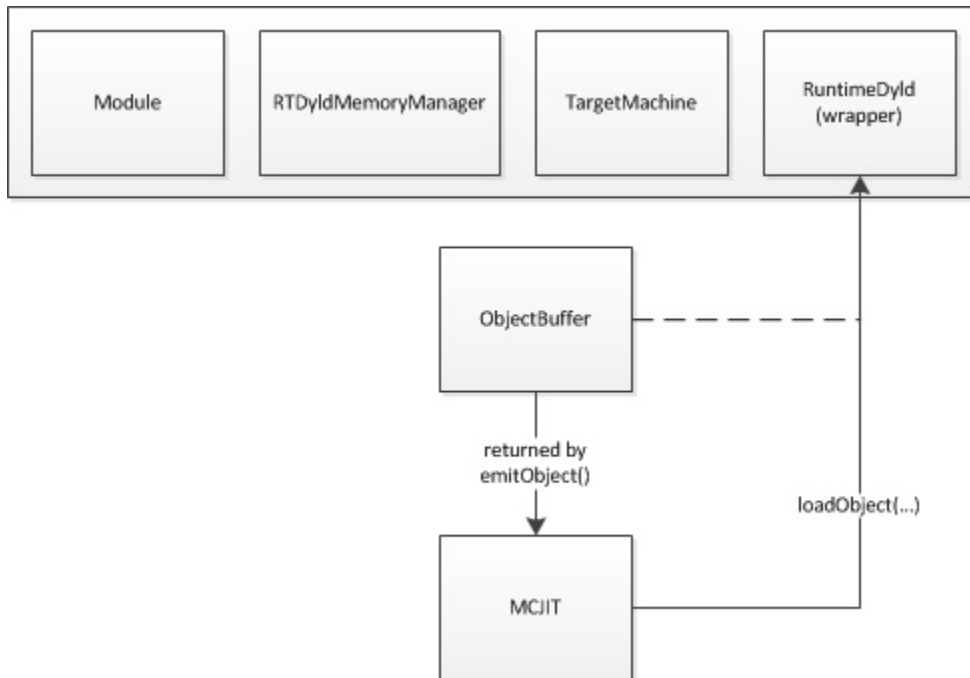

The MCJIT class has a member variable, `Dyld`, which contains an instance of the `RuntimeDyld` wrapper class. This member will be used for communications between MCJIT and the actual `RuntimeDyldImpl` object that gets created when an object is loaded.

Upon creation, MCJIT holds a pointer to the `Module` object that it received from `EngineBuilder` but it does not immediately generate code for this module. Code generation is deferred until either the `MCJIT::finalizeObject` method is called explicitly or a function such as `MCJIT::getPointerToFunction` is called which requires the code to have been generated.

2.26.3 Code Generation

When code generation is triggered, as described above, MCJIT will first attempt to retrieve an object image from its `ObjectCache` member, if one has been set. If a cached object image cannot be retrieved, MCJIT will call its `emitObject` method. `MCJIT::emitObject` uses a local `PassManager` instance and creates a new `ObjectBufferStream` instance, both of which it passes to `TargetMachine::addPassesToEmitMC` before calling `PassManager::run` on the `Module` with which it was created.

The `PassManager::run` call causes the MC code generation mechanisms to emit a complete relocatable binary object image (either in either ELF or MachO format, depending on the target) into the `ObjectBufferStream` object, which is flushed to complete the process. If an `ObjectCache` is being used, the image will be passed to the `ObjectCache` here.

At this point, the `ObjectBufferStream` contains the raw object image. Before the code can be executed, the code and data sections from this image must be loaded into suitable memory, relocations must be applied and memory permission and code cache invalidation (if required) must be completed.

2.26.4 Object Loading

Once an object image has been obtained, either through code generation or having been retrieved from an `ObjectCache`, it is passed to `RuntimeDyld` to be loaded. The `RuntimeDyld` wrapper class examines the object to determine its file format and creates an instance of either `RuntimeDyldELF` or `RuntimeDyldMachO` (both of which derive from the `RuntimeDyldImpl` base class) and calls the `RuntimeDyldImpl::loadObject` method to perform that actual loading.

`RuntimeDyldImpl::loadObject` begins by creating an `ObjectImage` instance from the `ObjectBuffer` it received. `ObjectImage`, which wraps the `ObjectFile` class, is a helper class which parses the binary object image and provides access to the information contained in the format-specific headers, including section, symbol and relocation information.

`RuntimeDyldImpl::loadObject` then iterates through the symbols in the image. Information about common symbols is collected for later use. For each function or data symbol, the associated section is loaded into memory and the symbol is stored in a symbol table map data structure. When the iteration is complete, a section is emitted for the common symbols.

Next, `RuntimeDyldImpl::loadObject` iterates through the sections in the object image and for each section iterates through the relocations for that sections. For each relocation, it calls the format-specific `processRelocationRef` method, which will examine the relocation and store it in one of two data structures, a section-based relocation list map and an external symbol relocation map.

When `RuntimeDyldImpl::loadObject` returns, all of the code and data sections for the object will have been loaded into memory allocated by the memory manager and relocation information will have been prepared, but the relocations have not yet been applied and the generated code is still not ready to be executed.

[Currently (as of August 2013) the MCJIT engine will immediately apply relocations when `loadObject` completes. However, this shouldn't be happening. Because the code may have been generated for a remote target, the client should be given a chance to re-map the section addresses before relocations are applied. It is possible to apply relocations multiple times, but in the case where addresses are to be re-mapped, this first application is wasted effort.]

2.26.5 Address Remapping

At any time after initial code has been generated and before `finalizeObject` is called, the client can remap the address of sections in the object. Typically this is done because the code was generated for an external process and is being mapped into that process' address space. The client remaps the section address by calling `MCJIT::mapSectionAddress`. This should happen before the section memory is copied to its new location.

When `MCJIT::mapSectionAddress` is called, `MCJIT` passes the call on to `RuntimeDyldImpl` (via its `Dyld` member). `RuntimeDyldImpl` stores the new address in an internal data structure but does not update the code at this time, since other sections are likely to change.

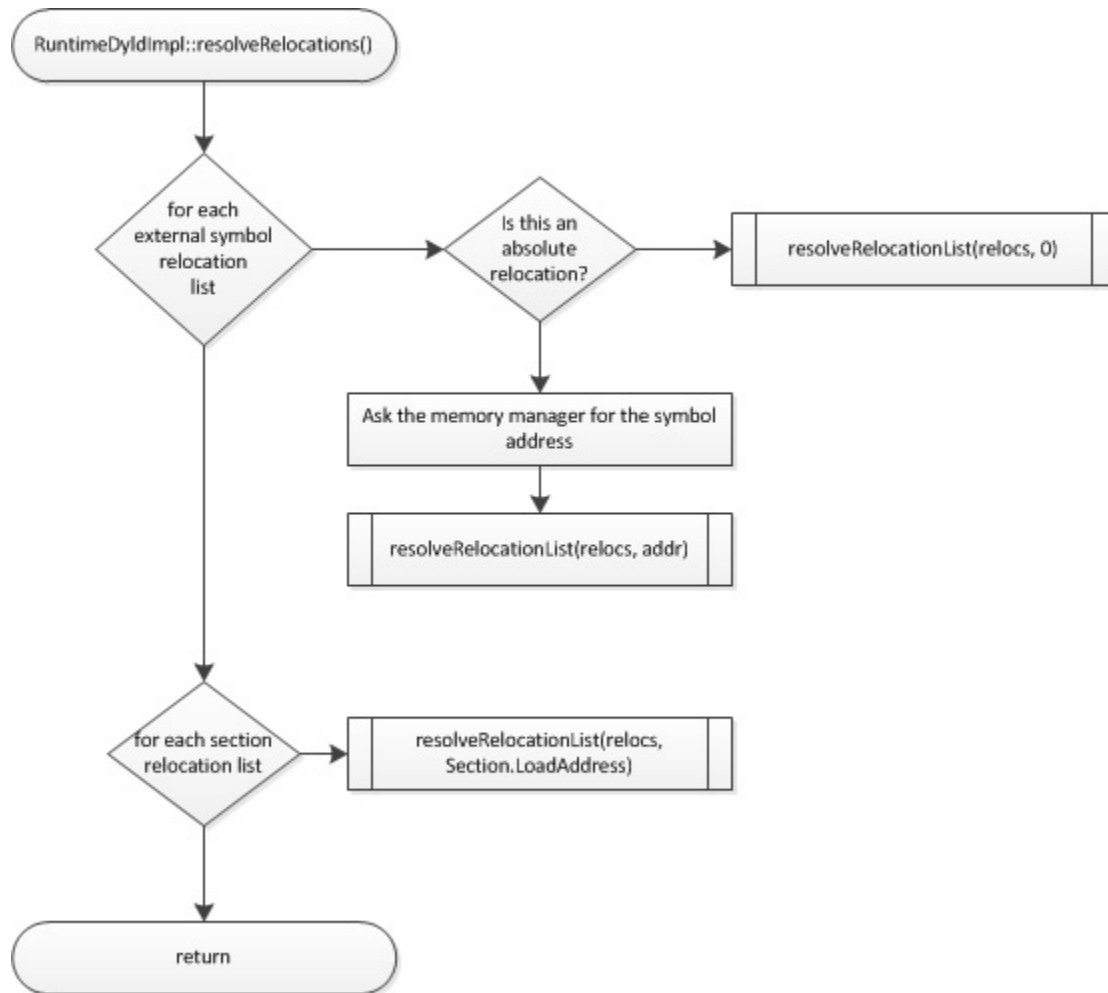

When the client is finished remapping section addresses, it will call `MCJIT::finalizeObject` to complete the remapping process.

2.26.6 Final Preparations

When `MCJIT::finalizeObject` is called, `MCJIT` calls `RuntimeDyld::resolveRelocations`. This function will attempt to locate any external symbols and then apply all relocations for the object.

External symbols are resolved by calling the memory manager's `getPointerToNamedFunction` method. The memory manager will return the address of the requested symbol in the target address space. (Note, this may not be a valid pointer in the host process.) `RuntimeDyld` will then iterate through the list of relocations it has stored which are associated with this symbol and invoke the `resolveRelocation` method which, through an format-specific implementation, will apply the relocation to the loaded section memory.

Next, `RuntimeDyld::resolveRelocations` iterates through the list of sections and for each section iterates through a list of relocations that have been saved which reference that symbol and call `resolveRelocation` for each entry in this list. The relocation list here is a list of relocations for which the symbol associated with the relocation is located in the section associated with the list. Each of these locations will have a target location at which the relocation will be applied that is likely located in a different section.

Once relocations have been applied as described above, MCJIT calls `RuntimeDyld::getEHFrameSection`, and if a non-zero result is returned passes the section data to the memory manager's `registerEHFrames` method. This allows the memory manager to call any desired target-specific functions, such as registering the EH frame information with a debugger.

Finally, MCJIT calls the memory manager's `finalizeMemory` method. In this method, the memory manager will invalidate the target code cache, if necessary, and apply final permissions to the memory pages it has allocated for code and data memory.

2.27 ORC Design and Implementation

- *How to Add Process and Library Symbols to the JITDylibs*
- *Future Features*

2.27.1 Introduction

This document aims to provide a high-level overview of the design and implementation of the ORC JIT APIs. Except where otherwise stated, all discussion applies to the design of the APIs as of LLVM version 9 (ORCv2).

2.27.2 Use-cases

ORC provides a modular API for building JIT compilers. There are a range of use cases for such an API. For example:

1. The LLVM tutorials use a simple ORC-based JIT class to execute expressions compiled from a toy language: Kaleidoscope.
2. The LLVM debugger, LLDB, uses a cross-compiling JIT for expression evaluation. In this use case, cross compilation allows expressions compiled in the debugger process to be executed on the debug target process, which may be on a different device/architecture.
3. In high-performance JITs (e.g. JVMs, Julia) that want to make use of LLVM's optimizations within an existing JIT infrastructure.
4. In interpreters and REPLs, e.g. Cling (C++) and the Swift interpreter.

By adopting a modular, library-based design we aim to make ORC useful in as many of these contexts as possible.

2.27.3 Features

ORC provides the following features:

- *JIT-linking* links relocatable object files (COFF, ELF, MachO)¹ into a target process at runtime. The target process may be the same process that contains the JIT session object and jit-linker, or may be another process (even one running on a different machine or architecture) that communicates with the JIT via RPC.
- *LLVM IR compilation*, which is provided by off the shelf components (IRCompileLayer, SimpleCompiler, ConcurrentIRCompiler) that make it easy to add LLVM IR to a JIT'd process.

¹ Formats/architectures vary in terms of supported features. MachO and ELF tend to have better support than COFF. Patches very welcome!

- *Eager and lazy compilation.* By default, ORC will compile symbols as soon as they are looked up in the JIT session object (`ExecutionSession`). Compiling eagerly by default makes it easy to use ORC as a simple in-memory compiler for an existing JIT. ORC also provides a simple mechanism, lazy-reexports, for deferring compilation until first call.
- *Support for custom compilers and program representations.* Clients can supply custom compilers for each symbol that they define in their JIT session. ORC will run the user-supplied compiler when the a definition of a symbol is needed. ORC is actually fully language agnostic: LLVM IR is not treated specially, and is supported via the same wrapper mechanism (the `MaterializationUnit` class) that is used for custom compilers.
- *Concurrent JIT'd code and concurrent compilation.* JIT'd code may spawn multiple threads, and may re-enter the JIT (e.g. for lazy compilation) concurrently from multiple threads. The ORC APIs also support running multiple compilers concurrently, and provides off-the-shelf infrastructure to track dependencies on running compiles (e.g. to ensure that we never call into code until it is safe to do so, even if that involves waiting on multiple compiles).
- *Orthogonality and composability:* Each of the features above can be used (or not) independently. It is possible to put ORC components together to make a non-lazy, in-process, single threaded JIT or a lazy, out-of-process, concurrent JIT, or anything in between.

2.27.4 LLJIT and LLLazyJIT

ORC provides two basic JIT classes off-the-shelf. These are useful both as examples of how to assemble ORC components to make a JIT, and as replacements for earlier LLVM JIT APIs (e.g. MCJIT).

The LLJIT class uses an `IRCompileLayer` and `RTDyldObjectLinkingLayer` to support compilation of LLVM IR and linking of relocatable object files. All operations are performed eagerly on symbol lookup (i.e. a symbol's definition is compiled as soon as you attempt to look up its address). LLJIT is a suitable replacement for MCJIT in most cases (note: some more advanced features, e.g. `JITEventListeners` are not supported yet).

The LLLazyJIT extends LLJIT and adds a `CompileOnDemandLayer` to enable lazy compilation of LLVM IR. When an LLVM IR module is added via the `addLazyIRModule` method, function bodies in that module will not be compiled until they are first called. LLLazyJIT aims to provide a replacement of LLVM's original (pre-MCJIT) JIT API.

LLJIT and LLLazyJIT instances can be created using their respective builder classes: `LLJITBuilder` and `LLazyJITBuilder`. For example, assuming you have a module `M` loaded on an `ThreadSafeContext Ctx`:

```
// Try to detect the host arch and construct an LLJIT instance.
auto JIT = LLJITBuilder().create();

// If we could not construct an instance, return an error.
if (!JIT)
    return JIT.takeError();

// Add the module.
if (auto Err = JIT->addIRModule(TheadSafeModule(std::move(M), Ctx))
    return Err;

// Look up the JIT'd code entry point.
auto EntrySym = JIT->lookup("entry");
if (!EntrySym)
    return EntrySym.takeError();

auto *Entry = (void(*)())EntrySym.getAddress();

Entry();
```

The builder classes provide a number of configuration options that can be specified before the JIT instance is constructed. For example:

```
// Build an LLLazyJIT instance that uses four worker threads for compilation,
// and jumps to a specific error handler (rather than null) on lazy compile
// failures.

void handleLazyCompileFailure() {
    // JIT'd code will jump here if lazy compilation fails, giving us an
    // opportunity to exit or throw an exception into JIT'd code.
    throw JITFailed();
}

auto JIT = LLLazyJITBuilder()
    .setNumCompileThreads(4)
    .setLazyCompileFailureAddr(
        toJITTargetAddress(&handleLazyCompileFailure))
    .create();

// ...
```

For users wanting to get started with LLJIT a minimal example program can be found at `llvm/examples/HowToUseLLJIT`.

2.27.5 Design Overview

ORC's JIT'd program model aims to emulate the linking and symbol resolution rules used by the static and dynamic linkers. This allows ORC to JIT arbitrary LLVM IR, including IR produced by an ordinary static compiler (e.g. clang) that uses constructs like symbol linkage and visibility, and weak and common symbol definitions.

To see how this works, imagine a program `foo` which links against a pair of dynamic libraries: `libA` and `libB`. On the command line, building this program might look like:

```
$ clang++ -shared -o libA.dylib a1.cpp a2.cpp
$ clang++ -shared -o libB.dylib b1.cpp b2.cpp
$ clang++ -o myapp myapp.cpp -L. -lA -lB
$ ./myapp
```

In ORC, this would translate into API calls on a "CXXCompilingLayer" (with error checking omitted for brevity) as:

```
ExecutionSession ES;
RTDyldObjectLinkingLayer ObjLinkingLayer(
    ES, []() { return llvm::make_unique<SectionMemoryManager>(); });
CXXCompileLayer CXXLayer(ES, ObjLinkingLayer);

// Create JITDylib "A" and add code to it using the CXX layer.
auto &LibA = ES.createJITDylib("A");
CXXLayer.add(LibA, MemoryBuffer::getFile("a1.cpp"));
CXXLayer.add(LibA, MemoryBuffer::getFile("a2.cpp"));

// Create JITDylib "B" and add code to it using the CXX layer.
auto &LibB = ES.createJITDylib("B");
CXXLayer.add(LibB, MemoryBuffer::getFile("b1.cpp"));
CXXLayer.add(LibB, MemoryBuffer::getFile("b2.cpp"));

// Specify the search order for the main JITDylib. This is equivalent to a
// "links against" relationship in a command-line link.
ES.getMainJITDylib().setSearchOrder({&LibA, false}, {&LibB, false});
CXXLayer.add(ES.getMainJITDylib(), MemoryBuffer::getFile("main.cpp"));
```

(continues on next page)

(continued from previous page)

```
// Look up the JIT'd main, cast it to a function pointer, then call it.
auto MainSym = ExitOnErr(ES.lookup({&ES.getMainJITDylib()}, "main"));
auto *Main = (int (*)(int, char*))MainSym.getAddress();
```

```
v int Result = Main(...);
```

This example tells us nothing about *how* or *when* compilation will happen. That will depend on the implementation of the hypothetical CXXCompilingLayer. The same linker-based symbol resolution rules will apply regardless of that implementation, however. For example, if a1.cpp and a2.cpp both define a function "foo" then ORCv2 will generate a duplicate definition error. On the other hand, if a1.cpp and b1.cpp both define "foo" there is no error (different dynamic libraries may define the same symbol). If main.cpp refers to "foo", it should bind to the definition in LibA rather than the one in LibB, since main.cpp is part of the "main" dylib, and the main dylib links against LibA before LibB.

Many JIT clients will have no need for this strict adherence to the usual ahead-of-time linking rules, and should be able to get by just fine by putting all of their code in a single JITDylib. However, clients who want to JIT code for languages/projects that traditionally rely on ahead-of-time linking (e.g. C++) will find that this feature makes life much easier.

Symbol lookup in ORC serves two other important functions, beyond providing addresses for symbols: (1) It triggers compilation of the symbol(s) searched for (if they have not been compiled already), and (2) it provides the synchronization mechanism for concurrent compilation. The pseudo-code for the lookup process is:

```
construct a query object from a query set and query handler
lock the session
lodge query against requested symbols, collect required materializers (if any)
unlock the session
dispatch materializers (if any)
```

In this context a materializer is something that provides a working definition of a symbol upon request. Usually materializers are just wrappers for compilers, but they may also wrap a jit-linker directly (if the program representation backing the definitions is an object file), or may even be a class that writes bits directly into memory (for example, if the definitions are stubs). Materialization is the blanket term for any actions (compiling, linking, splatting bits, registering with runtimes, etc.) that are required to generate a symbol definition that is safe to call or access.

As each materializer completes its work it notifies the JITDylib, which in turn notifies any query objects that are waiting on the newly materialized definitions. Each query object maintains a count of the number of symbols that it is still waiting on, and once this count reaches zero the query object calls the query handler with a *SymbolMap* (a map of symbol names to addresses) describing the result. If any symbol fails to materialize the query immediately calls the query handler with an error.

The collected materialization units are sent to the ExecutionSession to be dispatched, and the dispatch behavior can be set by the client. By default each materializer is run on the calling thread. Clients are free to create new threads to run materializers, or to send the work to a work queue for a thread pool (this is what LLJIT/LLLazyJIT do).

2.27.6 Top Level APIs

Many of ORC's top-level APIs are visible in the example above:

- *ExecutionSession* represents the JIT'd program and provides context for the JIT: It contains the JITDylibs, error reporting mechanisms, and dispatches the materializers.
- *JITDylibs* provide the symbol tables.
- *Layers* (ObjLinkingLayer and CXXLayer) are wrappers around compilers and allow clients to add uncompiled program representations supported by those compilers to JITDylibs.

Several other important APIs are used explicitly. JIT clients need not be aware of them, but Layer authors will use them:

- *MaterializationUnit* - When `XXXLayer::add` is invoked it wraps the given program representation (in this example, C++ source) in a `MaterializationUnit`, which is then stored in the `JITDylib`. `MaterializationUnits` are responsible for describing the definitions they provide, and for unwrapping the program representation and passing it back to the layer when compilation is required (this ownership shuffle makes writing thread-safe layers easier, since the ownership of the program representation will be passed back on the stack, rather than having to be fished out of a Layer member, which would require synchronization).
- *MaterializationResponsibility* - When a `MaterializationUnit` hands a program representation back to the layer it comes with an associated `MaterializationResponsibility` object. This object tracks the definitions that must be materialized and provides a way to notify the `JITDylib` once they are either successfully materialized or a failure occurs.

2.27.7 Handy utilities

TBD: absolute symbols, aliases, off-the-shelf layers.

2.27.8 Laziness

Laziness in ORC is provided by a utility called "lazy-reexports". The aim of this utility is to re-use the synchronization provided by the symbol lookup mechanism to make it safe to lazily compile functions, even if calls to the stub occur simultaneously on multiple threads of JIT'd code. It does this by reducing lazy compilation to symbol lookup: The lazy stub performs a lookup of its underlying definition on first call, updating the function body pointer once the definition is available. If additional calls arrive on other threads while compilation is ongoing they will be safely blocked by the normal lookup synchronization guarantee (no result until the result is safe) and can also proceed as soon as compilation completes.

TBD: Usage example.

2.27.9 Supporting Custom Compilers

TBD.

2.27.10 Transitioning from ORCv1 to ORCv2

Since LLVM 7.0, new ORC development work has focused on adding support for concurrent JIT compilation. The new APIs (including new layer interfaces and implementations, and new utilities) that support concurrency are collectively referred to as ORCv2, and the original, non-concurrent layers and utilities are now referred to as ORCv1.

The majority of the ORCv1 layers and utilities were renamed with a 'Legacy' prefix in LLVM 8.0, and have deprecation warnings attached in LLVM 9.0. In LLVM 10.0 ORCv1 will be removed entirely.

Transitioning from ORCv1 to ORCv2 should be easy for most clients. Most of the ORCv1 layers and utilities have ORCv2 counterparts[2]_ that can be directly substituted. However there are some design differences between ORCv1 and ORCv2 to be aware of:

1. ORCv2 fully adopts the JIT-as-linker model that began with MCJIT. Modules (and other program representations, e.g. Object Files) are no longer added directly to JIT classes or layers. Instead, they are added to `JITDylib` instances *by* layers. The `JITDylib` determines *where* the definitions reside, the layers determine *how* the definitions will be compiled. Linkage relationships between `JITDylibs` determine how inter-module references are resolved, and symbol resolvers are no longer used. See the section [Design Overview](#) for more details.

Unless multiple JITDylibs are needed to model linkage relationships, ORCv1 clients should place all code in the main JITDylib (returned by `ExecutionSession::getMainJITDylib()`). MCJIT clients should use LLJIT (see [LLJIT](#) and [LLLazyJIT](#)).

2. All JIT stacks now need an `ExecutionSession` instance. `ExecutionSession` manages the string pool, error reporting, synchronization, and symbol lookup.
3. ORCv2 uses uniqued strings (`SymbolStringPtr` instances) rather than string values in order to reduce memory overhead and improve lookup performance. See the subsection [How to manage symbol strings](#).
4. IR layers require `ThreadSafeModule` instances, rather than `std::unique_ptr<Module>s`. `ThreadSafeModule` is a wrapper that ensures that Modules that use the same `LLVMContext` are not accessed concurrently. See [How to use ThreadSafeModule and ThreadSafeContext](#).
5. Symbol lookup is no longer handled by layers. Instead, there is a `lookup` method on `JITDylib` that takes a list of `JITDylibs` to scan.

```
ExecutionSession ES;
JITDylib &JD1 = ...;
JITDylib &JD2 = ...;

auto Sym = ES.lookup({&JD1, &JD2}, ES.intern("_main"));
```

6. Module removal is not yet supported. There is no equivalent of the layer concept `removeModule/removeObject` methods. Work on resource tracking and removal in ORCv2 is ongoing.

For code examples and suggestions of how to use the ORCv2 APIs, please see the section [How-tos](#).

2.27.11 How-tos

How to manage symbol strings

Symbol strings in ORC are uniqued to improve lookup performance, reduce memory overhead, and allow symbol names to function as efficient keys. To get the unique `SymbolStringPtr` for a string value, call the `ExecutionSession::intern` method:

```
ExecutionSession ES;
/// ...
auto MainSymbolName = ES.intern("main");
```

If you wish to perform lookup using the C/IR name of a symbol you will also need to apply the platform linker-mangling before interning the string. On Linux this mangling is a no-op, but on other platforms it usually involves adding a prefix to the string (e.g. `'_'` on Darwin). The mangling scheme is based on the `DataLayout` for the target. Given a `DataLayout` and an `ExecutionSession`, you can create a `MangleAndInterner` function object that will perform both jobs for you:

```
ExecutionSession ES;
const DataLayout &DL = ...;
MangleAndInterner Mangle(ES, DL);

// ...

// Portable IR-symbol-name lookup:
auto Sym = ES.lookup({&ES.getMainJITDylib()}, Mangle("main"));
```

How to create JITDylibs and set up linkage relationships

In ORC, all symbol definitions reside in JITDylibs. JITDylibs are created by calling the `ExecutionSession::createJITDylib` method with a unique name:

```
ExecutionSession ES;
auto &JD = ES.createJITDylib("libFoo.dylib");
```

The JITDylib is owned by the `ExecutionEngine` instance and will be freed when it is destroyed.

A JITDylib representing the JIT main program is created by `ExecutionEngine` by default. A reference to it can be obtained by calling `ExecutionSession::getMainJITDylib()`:

```
ExecutionSession ES;
auto &MainJD = ES.getMainJITDylib();
```

How to use ThreadSafeModule and ThreadSafeContext

`ThreadSafeModule` and `ThreadSafeContext` are wrappers around `Modules` and `LLVMContexts` respectively. A `ThreadSafeModule` is a pair of a `std::unique_ptr<Module>` and a (possibly shared) `ThreadSafeContext` value. A `ThreadSafeContext` is a pair of a `std::unique_ptr<LLVMContext>` and a lock. This design serves two purposes: providing both a locking scheme and lifetime management for `LLVMContexts`. The `ThreadSafeContext` may be locked to prevent accidental concurrent access by two `Modules` that use the same `LLVMContext`. The underlying `LLVMContext` is freed once all `ThreadSafeContext` values pointing to it are destroyed, allowing the context memory to be reclaimed as soon as the `Modules` referring to it are destroyed.

`ThreadSafeContexts` can be explicitly constructed from a `std::unique_ptr<LLVMContext>`:

```
ThreadSafeContext TSCTX(llvm::make_unique<LLVMContext>());
```

`ThreadSafeModules` can be constructed from a pair of a `std::unique_ptr<Module>` and a `ThreadSafeContext` value. `ThreadSafeContext` values may be shared between multiple `ThreadSafeModules`:

```
ThreadSafeModule TSM1(
    llvm::make_unique<Module>("M1", *TSCTX.getContext()), TSCTX);

ThreadSafeModule TSM2(
    llvm::make_unique<Module>("M2", *TSCTX.getContext()), TSCTX);
```

Before using a `ThreadSafeContext`, clients should ensure that either the context is only accessible on the current thread, or that the context is locked. In the example above (where the context is never locked) we rely on the fact that both `TSM1` and `TSM2`, and `TSCTX` are all created on one thread. If a context is going to be shared between threads then it must be locked before the context, or any `Modules` attached to it, are accessed. When code is added to in-tree IR layers this locking is done automatically by the `BasicIRLayerMaterializationUnit::materialize` method. In all other situations, for example when writing a custom IR materialization unit, or constructing a new `ThreadSafeModule` from higher-level program representations, locking must be done explicitly:

```
void HighLevelRepresentationLayer::emit(MaterializationResponsibility R,
                                         HighLevelProgramRepresentation H) {
    // Get or create a context value that may be shared between threads.
    ThreadSafeContext TSCTX = getContext();

    // Lock the context to prevent concurrent access.
    auto Lock = TSCTX.getLock();
```

(continues on next page)

(continued from previous page)

```
// IRGen a module onto the locked Context.
ThreadSafeModule TSM(IRGen(H, *TSCtx.getContext()), TSCtx);

// Emit the module to the base layer with the context still locked.
BaseIRLayer.emit(std::move(R), std::move(TSM));
}
```

Clients wishing to maximize possibilities for concurrent compilation will want to create every new ThreadSafeModule on a new ThreadSafeContext. For this reason a convenience constructor for ThreadSafeModule is provided that implicitly constructs a new ThreadSafeContext value from a `std::unique_ptr<LLVMContext>`:

```
// Maximize concurrency opportunities by loading every module on a
// separate context.
for (const auto &IRPath : IRPaths) {
    auto Ctx = llvm::make_unique<LLVMContext>();
    auto M = llvm::make_unique<LLVMContext>("M", *Ctx);
    CompileLayer.add(ES.getMainJITDylib(),
                    ThreadSafeModule(std::move(M), std::move(Ctx)));
}
```

Clients who plan to run single-threaded may choose to save memory by loading all modules on the same context:

```
// Save memory by using one context for all Modules:
ThreadSafeContext TSCtx(llvm::make_unique<LLVMContext>());
for (const auto &IRPath : IRPaths) {
    ThreadSafeModule TSM(parsePath(IRPath, *TSCtx.getContext()), TSCtx);
    CompileLayer.add(ES.getMainJITDylib(), ThreadSafeModule(std::move(TSM)));
}
```

2.27.12 How to Add Process and Library Symbols to the JITDylibs

JIT'd code typically needs access to symbols in the host program or in supporting libraries. References to process symbols can be "baked in" to code as it is compiled by turning external references into pre-resolved integer constants, however this ties the JIT'd code to the current process's virtual memory layout (meaning that it can not be cached between runs) and makes debugging lower level program representations difficult (as all external references are opaque integer values). A better solution is to maintain symbolic external references and let the jit-linker bind them for you at runtime. To allow the JIT linker to find these external definitions their addresses must be added to a JITDylib that the JIT'd definitions link against.

Adding definitions for external symbols could be done using the `absoluteSymbols` function:

```
const DataLayout &DL = getDataLayout();
MangleAndInterner Mangle(ES, DL);

auto &JD = ES.getMainJITDylib();

JD.define(
    absoluteSymbols({
        { Mangle("puts"), pointerToJITTargetAddress(&puts) },
        { Mangle("gets"), pointerToJITTargetAddress(&gets) }
    }));
```

Manually adding absolute symbols for a large or changing interface is cumbersome however, so ORC provides an alternative to generate new definitions on demand: *definition generators*. If a definition generator is attached to a JITDylib, then any unsuccessful lookup on that JITDylib will fall back to calling the definition generator, and the

definition generator may choose to generate a new definition for the missing symbols. Of particular use here is the `DynamicLibrarySearchGenerator` utility. This can be used to reflect the whole exported symbol set of the process or a specific dynamic library, or a subset of either of these determined by a predicate.

For example, to load the whole interface of a runtime library:

```
const DataLayout &DL = getDataLayout();
auto &JD = ES.getMainJITDylib();

JD.setGenerator(DynamicLibrarySearchGenerator::Load("/path/to/lib"
                                                    DL.getGlobalPrefix()));

// IR added to JD can now link against all symbols exported by the library
// at '/path/to/lib'.
CompileLayer.add(JD, loadModule(...));
```

Or, to expose a whitelisted set of symbols from the main process:

```
const DataLayout &DL = getDataLayout();
MangleAndInterner Mangle(ES, DL);

auto &JD = ES.getMainJITDylib();

DenseSet<SymbolStringPtr> Whitelist({
    Mangle("puts"),
    Mangle("gets")
});

// Use GetForCurrentProcess with a predicate function that checks the
// whitelist.
JD.setGenerator(
    DynamicLibrarySearchGenerator::GetForCurrentProcess(
        DL.getGlobalPrefix(),
        [&](const SymbolStringPtr &S) { return Whitelist.count(S); }));

// IR added to JD can now link against any symbols exported by the process
// and contained in the whitelist.
CompileLayer.add(JD, loadModule(...));
```

2.27.13 Future Features

TBD: Speculative compilation. Object Caches.

2.28 LLVM Community Code of Conduct

Note: This document is currently a **DRAFT** document while it is being discussed by the community.

The LLVM community has always worked to be a welcoming and respectful community, and we want to ensure that doesn't change as we grow and evolve. To that end, we have a few ground rules that we ask people to adhere to:

- *be friendly and patient,*
- *be welcoming,*

- *be considerate,*
- *be respectful,*
- *be careful in the words that you choose and be kind to others,* and
- *when we disagree, try to understand why.*

This isn't an exhaustive list of things that you can't do. Rather, take it in the spirit in which it's intended - a guide to make it easier to communicate and participate in the community.

This code of conduct applies to all spaces managed by the LLVM project or The LLVM Foundation. This includes IRC channels, mailing lists, bug trackers, LLVM events such as the developer meetings and socials, and any other forums created by the project that the community uses for communication. It applies to all of your communication and conduct in these spaces, including emails, chats, things you say, slides, videos, posters, signs, or even t-shirts you display in these spaces. In addition, violations of this code outside these spaces may, in rare cases, affect a person's ability to participate within them, when the conduct amounts to an egregious violation of this code.

If you believe someone is violating the code of conduct, we ask that you report it by emailing conduct@llvm.org. For more details please see our [Reporting Guide](#).

- **Be friendly and patient.**
- **Be welcoming.** We strive to be a community that welcomes and supports people of all backgrounds and identities. This includes, but is not limited to members of any race, ethnicity, culture, national origin, colour, immigration status, social and economic class, educational level, sex, sexual orientation, gender identity and expression, age, size, family status, political belief, religion or lack thereof, and mental and physical ability.
- **Be considerate.** Your work will be used by other people, and you in turn will depend on the work of others. Any decision you take will affect users and colleagues, and you should take those consequences into account. Remember that we're a world-wide community, so you might not be communicating in someone else's primary language.
- **Be respectful.** Not all of us will agree all the time, but disagreement is no excuse for poor behavior and poor manners. We might all experience some frustration now and then, but we cannot allow that frustration to turn into a personal attack. It's important to remember that a community where people feel uncomfortable or threatened is not a productive one. Members of the LLVM community should be respectful when dealing with other members as well as with people outside the LLVM community.
- **Be careful in the words that you choose and be kind to others.** Do not insult or put down other participants. Harassment and other exclusionary behavior aren't acceptable. This includes, but is not limited to:
 - Violent threats or language directed against another person.
 - Discriminatory jokes and language.
 - Posting sexually explicit or violent material.
 - Posting (or threatening to post) other people's personally identifying information ("doxing").
 - Personal insults, especially those using racist or sexist terms.
 - Unwelcome sexual attention.
 - Advocating for, or encouraging, any of the above behavior.

In general, if someone asks you to stop, then stop. Persisting in such behavior after being asked to stop is considered harassment.

- **When we disagree, try to understand why.** Disagreements, both social and technical, happen all the time and LLVM is no exception. It is important that we resolve disagreements and differing views constructively. Remember that we're different. The strength of LLVM comes from its varied community, people from a wide range of backgrounds. Different people have different perspectives on issues. Being unable to understand why

someone holds a viewpoint doesn't mean that they're wrong. Don't forget that it is human to err and blaming each other doesn't get us anywhere. Instead, focus on helping to resolve issues and learning from mistakes.

2.28.1 Questions?

If you have questions, please feel free to contact the LLVM Foundation Code of Conduct Advisory Committee by emailing conduct@llvm.org.

(This text is based on the [Django Project](#) Code of Conduct, which is in turn based on wording from the [Speak Up!](#) project.)

2.29 Compiling CUDA with clang

- *Introduction*

- *Optimizations*
- *Publication*
- *Obtaining Help*

2.29.1 Introduction

This document describes how to compile CUDA code with clang, and gives some details about LLVM and clang's CUDA implementations.

This document assumes a basic familiarity with CUDA. Information about CUDA programming can be found in the [CUDA programming guide](#).

2.29.2 Compiling CUDA Code

Prerequisites

CUDA is supported since llvm 3.9. Current release of clang (7.0.0) supports CUDA 7.0 through 9.2. If you need support for CUDA 10, you will need to use clang built from r342924 or newer.

Before you build CUDA code, you'll need to have installed the appropriate driver for your nvidia GPU and the CUDA SDK. See [NVIDIA's CUDA installation guide](#) for details. Note that clang **does not support** the CUDA toolkit as installed by many Linux package managers; you probably need to install CUDA in a single directory from NVIDIA's package.

CUDA compilation is supported on Linux. Compilation on MacOS and Windows may or may not work and currently have no maintainers. Compilation with CUDA-9.x is **currently broken on Windows**.

Invoking clang

Invoking clang for CUDA compilation works similarly to compiling regular C++. You just need to be aware of a few additional flags.

You can use [this](#) program as a toy example. Save it as `axpy.cu`. (Clang detects that you're compiling CUDA code by noticing that your filename ends with `.cu`. Alternatively, you can pass `-x cuda`.)

To build and run, run the following commands, filling in the parts in angle brackets as described below:

```
$ clang++ axpy.cu -o axpy --cuda-gpu-arch=<GPU arch> \
    -L<CUDA install path>/<lib64 or lib> \
    -lcudart_static -ldl -lrt -pthread
$ ./axpy
y[0] = 2
y[1] = 4
y[2] = 6
y[3] = 8
```

On MacOS, replace `-lcudart_static` with `-lcudart`; otherwise, you may get "CUDA driver version is insufficient for CUDA runtime version" errors when you run your program.

- `<CUDA install path>` -- the directory where you installed CUDA SDK. Typically, `/usr/local/cuda`.

Pass e.g. `-L/usr/local/cuda/lib64` if compiling in 64-bit mode; otherwise, pass e.g. `-L/usr/local/cuda/lib`. (In CUDA, the device code and host code always have the same pointer widths, so if you're compiling 64-bit code for the host, you're also compiling 64-bit code for the device.) Note that as of v10.0 CUDA SDK **no longer supports compilation of 32-bit applications**.

- `<GPU arch>` -- the **compute capability** of your GPU. For example, if you want to run your program on a GPU with compute capability of 3.5, specify `--cuda-gpu-arch=sm_35`.

Note: You cannot pass `compute_XX` as an argument to `--cuda-gpu-arch`; only `sm_XX` is currently supported. However, clang always includes PTX in its binaries, so e.g. a binary compiled with `--cuda-gpu-arch=sm_30` would be forwards-compatible with e.g. `sm_35` GPUs.

You can pass `--cuda-gpu-arch` multiple times to compile for multiple archs.

The `-L` and `-l` flags only need to be passed when linking. When compiling, you may also need to pass `--cuda-path=/path/to/cuda` if you didn't install the CUDA SDK into `/usr/local/cuda` or `/usr/local/cuda-X.Y`.

Flags that control numerical code

If you're using GPUs, you probably care about making numerical code run fast. GPU hardware allows for more control over numerical operations than most CPUs, but this results in more compiler options for you to juggle.

Flags you may wish to tweak include:

- `-ffp-contract={on, off, fast}` (defaults to `fast` on host and device when compiling CUDA) Controls whether the compiler emits fused multiply-add operations.
 - `off`: never emit `fma` operations, and prevent `ptxas` from fusing multiply and add instructions.
 - `on`: fuse multiplies and adds within a single statement, but never across statements (C11 semantics). Prevent `ptxas` from fusing other multiplies and adds.
 - `fast`: fuse multiplies and adds wherever profitable, even across statements. Doesn't prevent `ptxas` from fusing additional multiplies and adds.

Fused multiply-add instructions can be much faster than the unfused equivalents, but because the intermediate result in an `fma` is not rounded, this flag can affect numerical code.

- `-fcuda-flush-denormals-to-zero` (default: `off`) When this is enabled, floating point operations may flush **denormal** inputs and/or outputs to 0. Operations on denormal numbers are often much slower than the same operations on normal numbers.
- `-fcuda-approx-transcendentals` (default: `off`) When this is enabled, the compiler may emit calls to faster, approximate versions of transcendental functions, instead of using the slower, fully IEEE-compliant versions. For example, this flag allows clang to emit the `ptx sin.approx.f32` instruction.

This is implied by `-ffast-math`.

2.29.3 Standard library support

In clang and `nvcc`, most of the C++ standard library is not supported on the device side.

`<math.h>` and `<cmath>`

In clang, `math.h` and `cmath` are available and **pass tests** adapted from `libc++`'s test suite.

In `nvcc` `math.h` and `cmath` are mostly available. Versions of `::foo` in namespace `std` (e.g. `std::sinf`) are not available, and where the standard calls for overloads that take integral arguments, these are usually not available.

```
#include <math.h>
#include <cmath.h>

// clang is OK with everything in this function.
__device__ void test() {
    std::sin(0.); // nvcc - ok
    std::sin(0);  // nvcc - error, because no std::sin(int) override is available.
    sin(0);       // nvcc - same as above.

    sinf(0.);     // nvcc - ok
    std::sinf(0.); // nvcc - no such function
}
```

<std::complex>

nvcc does not officially support `std::complex`. It's an error to use `std::complex` in `__device__` code, but it often works in `__host__ __device__` code due to nvcc's interpretation of the "wrong-side rule" (see below). However, we have heard from implementers that it's possible to get into situations where nvcc will omit a call to an `std::complex` function, especially when compiling without optimizations.

As of 2016-11-16, clang supports `std::complex` without these caveats. It is tested with libstdc++ 4.8.5 and newer, but is known to work only with libc++ newer than 2016-11-16.

<algorithm>

In C++14, many useful functions from `<algorithm>` (notably, `std::min` and `std::max`) become `constexpr`. You can therefore use these in device code, when compiling with clang.

2.29.4 Detecting clang vs NVCC from code

Although clang's CUDA implementation is largely compatible with NVCC's, you may still want to detect when you're compiling CUDA code specifically with clang.

This is tricky, because NVCC may invoke clang as part of its own compilation process! For example, NVCC uses the host compiler's preprocessor when compiling for device code, and that host compiler may in fact be clang.

When clang is actually compiling CUDA code -- rather than being used as a subtool of NVCC's -- it defines the `__CUDA__` macro. `__CUDA_ARCH__` is defined only in device mode (but will be defined if NVCC is using clang as a preprocessor). So you can use the following incantations to detect clang CUDA compilation, in host and device modes:

```
#if defined(__clang__) && defined(__CUDA__) && !defined(__CUDA_ARCH__)
// clang compiling CUDA code, host mode.
#endif

#if defined(__clang__) && defined(__CUDA__) && defined(__CUDA_ARCH__)
// clang compiling CUDA code, device mode.
#endif
```

Both clang and nvcc define `__CUDACC__` during CUDA compilation. You can detect NVCC specifically by looking for `__NVCC__`.

2.29.5 Dialect Differences Between clang and nvcc

There is no formal CUDA spec, and clang and nvcc speak slightly different dialects of the language. Below, we describe some of the differences.

This section is painful; hopefully you can skip this section and live your life blissfully unaware.

Compilation Models

Most of the differences between clang and nvcc stem from the different compilation models used by clang and nvcc. nvcc uses *split compilation*, which works roughly as follows:

- Run a preprocessor over the input `.cu` file to split it into two source files: `H`, containing source code for the host, and `D`, containing source code for the device.
- For each GPU architecture `arch` that we're compiling for, do:
 - Compile `D` using nvcc proper. The result of this is a `ptx` file for `P_arch`.
 - Optionally, invoke `ptxas`, the PTX assembler, to generate a file, `S_arch`, containing GPU machine code (SASS) for `arch`.
- Invoke `fatbin` to combine all `P_arch` and `S_arch` files into a single "fat binary" file, `F`.
- Compile `H` using an external host compiler (gcc, clang, or whatever you like). `F` is packaged up into a header file which is force-included into `H`; nvcc generates code that calls into this header to e.g. launch kernels.

clang uses *merged parsing*. This is similar to split compilation, except all of the host and device code is present and must be semantically-correct in both compilation steps.

- For each GPU architecture `arch` that we're compiling for, do:
 - Compile the input `.cu` file for device, using clang. `__host__` code is parsed and must be semantically correct, even though we're not generating code for the host at this time.
The output of this step is a `ptx` file `P_arch`.
 - Invoke `ptxas` to generate a SASS file, `S_arch`. Note that, unlike nvcc, clang always generates SASS code.
- Invoke `fatbin` to combine all `P_arch` and `S_arch` files into a single fat binary file, `F`.
- Compile `H` using clang. `__device__` code is parsed and must be semantically correct, even though we're not generating code for the device at this time.

`F` is passed to this compilation, and clang includes it in a special ELF section, where it can be found by tools like `cuobjdump`.

(You may ask at this point, why does clang need to parse the input file multiple times? Why not parse it just once, and then use the AST to generate code for the host and each device architecture?

Unfortunately this can't work because we have to define different macros during host compilation and during device compilation for each GPU architecture.)

clang's approach allows it to be highly robust to C++ edge cases, as it doesn't need to decide at an early stage which declarations to keep and which to throw away. But it has some consequences you should be aware of.

Overloading Based on `__host__` and `__device__` Attributes

Let "H", "D", and "HD" stand for "`__host__` functions", "`__device__` functions", and "`__host__ __device__` functions", respectively. Functions with no attributes behave the same as H.

nvcc does not allow you to create H and D functions with the same signature:

```
// nvcc: error - function "foo" has already been defined
__host__ void foo() {}
__device__ void foo() {}
```

However, nvcc allows you to "overload" H and D functions with different signatures:

```
// nvcc: no error
__host__ void foo(int) {}
__device__ void foo() {}
```

In clang, the `__host__` and `__device__` attributes are part of a function's signature, and so it's legal to have H and D functions with (otherwise) the same signature:

```
// clang: no error
__host__ void foo() {}
__device__ void foo() {}
```

HD functions cannot be overloaded by H or D functions with the same signature:

```
// nvcc: error - function "foo" has already been defined
// clang: error - redefinition of 'foo'
__host__ __device__ void foo() {}
__device__ void foo() {}

// nvcc: no error
// clang: no error
__host__ __device__ void bar(int) {}
__device__ void bar() {}
```

When resolving an overloaded function, clang considers the host/device attributes of the caller and callee. These are used as a tiebreaker during overload resolution. See [IdentifyCUDAPreference](#) for the full set of rules, but at a high level they are:

- D functions prefer to call other Ds. HDs are given lower priority.
- Similarly, H functions prefer to call other Hs, or `__global__` functions (with equal priority). HDs are given lower priority.
- HD functions prefer to call other HDs.

When compiling for device, HDs will call Ds with lower priority than HD, and will call Hs with still lower priority. If it's forced to call an H, the program is malformed if we emit code for this HD function. We call this the "wrong-side rule", see example below.

The rules are symmetrical when compiling for host.

Some examples:

```
__host__ void foo();
__device__ void foo();

__host__ void bar();
__host__ __device__ void bar();

__host__ void test_host() {
    foo(); // calls H overload
    bar(); // calls H overload
}

__device__ void test_device() {
    foo(); // calls D overload
    bar(); // calls HD overload
}

__host__ __device__ void test_hd() {
```

(continues on next page)

(continued from previous page)

```

foo(); // calls H overload when compiling for host, otherwise D overload
bar(); // always calls HD overload
}

```

Wrong-side rule example:

```

__host__ void host_only();

// We don't codegen inline functions unless they're referenced by a
// non-inline function. inline_hd1() is called only from the host side, so
// does not generate an error. inline_hd2() is called from the device side,
// so it generates an error.
inline __host__ __device__ void inline_hd1() { host_only(); } // no error
inline __host__ __device__ void inline_hd2() { host_only(); } // error

__host__ void host_fn() { inline_hd1(); }
__device__ void device_fn() { inline_hd2(); }

// This function is not inline, so it's always codegen'ed on both the host
// and the device. Therefore, it generates an error.
__host__ __device__ void not_inline_hd() { host_only(); }

```

For the purposes of the wrong-side rule, templated functions also behave like inline functions: They aren't codegen'ed unless they're instantiated (usually as part of the process of invoking them).

clang's behavior with respect to the wrong-side rule matches nvcc's, except nvcc only emits a warning for `not_inline_hd`; device code is allowed to call `not_inline_hd`. In its generated code, nvcc may omit `not_inline_hd`'s call to `host_only` entirely, or it may try to generate code for `host_only` on the device. What you get seems to depend on whether or not the compiler chooses to inline `host_only`.

Member functions, including constructors, may be overloaded using H and D attributes. However, destructors cannot be overloaded.

Using a Different Class on Host/Device

Occasionally you may want to have a class with different host/device versions.

If all of the class's members are the same on the host and device, you can just provide overloads for the class's member functions.

However, if you want your class to have different members on host/device, you won't be able to provide working H and D overloads in both classes. In this case, clang is likely to be unhappy with you.

```

#ifdef __CUDA_ARCH__
struct S {
    __device__ void foo() { /* use device_only */ }
    int device_only;
};
#else
struct S {
    __host__ void foo() { /* use host_only */ }
    double host_only;
};

__device__ void test() {
    S s;
}

```

(continues on next page)

(continued from previous page)

```

// clang generates an error here, because during host compilation, we
// have ifdef'ed away the __device__ overload of S::foo(). The __device__
// overload must be present *even during host compilation*.
S.foo();
}
#endif

```

We posit that you don't really want to have classes with different members on H and D. For example, if you were to pass one of these as a parameter to a kernel, it would have a different layout on H and D, so would not work properly.

To make code like this compatible with clang, we recommend you separate it out into two classes. If you need to write code that works on both host and device, consider writing an overloaded wrapper function that returns different types on host and device.

```

struct HostS { ... };
struct DeviceS { ... };

__host__ HostS MakeStruct() { return HostS(); }
__device__ DeviceS MakeStruct() { return DeviceS(); }

// Now host and device code can call MakeStruct().

```

Unfortunately, this idiom isn't compatible with nvcc, because it doesn't allow you to overload based on the H/D attributes. Here's an idiom that works with both clang and nvcc:

```

struct HostS { ... };
struct DeviceS { ... };

#ifdef __NVCC__
    #ifndef __CUDA_ARCH__
        __host__ HostS MakeStruct() { return HostS(); }
    #else
        __device__ DeviceS MakeStruct() { return DeviceS(); }
    #endif
#else
    __host__ HostS MakeStruct() { return HostS(); }
    __device__ DeviceS MakeStruct() { return DeviceS(); }
#endif

// Now host and device code can call MakeStruct().

```

Hopefully you don't have to do this sort of thing often.

2.29.6 Optimizations

Modern CPUs and GPUs are architecturally quite different, so code that's fast on a CPU isn't necessarily fast on a GPU. We've made a number of changes to LLVM to make it generate good GPU code. Among these changes are:

- **Straight-line scalar optimizations** -- These reduce redundancy within straight-line code.
- **Aggressive speculative execution** -- This is mainly for promoting straight-line scalar optimizations, which are most effective on code along dominator paths.
- **Memory space inference** -- In PTX, we can operate on pointers that are in a particular "address space" (global, shared, constant, or local), or we can operate on pointers in the "generic" address space, which can point to anything. Operations in a non-generic address space are faster, but pointers in CUDA are not explicitly annotated with their address space, so it's up to LLVM to infer it where possible.

- [Bypassing 64-bit divides](#) -- This was an existing optimization that we enabled for the PTX backend.

64-bit integer divides are much slower than 32-bit ones on NVIDIA GPUs. Many of the 64-bit divides in our benchmarks have a divisor and dividend which fit in 32-bits at runtime. This optimization provides a fast path for this common case.

- Aggressive loop unrolling and function inlining -- Loop unrolling and function inlining need to be more aggressive for GPUs than for CPUs because control flow transfer in GPU is more expensive. More aggressive unrolling and inlining also promote other optimizations, such as constant propagation and SROA, which sometimes speed up code by over 10x.

(Programmers can force unrolling and inline using clang's [loop unrolling pragmas](#) and `__attribute__((always_inline))`.)

2.29.7 Publication

The team at Google published a paper in CGO 2016 detailing the optimizations they'd made to clang/LLVM. Note that "gpucc" is no longer a meaningful name: The relevant tools are now just vanilla clang/LLVM.

2.29.8 Obtaining Help

To obtain help on LLVM in general and its CUDA support, see [the LLVM community](#).

2.30 Reporting Guide

Note: This document is currently a **DRAFT** document while it is being discussed by the community.

If you believe someone is violating the [code of conduct](#) you can always report it to the LLVM Foundation Code of Conduct Advisory Committee by emailing conduct@llvm.org. **All reports will be kept confidential.** This isn't a public list and only [members](#) of the advisory committee will receive the report.

If you believe anyone is in **physical danger**, please notify appropriate law enforcement first. If you are unsure what law enforcement agency is appropriate, please include this in your report and we will attempt to notify them.

If the violation occurs at an event such as a Developer Meeting and requires immediate attention, you can also reach out to any of the event organizers or staff. Event organizers and staff will be prepared to handle the incident and able to help. If you cannot find one of the organizers, the venue staff can locate one for you. We will also post detailed contact information for specific events as part of each events' information. In person reports will still be kept confidential exactly as above, but also feel free to (anonymously if needed) email conduct@llvm.org.

Note: The LLVM community has long handled inappropriate behavior on its own, using both private communication and public responses. Nothing in this document is intended to discourage this self enforcement of community norms. Instead, the mechanisms described here are intended to supplement any self enforcement within the community. They provide avenues for handling severe cases or cases where the reporting party does not wish to respond directly for any reason.

2.30.1 Filing a report

Reports can be as formal or informal as needed for the situation at hand. If possible, please include as much information as you can. If you feel comfortable, please consider including:

- Your contact info (so we can get in touch with you if we need to follow up).
- Names (real, nicknames, or pseudonyms) of any individuals involved. If there were other witnesses besides you, please try to include them as well.
- When and where the incident occurred. Please be as specific as possible.
- Your account of what occurred. If there is a publicly available record (e.g. a mailing list archive or a public IRC logger) please include a link.
- Any extra context you believe existed for the incident.
- If you believe this incident is ongoing.
- Any other information you believe we should have.

2.30.2 What happens after you file a report?

You will receive an email from the advisory committee acknowledging receipt within 24 hours (and we will aim to respond much quicker than that).

The advisory committee will immediately meet to review the incident and try to determine:

- What happened and who was involved.
- Whether this event constitutes a code of conduct violation.
- Whether this is an ongoing situation, or if there is a threat to anyone's physical safety.

If this is determined to be an ongoing incident or a threat to physical safety, the working groups' immediate priority will be to protect everyone involved. This means we may delay an "official" response until we believe that the situation has ended and that everyone is physically safe.

The working group will try to contact other parties involved or witnessing the event to gain clarity on what happened and understand any different perspectives.

Once the advisory committee has a complete account of the events they will make a decision as to how to respond. Responses may include:

- Nothing, if we determine no violation occurred or it has already been appropriately resolved.
- Providing either moderation or mediation to ongoing interactions (where appropriate, safe, and desired by both parties).
- A private reprimand from the working group to the individuals involved.
- An imposed vacation (i.e. asking someone to "take a week off" from a mailing list or IRC).
- A public reprimand.

- A permanent or temporary ban from some or all LLVM spaces (mailing lists, IRC, etc.)
- Involvement of relevant law enforcement if appropriate.

If the situation is not resolved within one week, we'll respond within one week to the original reporter with an update and explanation.

Once we've determined our response, we will separately contact the original reporter and other individuals to let them know what actions (if any) we'll be taking. We will take into account feedback from the individuals involved on the appropriateness of our response, but we don't guarantee we'll act on it.

After any incident, the advisory committee will make a report on the situation to the LLVM Foundation board. The board may choose to make a public statement about the incident. If that's the case, the identities of anyone involved will remain confidential unless instructed by those individuals otherwise.

2.30.3 Appealing

Only permanent resolutions (such as bans) or requests for public actions may be appealed. To appeal a decision of the working group, contact the LLVM Foundation board at board@llvm.org with your appeal and the board will review the case.

In general, it is **not** appropriate to appeal a particular decision on a public mailing list. Doing so would involve disclosure of information which would be confidential. Disclosing this kind of information publicly may be considered a separate and (potentially) more serious violation of the Code of Conduct. This is not meant to limit discussion of the Code of Conduct, the advisory board itself, or the appropriateness of responses in general, but **please** refrain from mentioning specific facts about cases without the explicit permission of all parties involved.

2.30.4 Members of the Code of Conduct Advisory Committee

The members serving on the advisory committee are listed here with contact information in case you are more comfortable talking directly to a specific member of the committee.

Note: FIXME: When we form the initial advisory committee, the members names and private contact info need to be added here.

(This text is based on the [Django Project](#) Code of Conduct, which is in turn based on wording from the [Speak Up!](#) project.)

2.31 Benchmarking tips

2.31.1 Introduction

For benchmarking a patch we want to reduce all possible sources of noise as much as possible. How to do that is very OS dependent.

Note that low noise is required, but not sufficient. It does not exclude measurement bias. See <https://www.cis.upenn.edu/~cis501/papers/producing-wrong-data.pdf> for example.

2.31.2 General

- Use a high resolution timer, e.g. perf under linux.
- Run the benchmark multiple times to be able to recognize noise.
- Disable as many processes or services as possible on the target system.
- Disable frequency scaling, turbo boost and address space randomization (see OS specific section).
- Static link if the OS supports it. That avoids any variation that might be introduced by loading dynamic libraries. This can be done by passing `-DLLVM_BUILD_STATIC=ON` to cmake.
- Try to avoid storage. On some systems you can use tmpfs. Putting the program, inputs and outputs on tmpfs avoids touching a real storage system, which can have a pretty big variability.

To mount it (on linux and freebsd at least):

```
mount -t tmpfs -o size=<XX>g none dir_to_mount
```

2.31.3 Linux

- Disable address space randomization:

```
echo 0 > /proc/sys/kernel/randomize_va_space
```

- Set scaling_governor to performance:

```
for i in $(ls /sys/devices/system/cpu/cpu*/cpufreq/scaling_governor)
do
    echo performance > $i
done
```

- Use <https://github.com/lpechacek/cpuset> to reserve cpus for just the program you are benchmarking. If using perf, leave at least 2 cores so that perf runs in one and your program in another:

```
cset shield -c N1,N2 -k on
```

This will move all threads out of N1 and N2. The `-k on` means that even kernel threads are moved out.

- Disable the SMT pair of the cpus you will use for the benchmark. The pair of cpu N can be found in `/sys/devices/system/cpu/cpuN/topology/thread_siblings_list` and disabled with:

```
echo 0 > /sys/devices/system/cpu/cpuX/online
```

- Run the program with:

```
cset shield --exec -- perf stat -r 10 <cmd>
```

This will run the command after `--` in the isolated cpus. The particular perf command runs the `<cmd>` 10 times and reports statistics.

With these in place you can expect perf variations of less than 0.1%.

Linux Intel

- Disable turbo mode:

```
echo 1 > /sys/devices/system/cpu/intel_pstate/no_turbo
```

2.32 A guide to Dockerfiles for building LLVM

2.32.1 Introduction

You can find a number of sources to build docker images with LLVM components in `llvm/utils/docker`. They can be used by anyone who wants to build the docker images for their own use, or as a starting point for someone who wants to write their own Dockerfiles.

We currently provide Dockerfiles with `debian8` and `nvidia-cuda` base images. We also provide an example image, which contains placeholders that one would need to fill out in order to produce Dockerfiles for a new docker image.

Why?

Docker images provide a way to produce binary distributions of software inside a controlled environment. Having Dockerfiles to build docker images inside LLVM repo makes them much more discoverable than putting them into any other place.

Docker basics

If you've never heard about Docker before, you might find this section helpful to get a very basic explanation of it. [Docker](#) is a popular solution for running programs in an isolated and reproducible environment, especially to maintain releases for software deployed to large distributed fleets. It uses linux kernel namespaces and cgroups to provide a lightweight isolation inside currently running linux kernel. A single active instance of dockerized environment is called a *docker container*. A snapshot of a docker container filesystem is called a *docker image*. One can start a container from a prebuilt docker image.

Docker images are built from a so-called *Dockerfile*, a source file written in a specialized language that defines instructions to be used when build the docker image (see [official documentation](#) for more details). A minimal Dockerfile typically contains a base image and a number of RUN commands that have to be executed to build the image. When building a new image, docker will first download your base image, mount its filesystem as read-only and then add a writable overlay on top of it to keep track of all filesystem modifications, performed while building your image. When the build process is finished, a diff between your image's final filesystem state and the base image's filesystem is stored in the resulting image.

2.32.2 Overview

The `llvm/utils/docker` folder contains Dockerfiles and simple bash scripts to serve as a basis for anyone who wants to create their own Docker image with LLVM components, compiled from sources. The sources are checked out from the upstream svn repository when building the image.

The resulting image contains only the requested LLVM components and a few extra packages to make the image minimally useful for C++ development, e.g. `libstdc++` and `binutils`.

The interface to run the build is `build_docker_image.sh` script. It accepts a list of LLVM repositories to checkout and arguments for CMake invocation.

If you want to write your own docker image, start with an `example/` subfolder. It provides an incomplete Dockerfile with (very few) FIXMEs explaining the steps you need to take in order to make your Dockerfiles functional.

2.32.3 Usage

The `llvm/utils/build_docker_image.sh` script provides a rather high degree of control on how to run the build. It allows you to specify the projects to checkout from svn and provide a list of CMake arguments to use during when building LLVM inside docker container.

Here's a very simple example of getting a docker image with clang binary, compiled by the system compiler in the debian8 image:

```
./llvm/utils/docker/build_docker_image.sh \
  --source debian8 \
  --docker-repository clang-debian8 --docker-tag "staging" \
  -p clang -i install-clang -i install-clang-resource-headers \
  -- \
  -DCMAKE_BUILD_TYPE=Release
```

Note that a build like that doesn't use a 2-stage build process that you probably want for clang. Running a 2-stage build is a little more intricate, this command will do that:

```
# Run a 2-stage build.
# LLVM_TARGETS_TO_BUILD=Native is to reduce stagel compile time.
# Options, starting with BOOTSTRAP_* are passed to stage2 cmake invocation.
./build_docker_image.sh \
  --source debian8 \
  --docker-repository clang-debian8 --docker-tag "staging" \
  -p clang -i stage2-install-clang -i stage2-install-clang-resource-headers \
  -- \
  -DLLVM_TARGETS_TO_BUILD=Native -DCMAKE_BUILD_TYPE=Release \
  -DBOOTSTRAP_CMAKE_BUILD_TYPE=Release \
  -DCLANG_ENABLE_BOOTSTRAP=ON -DCLANG_BOOTSTRAP_TARGETS="install-clang;install-
  clang-resource-headers"
```

This will produce a new image `clang-debian8:staging` from the latest upstream revision. After the image is built you can run bash inside a container based on your image like this:

```
docker run -ti clang-debian8:staging bash
```

Now you can run bash commands as you normally would:

```
root@80f351b51825:/# clang -v
clang version 5.0.0 (trunk 305064)
Target: x86_64-unknown-linux-gnu
```

(continues on next page)

(continued from previous page)

```

```

2.32.4 Which image should I choose?

We currently provide two images: debian8-based and nvidia-cuda-based. They differ in the base image that they use, i.e. they have a different set of preinstalled binaries. Debian8 is very minimal, nvidia-cuda is larger, but has preinstalled CUDA libraries and allows to access a GPU, installed on your machine.

If you need a minimal linux distribution with only clang and libstdc++ included, you should try debian8-based image.

If you want to use CUDA libraries and have access to a GPU on your machine, you should choose nvidia-cuda-based image and use [nvidia-docker](#) to run your docker containers. Note that you don't need nvidia-docker to build the images, but you need it in order to have an access to GPU from a docker container that is running the built image.

If you have a different use-case, you could create your own image based on `example/` folder.

Any docker image can be built and run using only the docker binary, i.e. you can run debian8 build on Fedora or any other Linux distribution. You don't need to install CMake, compilers or any other clang dependencies. It is all handled during the build process inside Docker's isolated environment.

2.32.5 Stable build

If you want a somewhat recent and somewhat stable build, use the `branches/google/stable` branch, i.e. the following command will produce a debian8-based image using the latest `google/stable` sources for you:

```

./llvm/utils/docker/build_docker_image.sh \
-s debian8 --d clang-debian8 -t "staging" \
--branch branches/google/stable \
-p clang -i install-clang -i install-clang-resource-headers \
-- \
-DCMAKE_BUILD_TYPE=Release

```

2.32.6 Minimizing docker image size

Due to how Docker's filesystem works, all intermediate writes are persisted in the resulting image, even if they are removed in the following commands. To minimize the resulting image size we use [multi-stage Docker builds](#). Internally Docker builds two images. The first image does all the work: installs build dependencies, checks out LLVM source code, compiles LLVM, etc. The first image is only used during build and does not have a descriptive name, i.e. it is only accessible via the hash value after the build is finished. The second image is our resulting image. It contains only the built binaries and not any build dependencies. It is also accessible via a descriptive name (specified by `-d` and `-t` flags).

2.33 Building a Distribution of LLVM

- *Introduction*
- *General Distribution Guidance*
 - *Difference between `install` and `install-distribution`*
 - *Special Notes for Library-only Distributions*
- *Options for Optimizing LLVM*
- *Options for Reducing Size*
- *Relevant CMake Options*

2.33.1 Introduction

This document is geared toward people who want to build and package LLVM and any combination of LLVM sub-project tools for distribution. This document covers useful features of the LLVM build system as well as best practices and general information about packaging LLVM.

If you are new to CMake you may find the [Building LLVM with CMake](#) or [CMake Primer](#) documentation useful. Some of the things covered in this document are the inner workings of the builds described in the [Advanced Build Configurations](#) document.

2.33.2 General Distribution Guidance

When building a distribution of a compiler it is generally advised to perform a bootstrap build of the compiler. That means building a "stage 1" compiler with your host toolchain, then building the "stage 2" compiler using the "stage 1" compiler. This is done so that the compiler you distribute benefits from all the bug fixes, performance optimizations and general improvements provided by the new compiler.

In deciding how to build your distribution there are a few trade-offs that you will need to evaluate. The big two are:

1. Compile time of the distribution against performance of the built compiler
2. Binary size of the distribution against performance of the built compiler

The guidance for maximizing performance of the generated compiler is to use LTO, PGO, and statically link everything. This will result in an overall larger distribution, and it will take longer to generate, but it provides the most opportunity for the compiler to optimize.

The guidance for minimizing distribution size is to dynamically link LLVM and Clang libraries into the tools to reduce code duplication. This will come at a substantial performance penalty to the generated binary both because it reduces optimization opportunity, and because dynamic linking requires resolving symbols at process launch time, which can be very slow for C++ code.

Warning: One very important note: Distributions should never be built using the `BUILD_SHARED_LIBS` CMake option. That option exists for optimizing developer workflow only. Due to design and implementation decisions, LLVM relies on global data which can end up being duplicated across shared libraries resulting in bugs. As such this is not a safe way to distribute LLVM or LLVM-based tools.

The simplest example of building a distribution with reasonable performance is captured in the `DistributionExample` CMake cache file located at `clang/cmake/caches/DistributionExample.cmake`. The following command will perform and install the distribution build:

```
$ cmake -G Ninja -C <path to clang>/cmake/caches/DistributionExample.cmake <path to_  
↪ LLVM source>  
$ ninja stage2-distribution  
$ ninja stage2-install-distribution
```

Difference between `install` and `install-distribution`

One subtle but important thing to note is the difference between the `install` and `install-distribution` targets. The `install` target is expected to install every part of LLVM that your build is configured to generate except the LLVM testing tools. Alternatively the `install-distribution` target, which is recommended for building distributions, only installs specific parts of LLVM as specified at configuration time by `LLVM_DISTRIBUTION_COMPONENTS`.
